The results showed that Vietnamese enterprises evaluate the competitiveness of themselves at 2.13 on products imported from the U.S; 2.44 and 2.69 for imported products from Australia and Singapore, which is competitive at low (2-3 points / 5 points). Therefore, the Vietnam textile enterprises need to actively improve their products to meet the competition with foreign products in the domestic market.

5.3 The level of understanding of the business about TPP and the ability to meet the conditions of TPP

As Vietnam is ready to join in TPP, the requirement is that Vietnamese enterprises need to have savvy about the TPP to proactively take steps promptly to take advantage of the opportunities and challenges that limit the TPP offers. For instance, to satisfy the condition of 0% tax when importing goods into the U.S market, Vietnam garment enterprises have to ensure criteria on rules of origin. When having timely insight, enterprises can be early proactive to solve input materials, look for new suppliers of raw materials in joining the TPP countries to qualify for incentives. However, the survey results in Table 7 showed that the level knowledge of TPP agreement and ability to meet the conditions which give TPP agreement of enterprises are not high, just above average. This is also a limiting problem of the textile and garment enterprises in Vietnam. For understanding, the level at 2.86 and the ability to meet the conditions are at 2.52 with 5 points scale (1: low competitiveness, ..., 5: high competitiveness).

Table 7. Level of understanding of the business and the ability to meet the conditions

Target	**Level**
Level of understanding	2.86
The ability to meet the conditions	2.52

Source: Survey of 65 textile enterprises

6. Factors affecting the level of agreement of the textile enterprises when Vietnam joins the TPP

Table 8. Results of regression models

Model Summary

Model	R	R Square	Adjusted R Square	Std. Error of the Estimate	Durbin-Watson
1	0.964	0.929	0.923	0.22079	1.963

According to Muthen and Kaplan (1985). Demaris (2004). the Likert 5-points scale upwards can fit regression model. Thus. this research uses Liker 5 points scale to collect data in order to analyze factors such as the level of tax reduction. expanding export markets. understanding of enterprise. competitiveness. ability to meet the conditions in an aspect that how it affect the degree to join in TPP of Vietnam's garment enterprises through regression model.

The results analyzed in Table 8 showed that the factors included in the model were significant in impacting on the level of agreement to join in TPP of the Vietnam textile enterprises. In which. the factor X_1 (tax reduction) is the most powerful factor to the degree of consensus (0.25). it means that when the other factors remain unchanged. assuming use tax rate is reduced by 1%. the level of agreement increases by 0.25; next is an understanding of the business impacting to the degree of consensus 0.186; ability to meet the conditions. expanding markets. and competitiveness of enterprises respectively have an impact on the level of consensus at 0.177; 0.150; and 0.123. The result is appropriate with fact when tax rate is reduced. the Vietnam textile enterprises will not have to pay tax arising on the US market. reducing the cost of this will help Vietnam businesses saves charges and makes the product cheaper which make increase accumulation to expand production.

7 Some recommendations for the Vietnam textile industry exports to the U.S market

To increase the exports to the U.S market when TPP affects, Vietnam's textile and garment industry needs to solve following problems which are still stagnant in the industry, namely:

For source of raw materials: Vietnam textile enterprises should invest in establish local sources of raw materials or find joint venture partners to produce domestic raw materials or govern policies to attract foreign investment, especially from the TPP member countries, into production of raw materials of textile industry to generate high-quality, stable, low cost materials, and meet the requirements of the U.S market.

The firms in the industry have to link together: form chains and improve linking chain together, close production process from fiber - textile - dyeing and finishing –sew, move away from a form of processing to do FOB (purchase of raw materials, semi-finished products) and ODM (design, production and sale of products). This will help increase the localization of industries, enhance the adding value of products, reduce deficit. etc. When Vietnam textile industry gets the localization rate of about 60% - 70%, the tax benefit truly prove effect.

In addition, an important issue is that enterprises should actively learn about TPP and join in commenting on the negotiations. TPP is an open agreement, which means that in the negotiations of the agreement, all of the issues negotiated and agreed by TPP countries have been discussed by business representatives, associations and experts participating comments. If Vietnam textile enterprises know how to take advantage of this condition, it will be able to affect the content of negotiations, leading to the results achieved by favorable direction which fits to the capacity of the textile industry in Vietnam.

Due to the paucity of disclosed information, especially prior to 2006, deferred compensation is the least understood among various categories of executive pay. This paper fills this gap and provides a comprehensive analysis of the nature of deferred compensation and tests several hypotheses explaining why firms use deferred compensation and why CEOs would make voluntary contributions. The unique properties of deferred compensation (pay at retirement, low transparency) allow us new approaches to test several hypotheses with respect to both Optimal Contracting (alignment) and Managerial Power (agency theory). We find some support for Optimal Contracting. While we do not find any evidence of ex-post settling up, we do show that firms' contributions increase with leverage, which is consistent with using firms using deferred compensation to increase alignment with debtholders (the inside debt hypothesis). We also find evidence that is consistent with Managerial Power hypothesis. Our results suggest that boards utilize deferred compensation, which is less transparent, in order to avoid having to report excess pay in periods of high investors outrage toward executive pay. We also find evidence that firms use deferred compensation to at least partially offset the cuts in current compensation.

1. Introduction

Prior to 2006 firms were not required to disclose information on post-retirement benefits; as a result there are relatively few studies examining deferred compensation.[1] In 2006 the SEC issued new regulations which now require firms to disclose all post-retirement benefits, including pensions and deferred compensation (see SEC Release No. 33-8732A). While several studies have examined the impact of pensions on CEO incentives and investor behavior, ours is the first to examine the determinants of non-qualified deferred compensation.

There are three components to non-qualified deferred compensation, and each component makes up a significant portion of the executive's annual earnings. The first element is the amount the executive elects to defer ("executive contribution") from his base salary and bonus. The average executive contribution is $244,000 per year (or approximately 6.5% of his total annual compensation). The second component is any additional amounts promised by the firm ("firm contribution") and can take the form of fixed matching or can be based on firm performance. On average, firms that participate in deferred compensation make annual contributions of $156,000 per year (approximately 2.95% of annual compensation). Finally, the third component is the "above-market earnings" on deferred compensation ("earnings"). Above-market earnings result from the firm guaranteeing a fixed rate of return which exceeds the amount the executive would have received had the deferred compensation been invested in the market or in the firm's securities. The average executive in our sample received "above-market" earnings of $195,000 per year (about 4.5% of total annual pay).

In this paper we examine the determinants of firm's contribution to deferred compensation using the post-2006 data and test two competing theories: alignment ("optimal contracting") and agency problems ("managerial power"). According to the Optimal Contracting theory, compensation should be designed to align the CEO's interests with those of the firm's stakeholders, which include both shareholders and bondholders. Many executive compensation plans focus primarily on incentivizing executives to maximize shareholder value, often at the expense of total firm value. For example, stock and option grants increase the executive's equity stake in the firm, thereby encouraging him to focus on maximizing *shareholder* value rather than total firm value. Management has the incentive to engage in risk behavior because he bears the upside potential, while the bondholders bear the downside. Sundaram and Yermack (2007) note how using deferred compensation and pensions ("inside debt") greatly alters the CEO's payoff and corporate decision making. By including deferred compensation, which is tied to the long-term prospects of the firm (and remains subject to the reach of the firm's creditors in the event of bankruptcy), firms can better align the interests of management with both shareholders and bondholders. Our results suggest this may be a partial explanation. We find a positive relationship between leverage (both the firm leverage and the CEO's "inside" leverage) and firm contributions to deferred compensation. The more levered firms tend to pay more deferred compensation.

[1] Deferred compensation and pensions are often lumped together as "inside debt". Most studies examining inside debt focus primarily on pensions. See, for example, Sundaram and Yermack (2007), who examine how pensions affect management incentives and decision-making. Other studies examine both pensions and deferred compensation together. See Wei and Yermack (2011); Cen (2012).

Another problem is that the short-term nature of annual compensation may lead management to focus on short-term profits in order to maximize their annual pay. Fama (1980) suggests that any rent extraction in one period should be resolved in future periods through the wage revision process, or ex-post settling up. We explore whether deferred compensation can be used for ex-post settling up. Contrary to annual compensation, which is difficult for firms to recover once it has been paid out, amounts allocated to deferred compensation are withheld until the executive retires and remain the property of the firm. To encourage better pay-for-performance alignment, firms could make annual adjustments to the deferred compensation balance based on long-term firm performance. Under the alignment hypothesis, we expect firms to increase the firm contributions to deferred compensation following positive firm performance and to decrease or make negative adjustments following poor firm performance. Our results suggest that firms do not use deferred compensation as a means of ex-post settling up. While the amount of firm contributions tends to increase following positive firm performance, there is no evidence to suggest that firms make downward adjustments following negative firm performance.

The second, competing theory is Managerial Power. Under this theory the CEO seeks to maximize his total compensation, regardless of firm performance.[2] Prior to 2006 firms were not required to disclose most elements of deferred compensation. Thus there existed the potential for firms to hide large amounts of compensation from shareholders. Following the rule change in 2006, there still exists the possibility to obscure total compensation due to the non-standard reporting requirements. Although all compensation (both current and deferred) is now required to be disclosed in the proxy statement, firms still have control over how the information is presented. Firms are required to disclose deferred compensation in the Non-Qualified Deferred Compensation Tables (NQDC), but not all elements of deferred compensation are required to be reported in the Summary Compensation Tables (SCT): firms are not required to disclose the firm contribution or total earnings on the deferred balance in the Summary Compensation Table. Thus the "Total Compensation" as reported in the Summary Compensation Tables may be understated. That is, firms may still be able to hide some elements of deferred compensation or use deferred compensation to offset current compensation in bad years. There are two implications to this: (1) firms may use deferred compensation, which is less scrutinized by investors, as a means of hiding compensation or (2) firms may use deferred compensation to substitute for current compensation following a pay cut. Our results indicate that Managerial Power hypothesis is a stronger explanation for firm contributions. We find some evidence that firms shift compensation away from current compensation and toward deferred compensation in periods of high outrage over executive compensation. Further, we find support for our substitution hypotheses: CEOs who suffer "extreme pay cuts" (defined as more than 25% decrease from prior year bonus) are at least partially offset by an increase in firm contributions to deferred compensation. Thus firm may be reducing annual compensation, but are at least partially offsetting this reduction with an increase in deferred compensation.

---

[2] The only constraint is "outrage costs". Bebchuck and Fried (2003) use the term "outrage costs" to denote costs associated with (a) reputational harm to the executive in future employment or (b) costs associated with shareholder activism, including proxy contests and take-over bids.

The remainder of this paper is organized as follows: Section II provides a background on deferred compensation. The hypotheses are outlined in Section III. Section IV describes the data and sample selection and provides summary statistics. The methodology and results are presented in Section V. Section VI concludes.

2. Background on Deferred Compensation

Section 409A of the Internal Revenue Code ("Non-Qualified Deferred Compensation") allows the CEO and other "key executives" to defer taxes on a portion of their salary and bonus that is set aside for future payment (executive contributions). Because the plan is "non-qualified" (i.e. does not meet the tax requirements of qualified plans such as 401(k)), it is not subject to many of the requirements of "qualified" plans, such as participation or contribution limits. Thus firms are given wide latitude in designing their executive deferred compensation arrangements and can have separate plans for the CEO and the Vice President, each with different contribution policies. Unlike other post-retirement compensation arrangements, the firm does not get a tax deduction for deferrals under Section 409A for either the executive contribution or the firm contribution. Although these amounts are non-deductible for tax purposes, the firm must still report both the executive contribution and the firm contribution as an expense on the income statement and as a liability on the balance sheet.[3] Thus from the firm's perspective, there is little, if any, benefit to nonqualified deferred compensation.

The finance literature often refers to deferred compensation as "inside debt" because it represents a liability the firm owes to the executive(s). In order to qualify for tax-deferral status under 409A the plan must be unfunded, meaning that the firm cannot set aside funds in a separate account for the benefit of any particular employee. Further, to the extent that the firm does set aside funds for a group of employees, the funds are still subject to the reach of the firm's creditors in the event of bankruptcy.[4] There are, however, several distinct differences between deferred compensation ("inside debt") and other forms of debt: contributions to deferred compensation and earnings on deferred compensation can vary with firm performance, there is generally not a fixed payment schedule, and non-payment will not result in bankruptcy.

There are three components to deferred compensation:the executive contribution, the firm contribution, and earnings on the deferred compensation balance. The executive contributions are amounts promised to the executive as annual compensation that the executive elects to defer until retirement. These amounts are reported in both the Summary Compensation Table (as salary or bonus) and the Non-Qualified Deferred Compensation (NQDC) Table. Firm contributions are additional amounts above and beyond annual compensation which can be

---

[3] FASB ASC 710-10-25-9 indicates that all income should be expensed in the year *earned* rather than in the year paid out.

[4] In practice, firms often set aside money in a rabbi trust or use life insurance policies to indirectly fund these obligations, but any proceeds as still subject to reach of the firm's creditors. Firms are able to get around the "unfunded" requirement by purchasing an insurance policy such as a Corporate Owned Life Insurance (COLI). The policy cannot be for the benefit of a particular employee, but the policy guarantees the funds will be available when due to the employee (retirement or separation, death or disability, change in control). See Fidelity https://www.fidelity.com/viewpoints/personal-finance/nqdcfdsa

based on firm performance or matching contributions. Firms are only required to report these amounts in the NQDC, but may choose to also report these amounts in the SCT.[5] Finally, while all earnings on the deferred balance are required to be reported in the NQDC table, only the "above-market" earnings are required to be reported in the SCT. Thus the "Total" column of the SCT may not include all elements of compensation.

There is also a timing issue with deferred compensation. In order to meet the requirements of IRC 409A, the executive must decide what portion of salary and bonus to defer before the compensation is earned or received. As to salary, the election must be made prior to the beginning of the fiscal year in which it was earned and for bonuses the election must be made at least six months before the end of the fiscal year in which it was earned. Further, once the election is made for the year it cannot be changed or revoked. The firm then selects whether or not to make a contribution towards deferred compensation.[6] Firm contributions are often based, at least in part, on some performance metric such as return on assets, net income, return on equity, or stock returns.

Firms can offer additional deferred compensation in the form of earnings on the deferred balance. While a typical "qualified" plan will invest in the company stock or an index fund, earning market returns, "non-qualified" plans can offer fixed or guaranteed earnings. Since deferred compensation is an unfunded liability the firm does not need to set aside the money in stocks or other investments in order to generate returns. Rather, "imputed" earnings may be credited based on the returns of the target fund or some guaranteed rate of return. In either case the firm must report annually the total earnings on the deferred compensation balance in the Non-Qualified Deferred Compensation Table, but need only report the "above market" earnings in the Summary Compensation Table.[7]

Prior to 2006 firms were not required to disclose post-retirement compensation to shareholders. As a result, firms were able to hide large amounts of compensation from shareholders. In 2006 the SEC updated its disclosure requirements. As noted in the Final Rule (SEC Release No. 33-8732A), the new Summary Compensation Table is intended to disclose all elements of executive compensation (current and deferred) and includes a column for "Total Compensation".[8] However, neither the firm contributions to deferred compensation nor the total earnings on the deferred balance are required to be reported in the Summary Compensation Table.[9]Instead, firms are required to report these amounts in the Non-

[5] SEC regulations require that firms report the amount of firm (registrant) contribution in the Non-Qualified Deferred Compensation Table (NQDC). Firms are not required to report the amount of firm contributions in the Summary Compensation Table (SCT). However, footnotes are required to the extent that these amounts are reported in both tables so as to avoid double-counting. See SEC Release No. 33-8732A; 17 CFR 228.

[6] The Internal Revenue Code does not specify the timing of the firm's contribution. Performance-based firm contributions generally made at the end of the fiscal year.

[7] "Above market" means earnings generated from a guaranteed fixed rate that exceeds 120% of the applicable federal rate (AFR). To the extent that earnings are less than 120% of AFR, such earnings are not required to be disclosed in the Summary Compensation Table. See Donahue (2006).

[8] The Total Compensation column is intended to include all current and deferred compensation. See Summary Compensation Table in Appendix B.

Qualified Deferred Compensation ("NQDC") Table. Because of the discrepancy in reporting requirements, the "Total Compensation" column in the Summary Compensation Table may be significantly understated. Shareholders must carefully read the footnotes to determine how Total Compensation is calculated. This presents a potential means of hiding excess compensation by executives.

3. Hypothesis Development

There are two standard theories of executive compensation: optimal contracting and managerial power. The optimal contracting approach views executive compensation as a remedy to agency problems. See Jensen and Meckling (1976), Jensen and Murphy (1990), Coles et al., (2006), and Cassell et al., (2011). Under this approach, boards use executive compensation as an alignment tool to help motivate management to maximize shareholder value.[10] Under the managerial power approach executive compensation is viewed as *creating*, rather than solving, an agency problem, see Shleifer and Vishny (1989), Yermack (1997), Bertrand and Mullainathan (2001), Bebchuck and Fried (2004), Bebchuck and Jackson (2005), Lee and Tang (2011). This theory suggests that powerful executives receive more compensation than they would otherwise under an arms-length bargaining. We examine these two theories in light of deferred compensation.

3.1. *Optimal Contracting: Deferred Compensation as Alignment*

Jensen and Meckling (1976) propose using equity incentive compensation to align management interest with shareholders. One problem, however, is that equity compensation rewards risk-taking, often at the expense of long-term firm value (Denis et al., 2006; Efendi et al., 2007; Bergstressor and Philippon, 2006). Jensen and Murphy (1990) suggest that compensation should be structured in a way that rewards positive performance but also penalizes poor performance. Ex ante, the board cannot observe firm performance when designing compensation. Ex-post the remedies include termination, which prior research has shown to be relatively rare,[11] or pay cuts.[12] Fama (1980) indicates that this problem can largely be overcome through the wage revision process (ex-post settling up), whereby pay and performance, including the long term consequence of the CEO's decisions, would be finally balanced at the end of the CEO's career with the firm. The process requires a process to adjust pay over a CEO's career; one that can positive as well as negative adjustments. Bebchuck and Fried (2010) and Bhagat and Romano (2009) suggest restricting an executive's ability to sell his shares until post-retirement. We examine whether firms use deferred compensation as a means of ex-post settling up. Deferred compensation has a desirable property that would make it uniquely suitable to make managers be responsible for the

---

[10] Survey papers on optimal contracting include Murphy (1999) and Core et al. (2001). See also Jensen and Meckling (1976), Edman and Liu (2010) Cassell et al. (2011).

[11]See Coughlan and Schmidt, 1985; Warner et al., 1988; Denis and Denis, 1995; Parrino, 1997; Huson et al., 2001; Brookman and Thistle, 2009; Ang et al., 2013. The termination rate is typically around 10%.

[12]Gao et al. (2012) examine "extreme pay cuts" of greater than 25% reduction in total compensation from the prior year compensation

consequences of their actions. This is because unlike other components of pay such as salary and bonus where once given getting back would be very difficult in practice. The same goes for options and restricted stocks in which the executives could exercise before retirement. If an executive receives annual compensation in one period based on some performance metric, which turns out to be less than expected, the firm cannot easily recover the "extra" compensation paid out. However, because deferred compensation is simply an accounting entry and is not a realized expense until the executive retires, which allows the firm to make book adjustments to deferred compensation based on ex post firm performance. Thus our first hypothesis is stated as follows:

> *H1: Deferred compensation is used as a means of ex-post settling up.*

If the hypothesis is true, we would expect to see the firm contribution increase following positive firm performance and decrease following negative firm performance.

Jensen and Meckling (1976) also suggest that executives should be compensated in a manner similar to overall firm structure in order to reduce excessive risk taking and align management with the overall firm. That is, they should be aligned with both shareholders *and* bondholders. Eaton and Rosen (1983) suggest firms use "delayed compensation" to bond executives to the firm (rather than just shareholders).[13]Little research has been done on the relationship between deferred compensation and firm leverage. Wei and Yermack (2010) examine the market response upon disclosure of "inside debt" and finds evidence to suggest that the market perceives inside debt holding as alignment with debt holders. Upon disclosure bond prices rise (increased perception of alignment with debt holders) and stock prices drop (decreased perception of alignment with shareholders). We test the relationship between firm leverage and deferred compensation. Our second hypothesis suggests there should be a positive relationship between firm leverage and deferred compensation.

> *H2: Highly levered firms pay a higher percentage of total compensation as deferred compensation (firm contributions) than less levered firms.*

3.2. *Managerial Power: Deferred Compensation as an Agency Problem*

Under the managerial power approach, executives use their position and power to extract more compensation than they otherwise would under an arm's length bargaining. However, due to "outrage costs", management prefers to receive compensation in a way that obscures total compensation. Bebchuck and Fried (2004) suggest that firms use deferred compensation and other retirement benefits to "camouflage large amounts of executive compensation".[14]

---

[13]Sundaram and Yermack (2007) also support using inside debt as a means to bond the executive to the firm, noting that "inside equity aligns managers with equity holders in good states, but inside debt aligns managers with debt holders in bad states". See also Edmans and Liu (2010).

[14] Cen (2012) finds that "powerful" CEOs and firms with lower board efficiency tend to pay more inside debt, suggesting that inside debt is evidence of managerial power or rent extraction.

They note that as disclosures on current compensation increased,[15] firms shifted compensation away from bonuses and equity and instead towards post-retirement compensation (pensions, deferred compensation, post-retirement perquisites, and consulting fees). Andrews et al. (2009) find that prior to the 2006 disclosure requirements firms used perquisites to hide large amounts of compensation. Upon disclosure, firms that hid large perks suffered negative stock market reaction, with poorly governed firms suffering a greater decline.[16] We can expect similar tactics by these boards by using deferred compensation.

The 2006 compensation disclosure rule were intended to make executive compensation more transparent. The Total Compensation column in the Summary Compensation Table is supposed to include *all* compensation (current and deferred). However, because not all elements of deferred compensation are required to be disclosed in the Summary Compensation Tables, even under the new disclosure rules there is still the opportunity for firms to hide or obscure total pay. If deferred compensation is a way for firms to obscure total compensation then we would expect to see a shift in deferred compensation during periods of high attention on executive compensation or periods of high outrage. The third hypothesis is stated as follows:

> *H3: Firms use deferred compensation to hide total compensation from shareholders; firm contributions increase in periods of high outrage*

Weak board/ powerful CEO may use deferred compensation as a means to (partially) offset a pay cut but giving the appearance of doing so. Gerakos (2007) suggests that firms use "inside debt" to substitute for other forms of compensation.[17] If deferred compensation substitutes for other forms of compensation in period of 'apparent pay cut after poor performance' for cosmetic purpose, we would expect to see a positive relationship between pay cuts and firm contributions.

> *H4: Firms use deferred compensation to substitute for current compensation following a pay cut.*

4. Data and Sample Selection

4.1. *Sample Selection and Data Description*

---

[15] In 1938 the SEC first adopted rules that firms must disclose compensation in their annual report or proxy statement. SEC Release No. 34-1823 (August 11, 1938) [3 Federal Register 1991]. Firms were free to choose *how* to disclose, and many firms choose long narratives. In 1992, the SEC amended the requirement that firms disclosure compensation in a standardized table format. See Executive Compensation Disclosure, Release No. 33-6962 (October 16, 1992) [57 Federal Register 48126]. Deferred compensation and other post-retirement compensation was not required to be disclosed until 2006. See Executive Compensation and Related Person Disclosure, Release No. 33-8655 (DATE) [17 CFR 228-274]

[16] The authors interpret the negative stock market reaction as consistent with managerial power. See also Yermack (2006), who finds negative market reaction of -1.65% when firms disclose executive use of company jets.

[17] He looks primarily at pensions, not deferred compensation

Our sample includes all CEOs in the S&P 1,500 for fiscal years 2006-2012. We have 11,244 firm-year observations for 2,164 individual CEOs. Annual and deferred compensation data come from Execucomp Annual Compensation and Deferred Compensation files. Annual compensation consists of salary, bonus, non-equity incentive awards, and stock and option grants. Deferred compensation consists of executive contributions, firm contributions, and earnings on the deferred balance. We include only the deferred compensation and exclude pensions and other post-retirement benefits.

Firm characteristics and performance variables come from Compustat and CRSP. Governance variables are constructed using Risk Metrics and hand-collected from the firm's proxy statement (DEF 14A) in SEC EDGAR. Because executive compensation is generally linked to firm size (Rosen, 1982; Smith and Watts, 1992) we include the log of total assets to proxy for firm size. We use several performance measures, including return on assets (ROA), net income (NI), and one-year buy-and-hold stock returns (BHR).

4.2. *Summary Statistics*

Summary statistics are displayed in Table 1. All variables are winsorized at the 1st and 99th percentile. The average firm in the S&P 1500 pays $776,000 in salary, $194,000 in bonus, and over $5.1 million in total compensation. Less than half of the CEOs in the sample receive any form of deferred compensation (executive contributions, firm contributions, or earnings). Of those who do receive deferred compensation, the average CEO defers $244,000 each year (approx. 14.2% of his annual cash pay, or 6.5% of his total annual compensation), and the average firm contribution is $156,000 per year (8.3% of annual cash pay, or 2.9% of total annual compensation).

The sample is further broken down into "Contributors" and "Non-Contributor" based on whether the firm makes a contribution to deferred compensation. When we compare Contributors to Non-Contributors we see that on average, Contributor CEOs are from larger firms (total assets), more profitable firms (net income, ROA), and invest more heavily in long-term assets (CAPX). However, these firms also tend to have higher leverage (debt/equity ratio) and are lower liquidity (cash/assets ratio). Additionally, CEOs from Contributor firms receive more current compensation (salary, bonus, total compensation) and are more likely to serve as the Chairman of the Board of Directors (duality).

5. Results for Firm Contributions to Deferred Compensation

To test whether deferred compensation is different from other forms of compensation, we examine which variables explain the various components of annual compensation (bonus, stock grants, option grants, and total compensation) and what factors explain deferred compensation (firm contributions). We then test whether the coefficients between the regressions are significantly different. The results are displayed in Table 2.

As we see in Table 2, the coefficients that load significant on each annual compensation component are significantly different from the coefficients for firm contributions, thus establishing that firm contribution are, in fact, different from other forms of compensation. The coefficients on firm contributions are most similar to the coefficients on bonus.

Comparing Firm Contributions to Bonus, we see that total assets, return on assets (ROA), asset turnover, and capital expenditures load significantly for both bonus and firm contributions. A test of the coefficients, however, shows that these variables have different impact on Bonus than on Firm Contributions (i.e., the coefficients are significantly different). Comparing other elements of annual compensation to firm contributions we find similar results – the variables that load significantly in both regressions load significantly different. The fact that deferred compensation does not duplicate other pay type provide a reason to understand better it, as there have been few in depth studies of this item.

[Insert Table 2 Here]

5.1. *Firm Contributions as an Alignment Tool*

Next we look at firm contributions to deferred compensation. Our first hypothesis predicts firms can use deferred compensation as a mechanism to achieve ex-post settling up. Fama (1980) indicates that although an executive may be overpaid relative to performance in one period, over the executive's tenure the wage revision process will result in ex-post settling up at the end of the executive's career. Relatively few studies have empirically tested whether the ex-post settling up mechanism has been applied in practice.[18] Bebchuck and Fried (2010) and Bhagat and Romano (2009) suggest firms restrict the ability of executives to cash out stock and options until after retirement. While deferred compensation need not be invested in the firm's stock, the idea is the same – to hold back some compensation until after retirement, when the manager's performance can be evaluated over his tenure. The ideal form of ex-post settling up would be for firms to make positive contributions when firm performance is good and make negative adjustments in periods when performance is poor. The data, however, could not support this stronger version of ex post settling up. An examination of the data shows that there is no instance of reduction in the deferred compensation cumulative balance after a poor performance.[19] Thus we proceed to test a weaker version of the hypothesis, which is to see whether firms decrease their contributions or not in periods when firm performance is poor.

In univariate analysis (Table 4) we examine the relationship between the change in firm performance from the prior year (increase, decrease, or same (within 5%)) and the change in firm contributions from the prior year (increase, decrease, or same (within 5%)). We use return on assets (ROA), net income (NI), and one-year buy-and-hold stock returns (BHR) to proxy for firm performance. The results are displayed in Table 4. Approximately 42.5% of the sample (2,940 firm-year observations) has an increase in ROA. Not surprisingly, the majority of this group (66.5%) increases firm contributions to deferred compensation. Nearly 40% of the sample has a decrease in ROA. If firm contributions work as an alignment tool we would expect to see most firms decrease firm contributions. However, only 27.2% of this

[18] Gao et al. (2012) examine Fama's ex-post settling up in the context of extreme pay cuts. Harford (2012) examines ex-post settling up in the director labor market.

[19] Three observations have negative values for firm contributions. On closer examination, the negative adjustments were due to the CEO leaving prior to vesting, thereby forfeiting his deferred compensation.

group actually decreases firm contributions. The results are consistent using either net income or stock returns as the performance metric: most firms increase deferred compensation following an increase in firm performance but relatively few firms decrease deferred compensation following a decrease in firm performance.

[Insert Table 4 Here]

In multivariate analysis we model firm contributions as a function of firm size, firm performance, tenure, governance, and other controls. We use both current performance (ROA), as well as lagged performance variables. Further, because several studies have shown an asymmetric relationship between positive and negative firm performance (see, for example, Gaver and Gaver (1998), Leon Wu and Zimmerman (2006)), and because we want to highlight pay reduction in periods of low performance, we also examine the positive and negative impact of these variables separately. ROA_Pos is equal to ROA if positive and zero otherwise. Likewise, ROA_Neg is equal to the absolute value of ROA if negative and zero otherwise. We follow the same method for lagged performance variables. The results are displayed in Table 5. A notable result is that firm contribution is a negative function of firm cash ratio, consistent with cash constrained firms using deferred contribution as a non cash means to pay executives. However, this explanation begs the question why the firms do not choose to use the other non cash pay such as options and restricted stocks that are more tax efficient (as in tax deductible in the current period).

According to Fama (1980), ex-post settling up (wage revision process) should occur over the executive's tenure. Thus current pay should be a function of both current and prior performance. We find little evidence to support this. In nearly all models lagged ROA is insignificant (the exception is ROA_{t-4}, significant at the 10% level). Further, when we break the performance variable into positive and negative, we see that while positive ROA increases firm contributions, there is no evidence that negative ROA decreases firm contributions. ROA_Neg (Models 3-5) positive (sometimes significant) coefficients. Because ROA_Neg is the absolute value of ROA, the positive coefficient indicates that the more negative performance, the higher the firm contributions.

[Insert Table 5 Here]

Fama's ex-post settling up theory suggests that performance and pay will equalize over the CEO's tenure. If deferred compensation were a means of ex-post settling up, we would expect firms to set aside more money in the early years (increase the holdback balance), and this amount would decrease over time as the holdback balance built up. To test this relationship we include a variable "Retire" which is the estimated number of years to retirement. We would expect to see a positive relationship between the time to retirement and the amount of firm contributions. We find the opposite. In Models 2 and 5 we see there is a negative relationship between years to retirement and firm contributions, suggesting the farther away (closer to) retirement, the less (more) deferred compensation. In unreported results we also examine the interaction between years to retire and the performance variables (ROA_Pos, ROA_Neg, and lags). We find the interaction terms insignificant and therefore do not report in our main analysis. Based on the results in Table 5 we do not find evidence to support the ex-post settling up hypothesis as related to deferred compensation.

Our second hypothesis tests whether firms use deferred compensation as a form of "inside debt". Jensen and Meckling (1976) suggest that a manager holding debt and equity compensation in similar proportion to the overall firm would be perfectly aligned with the firm and would have no incentive to shift resources from shareholders to bondholders or visa versa. To test whether firm contributions to deferred compensation are "inside debt" we regress firm contributions on the firm's leverage ratio (Total Debt divided by Total Assets). Model 1 looks only at the relationship between firm leverage and deferred compensation. The coefficient on firm leverage (Firm D/E) shows there is a positive and significant relationship between firm leverage and deferred compensation. Cen (2010) finds a non-linear relationship between inside debt and the firm's leverage ratio. For this reason we also include squared term in Model 2. We see across all models that as leverage increase, so does firm contributions to deferred compensation. Overall the results suggest that deferred compensation may be used as "inside debt" to align the CEO's incentives with the whole firm, rather than just the shareholders.

[Insert Table 6 Here]

5.2. *Firm Contributions as an Agency Problem*

Our third and fourth hypotheses indicate that firm contributions to deferred compensation represent an agency problem, in that executives use their power to extract additional rents. Bebchuck and Fried (2004) suggest that firms use deferred compensation as a means to "camouflage" total compensation. Although firm contributions are required to be reported in the NQDC tables, it is not required to be reported in the SCT, and thus not included in the "Total Compensation" column. Further, Bebchuck and Fried (2004) suggest executives use deferred compensation to hide excess compensation due to "outrage costs".

We test our third hypothesis by examining whether firms that pay "excess" current compensation also pay high deferred compensation, and whether the incentive to hide excess pay increases in periods of high outrage (or attention). Our hypothesis suggests that in periods of high outrage (attention), firms will increase contributions to deferred compensation as a means of obscuring total pay. Under this hypothesis we would expect to see that when the outrage (attention) index is high, firms that pay high excess current compensation will shift some to deferred compensation.

Excess Pay is defined as the difference between total annual compensation less 125% of the size/industry median.[20] For example, suppose a CEO earns $500,000 in total compensation. If the size/industry median is $350,000 then the excess compensation would be $500,000 – (125% * $350,000), or $125,000 excess compensation. The Outrage Index measures sentiment towards excessive executive compensation and is calculated using search volume in Google Trends. This measure captures how often a particular term is searched,

[20]Size/Industry median compensation is calculated by scaling compensation by total assets and then taking the median ratio by industry.

relative to the highest search over a specified period. We search key words such as "excess CEO compensation", "overpaid CEOs" and "say-on-pay" to see how often these words are searched on Google. We annualize the weekly search measures from Google Trends. Figure 2 shows that there is a positive relationship between excess compensation and deferred compensation. Further, the level of firm contributions relative to excess compensation is greater in periods of high outrage (sentiment, attention) than during periods of low outrage (sentiment, attention).

[Insert Table 7 Here]

We regress firm contributions on Excess Pay, the Outrage Index, and controls for firm size, tenure, and governance. The results are displayed in Table 7. In Model 1 we see there is a positive and significant relationship between Excess Pay and Firm Contributions; that is, firms that pay large amounts of excess current compensation also pay more deferred compensation. In Model 2 we add Outrage, which is also positive and significant, suggesting that firms pay more deferred compensation during periods of high outrage towards executive compensation. This is consistent with the hiding hypothesis. In Model 3 we include an interaction term to test the simultaneous relationship between excess pay during periods of high outrage. Although we lose significance on both our primary measures, we do see the interaction term is positive and significant (at the 1% level). Together with the negative coefficient on Excess Pay, these results suggest firms that pay high excess pay shift compensation towards deferred compensation in periods of high outrage. Finally, in Model 4 we include our primary controls and see the relationship between Firm Contributions, Excess Pay, and Outrage holds. Thus we find some support for the hiding hypothesis.

Our fourth hypothesis suggests that firms use deferred compensation to offset pay cuts. To test this, we study whether the executive had an "extreme pay cut". We follow Gao et al. (2012) in defining "extreme pay cut" as a decrease of more than 25% from the prior year compensation. We use Bonus as our measures for pay cuts. To control for firms that pay bi-annual bonuses we also require that the executive not have more than 25% increase from the prior year. Thus restrictions are as follows: $Bonus_t < 0.75*Bonus_{t-1}$ and $Bonus_{t-1} < 1.25*Bonus_{t-2}$. We find that approximately 16.3% of the sample experience an extreme pay cut. Pay Cut is a binary variable equal to 1 if the executive had an extreme pay cut in year t and 0 otherwise. We regress firm contributions on Pay Cut and our other control variables.

[Insert Table 8 Here]

The results are displayed in Table 8. The odd specifications look at the relationship between pay cuts (1/0) and the dollar amount of deferred compensation, while the even specifications examine the relationship between the dollar amount of pay cut and the dollar amount of deferred compensation following a pay cut. Controlling only for pay cut and size (Model 1), we see there is a positive and significant relationship between pay cut and deferred compensation. This relationship holds when we add out other control variables (Model 3). When we include Bonus and an interaction term (Model 5) we see that there is an insignificant relationship between Bonus and deferred compensation; however, the positive coefficient on the interaction term suggests that the greater the magnitude of the bonus cut, the more firms put towards deferred compensation. Thus where the executive has a pay cut, the firm increases contribution to deferred compensation. In the even models we include the absolute value of the dollar amount of the pay cut. Controlling for the amount of the pay cut (Model 2), we see a positive and significant coefficient, indicating that the greater the pay cut, the more the firm pays toward deferred compensation. The results are virtually unchanged when we include our control variables (Model 4). When we include Bonus and the interaction term (Model 6) we see the same positive relationship between the dollar amount of pay cut and firm contributions to deferred compensation. Further, we continue to see the positive coefficient on the interaction term. Overall, the results suggest that Firm Contributions to deferred compensation are used to at least partially offset the impact of a bonus cut.

6. Conclusion

In this paper we examine several hypotheses related to deferred compensation. We test whether deferred compensation is used to align managerial interests with the firm (Optimal Contracting) or is evidence of agency problems (Managerial Power). Under the alignment theory, we examine whether firms use deferred compensation as a means of ex-post settling up. We find no evidence to support this theory. Under the ex-post settling up, there should be a symmetric relationship between firm performance and deferred compensation. We find that while deferred compensation increases following positive firm performance, there deferred compensation does not decrease following negative firm performance. We also look at whether firm use deferred compensation “inside debt” to align managerial interest with the whole firm (not just the shareholders). We find some evidence to support this hypothesis. There is a positive relationship between the firm’s leverage and the amount of firm contributions to deferred compensation. Further, there is a positive (although non-linear) relationship between the CEO’s leverage and firm contributions to deferred compensation.

We also examine whether deferred compensation represents additional agency problems. We look at whether firms used deferred compensation as a means to hide excess pay or to substitute for cuts in bonus. We find support for both. Firms tend to pay more deferred compensation and shift from current compensation to deferred compensation in periods of high outrage (or periods of high attention on executive compensation). We also see evidence that firms increase deferred compensation in periods where the CEO experiences a bonus cut. Overall, our results indicate there is an inherent agency problem in deferred compensation.

Table 1: Summary Statistics

This table displays the summary statistics for the sample period 2006-2012. The first line under each variable shows the summary statistics for the full sample, while the second and third line break the sample into whether the firm made contributions to deferred compensation (Firm Contributions) or not (No Firm Contributions). Values are winsorized at the 1st and 99th percentiles and are scaled in thousands of dollars. ***, **, and * indicate significance at the 1%, 5%, and 10% levels, respectively.

Variable	N	Mean	Median	Min (1%)	Max (99%)	Std. Dev.

Table 2: Preliminary Analysis

In this table we test to see whether firm contributions to deferred compensation are significantly different from other forms of compensation.. The dependent variable is the amount of firm contributions and independent variables are factors common to executive compensation. We test whether the coefficients are significantly different for the two equations using the lincom command in stata. Z-scores

Table 3: Probability of Firm Contributions

This table examines the probability that a firm will make a contribution to deferred compensation in a given year as a function of firm size, profitability, and other control variables. Contribution equal 1 if the firm made a contribution in the fiscal year and zero otherwise. The equation is as follows:

$$Pr(Contributions_t) = a + b_1 log(Assets) + b_2 ROA + b_3 D/E + b_4 (Controls)$$

where log(Assets) is the natural log of total assets, ROA is the return on assets, which proxies for firm performance, D/E is the firm's debt-to-equity ratio, and controls include free cash flow, asset turnover, capital expenditures, tenure (the number of years the individual has served as CEO), and duality (whether the CEO is also the chairman of the board). ***, **, and * denote significance at the 1%, 5%, and 10% levels, respectively. Z-scores are shown in brackets.

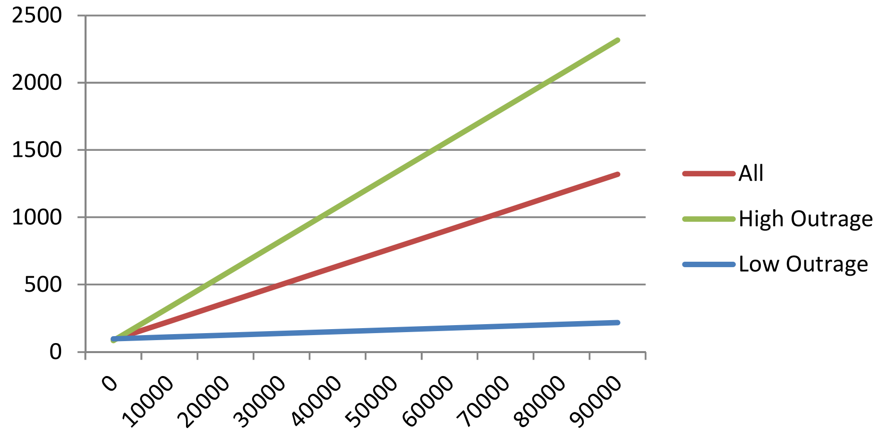
Figure 1: Excess Current Compensation and Deferred Compensation

Model: Firm Contributions (Y) = Excess Pay (X)



This figure graphs the relationship between excess pay (X) and deferred compensation (Y). Excess Pay is defined as the difference between actual pay minus 125% of size/industry median pay. The Outrage Index is a measure based on how often searches on “excess compensation” “overpaid CEO”, “say-on-pay” etc. are searched. High outrage indicates periods of high search volume on these and similar terms that indicate dissatisfaction with excess executive compensation.

Table 5: Multivariate Regression Analysis on Firm Contributions and Ex-Post Settling Up

This table examines the relationship between firm contributions to deferred compensation and firm performance. We use return on assets (ROA) as our primary measure of firm performance and include lags of return on assets. Return on Assets (ROA) is defined as Net Income divided by Total Assets. Panel A examine the relationship between the dollar value of deferred compensation and firm performance while Panel B examines the probability that a firm will increase deferred compensation based on firm performance. T-stats are shown in parentheses. ***, **, and * denote significance at the 1%, 5%, and 10% levels, respectively.

Table 6: Inside Debt

This table examines the relationship between firm contributions and leverage. We examine both firm leverage (Firm D/E) and CEO leverage (CEO D/E). Firm leverage is defined as Total Debt divided by Total Assets. CEO Leverage is defined as the percentage of CEO holdings that is deferred compensation relative to total debt and equity holdings. We measure firm contributions as a function of firm size, performance, firm leverage, CEO leverage, and controls. T-stats are displayed in parentheses. ***, **, and * denote significance at the 1%, 5%, and 10% levels, respectively.

Table 8: Substitution Hypothesis

This table examine the relationship between pay cuts and firm contributions to deferred compensation. We defined pay cut as a 25% or more decrease in bonus from the prior year. However, to ensure that we are not simply capturing firms that pay bi-annual bonuses we also require that the bonus had not increase more than 25% from the prior year. Thus $Bonus_t < 0.75*Bonus_{t-1}$ and $Bonus_{t-1} < 1.25*Bonus_{t-2}$.The odd specifications examine whether a pay cut (1/0) impacts the dollar value of deferred compensation using OLS regression. The even specifications estimate the magnitude of the substitution effect using the dollar amount of the pay cut as an explanatory variable. All values are in thousands of dollars. T-stats are shown in parentheses. ***, **, and * denote significance at the 1%, 5%, and 10% levels, respectively.

Credit Valuation Adjustment of Cap and Floor with Counterparty Risk: A Structural Pricing Model for Vulnerable European Options

Lie-Jane Kao
Department of Finance and Banking
KaiNan University
No.1 Kainan Road, Luzhu Shiang, Taoyuan 33857, Taiwan
ljkao@mail.knu.edu.tw

This study develops a structural pricing model based on the Black 76 formula (Black, 1976) for the evaluation of the Credit Value Adjustment (CVA) of OTC traded caps and floors, which is mandated as an integral part of Basel III (Basel III, 2011). The proposed structural pricing model improves the existing structural pricing models for vulnerable European options by Klein and Inglis (Journal of Banking and Finance 25: 993-1012, 1999) and Liao and Huang (Quantitative Finance 5 (5): 443-457, 2005) by allowing payments made after the exercise of the options. Four crucial determinants of caps' and floors' CVAs are identified by the proposed structural model, they are: the cap's/floor's tenor, the correlation between the cap's/floor's underlying and the writer's asset value, the volatility of the writer's asset value, and the writer's aggregate liabilities. Numerical examples are given to demonstrate the effects of the four parameters. Compared to the market practice of CVA calculation based on reduced-form models, the four crucial parameters are the unique features of the proposed structural model.

Keywords: Structural pricing model; Credit Value Adjustment (CVA); Cap; Floor; Basel III; Tenor; Aggregate liabilities; Reduced-form model.

1. INTRODUCTION

After the 2008 financial crisis, the Basel Committee on Banking Supervision noted that roughly two-thirds of credit losses were due to counterparty's creditworthiness deterioration and only one-third were due to counterparty defaults. For this reason, accurate valuation of the market value of counterparty credit risk is now mandated as an integral part of accounting rules and Basel III (Basel III 2011). Under these regulatory initiatives, larger institutions need to calculate the Credit Value Adjustment (CVA), which is the difference between the values of the OTC derivatives calculated with and without counterparty credit risk exposures, respectively (Basel III 2011).

The market practice often adopted the reduced-form models to calculate the CVAs (Sorensen and Bollier 1994; Picault 2005; Cespedes, Rosen and Saunders 2010; Rebonato et al. 2010; Pengelley 2011; Basel III 2011; Hull and White 2012; Rosen and Saunders 2012; and Cherubini 2013). According to the Basel III, the counterparty's default probability is assumed to be independent of the market variables that underlie the derivative exposures, which is in line with the assumption made by the pioneering paper on the credit risk in swap contracts by Sorensen and Bollier (1994). In practice, however, the market variables and the counterparty's default probability are not independent. If the market value of the derivative exposure increases as the counterparty's credit quality deteriorates, the associated risk is referred as the wrong-way risk (WWR) (Cespedes, Rosen and Saunders 2010; Rosen and Saunders 2012; Hull and White 2012; Cherubini 2013). To the contrary, if the value of the derivative exposure decreases as the counterparty's credit quality deteriorates, right-way risk (RWR) occurs.

The wrong-way risk (WWR) can represent a significant increase in the CVAs, as compared to the CVAs calculated under the assumption that the market variables and the counterparty's credit risk are independent (Rosen and Saunders 2012; Hull and White 2012; Cherubini 2013). To handle the WWR, the simplest way is to use the alpha multiplier approach (Cespedes, Rosen and Saunders 2010), in which the market values of the derivative exposures are enlarged by the alpha multiplier and the CVA is calculated under the framework that the market variables and the counterparty's default probability are independent. Alternatively, one can increase the counterparty's default probability to reflect the positive relationship between the market value of the derivative exposure and the counterparty's default probability (Hull and White 2012). The third approach to handle WWR is to employ the copula technique to evaluate the CVAs, in which the unobservable dependence structure between the market values of derivative exposures and the counterparty's default probability is built based on a flexible copula function (Rosen and Saunders 2012; Cherubini 2013).

Instead of a reduced-form model, this study develops a structural model for the evaluation of OTC traded caps' and floors' CVAs, which are amongst the largest and most liquid derivatives market (Gupta and Subrahmanyam 2005). Being a strip of caplets/floorlets, the market practice of pricing non-vulnerable caps/floors is based on the Black 76 formula for European call/put options (Black, 1976; Brace, Gatarek, and Musiela 1997; Jamshidian 1997). To take into consideration of the counterparty's credit risk, this study adopts the framework of the existing structural models for vulnerable European options (John and Stulz 1987; Klein 1996; Klein and Inglis 1999;

Klein and Inglis 2001; Cherubini 2002; Liao and Huang 2005), in which the counterparty's asset value is dynamically modelled by a stochastic process. In addition, as the transactions of a cap (floor) might be only a small part of the counterparty's OTC book, a default threshold that represents the sum of all the liabilities in the counterparty's OTC book is assumed (Klein 1996; Klein and Inglis 1999; Liao and Huang 2005). In this way, the possible default due to other liabilities in the counterparty's OTC book (Rosen and Saunders 2012) is also considered.

Compared to the existing structural pricing models for vulnerable European options (John and Stulz 1987; Klein 1996; Klein and Inglis 1999; Klein and Inglis 2001; Cherubini 2002; Liao and Huang 2005), which are mainly developed for options with payments made upon the exercises of the options, the proposed structural model improves the existing structural models by allowing payments to be made one period of time after the exercise of the option. In this way, the proposed structural model fits into the purpose of the valuation of the caplet/floorlet in which the payment is made one tenor after the exercise of the caplet/floorlet at its reset date.

Four parameters that are crucial determinants of caps' and floors' CVAs are identified by the proposed structural model, they are: the cap's/floor's tenor, the correlation ρ between the cap's/floor's underlying and the writer's asset value V, the volatility σ_V of the writer's asset value V, and the writer's aggregate liabilities D. Numerical examples are given to demonstrate the effects of the four parameters. In summary, this study finds that: 1) Caps and floors having longer tenors have larger CVAs; 2) The correlation ρ has a negative effect on a cap's CVAs, and a positive effect on a floor's CVAs. The effect of the correlation ρ is most pronounced for the out-of-money caps or floors; 3) The volatility σ_V of the writer's asset has a positive effect on the CVAs: for a cap contract, the effect of the volatility σ_V is most (least) significant as the correlation $\rho = -0.9$ ($=0.9$). On the other hand, for a floor contract, the effect of the volatility σ_V is most (least) significant as the correlation $\rho = 0.9$ ($= -0.9$).

4) The aggregate liabilities D has a positive effect on the CVAs, however, the shorter the tenor, the less sensitivity of the CVAs to the aggregate liabilities D.

This paper is organized as follows. Literature review of the pricing of vulnerable European options is given in Section 2. A structural pricing model for vulnerable European options with deferred payment is developed in Section 3. The CVA of a cap or a floor is derive in Section 4. Numerical examples that illustrate the calculation of the CVAs are given in Section 5. Section 6 concludes.

2. REVIEW OF PRICING MODELS OF VULNERABLE EUROPEAN OPTIONS

In literature, there are two types of pricing models for vulnerable options subject to pre-settlement default events, they are the reduced-form and structural models, respectively (John and Stulz 1987; Klein 1996; Hull and While 1995; Jarrow and Turnbull 1995; Klein and Inglis 1999; Klein and Inglis 2001; Liao and Huang 2005). In the reduced-form approach, default occurs if a vector of exogenously determined state variables ϕ reaches a specified default boundary for the first time before the option's maturity date (Hull and White 1995; Jarrow and Turnbull 1995). In case of default, the option holder was paid by the nominal amount of the option times a stochastic paid-out ratio that is determined by the state variables ϕ. Usually, two independent diffusion processes are assumed for the option's underlying and the vector of state variables ϕ. Nevertheless, the independent assumption is only sensible when the option writer's total asset is well-diversified or fully-hedged (Hull and White 1995). For most situations, the assumption is not realistic. In particular, when firms issue options to hedge their price risks, it is almost certain the option issuer's total asset is correlated with the option's underlying (Klein 1996).

In contrast to the reduced-form models, the structural models address the correlation between the option's underlying and the writer's total asset. Johnson and Stulz (1987) pioneer the work in developing a structural model for the pricing of vulnerable call options. By assuming the option is the only liability of the option writer and default occurs when the writer's total asset value is less than the option's payoff at the maturity date T_m, Johnson and Stulz's model explains the substantial reduction in the prices of vulnerable European call (put) options when the writer's asset is strongly positively (negatively) correlated with the option's underlying asset.

Since in most business settings, the liability attributed to the option takes only a very small proportion of the option writer's aggregate liabilities, Klein (1996) extends Johnson and Stulz (1987) by allowing the option writer to have other liabilities which rank equally with the underlying option. It is assumed the aggregate liabilities at the maturity date T_m of the option is a constant D and default occurs if the option writer's total asset value is less than D at T_m. In the event of default, a proportion of the nominal claim is paid out, which depends on the bankruptcy cost and the option writer's total asset at the maturity T_m. Later, Klein and Inglis (1999) generalize the framework of Klein (1996) by incorporating a stochastic interest rate (Vasicek 1977). Klein and Inglis (2001) consider a stochastic default barrier which is the sum of the stochastic default barrier of Johnson and Stulz (1987) and the deterministic default barrier of Klein (1996) to account for the situation that the option represents a significant proportion of the writer's aggregate liabilities and the outgrow of the option's value may be the primary cause of the writer's financial distress.

All the aforementioned structural models assume that default can occur only at the maturity T_m. Liao and Huang (2005) extend the structural model of Klein and Inglis (1999), in which default is allowed to occur prior to the maturity T_m with default boundary modeled as the discounted value of the writer's aggregate liabilities at the maturity T_m. In the following, a structural model that extends Liao and Huang (2005) by allowing the default to occur prior to the maturity T_m as well as during the maturity T_m and the payment date T_p, T_m<T_p, is developed.

3. VALUATION OF VULNERABLE OPTIONS WITH DEFERRED PAYMENT

In this section, the traditional Black-Scholes economy is followed to value a vulnerable European option issued by a writer subject to credit risk under the assumption of no arbitrage. For $0<t<T_p$, let $P(t, T_p)$ be the time-t price of a discount zero-coupon bond paying \$1 at time T, and Q be the T_p-forward measure that uses $P(t, T_p)$ as the numeraire. Under the T_p-forward measure Q, $X(t)/P(t, T_p)$ is a martingale for the price $X(t)$ of any traded asset (Harrison and Kreps 1979), and therefore

$$X(t)=P(t,T_p)E_Q\left[\frac{X(T)}{P(T,T_p)}\bigg|\mathcal{F}_t\right] \tag{3.1}$$

for $0\le t<T\le T_p$, the expectation E_Q is taken with respect to the T_p-forward measure Q, and $\mathcal{F}_t$ is the information set up to the time t.

Suppose an option writer has competing liabilities outstanding of equal rankings and the aggregate amount of the liabilities at the payment date T_p is D. Similar to Liao and Huang's structural model for vulnerable European option (Liao and Huang 2005), default occurs as soon as the option writer's total asset $V(t)$ is less than the default boundary, which is the discounted value of the aggregate liability $P(t, T_p)D$. Let τ_D be the default time and α represents the percentage of the deadweight costs associated with the default event. If no default occurs, the payoff $X(T_p)$ at the payment date T_p is the full payment $(S(T_m)-K)^+$ for the call and $(K-S(T_m))^+$ for the put options, where $S(T_m)$ is the price of the underlying asset at the maturity date T_m and K is the option's strike price. As default occurs, the scrap value of the writer's asset is $(1-\alpha)V(\tau_D)$ and the option's payoff $X(T_p)$ at the payment date T_p is $(1-\alpha)(S(T_m)-K)^+$ for the call and $(1-\alpha)(K-S(T_m))^+$ for the put, respectively. Therefore at the payment date T_p, the option's value is

$$C(T_p)=(S(T_m)-K)^+-\alpha(S(T_m)-K)^+1_{\{\tau_D\le T_p\}} \tag{3.2}$$

$$P(T_p)=(K-S(T_m))^+-\alpha(K-S(T_m))^+1_{\{\tau_D\le T_p\}} \tag{3.3}$$

for the call and put, respectively, $1_{\{\}}$ is the indicator function. According to (3.1), the time-0 value $C(0)$ of a vulnerable European call and time-0 value $P(0)$ and of a vulnerable European put with payoff $X(T_p)$ at the payment date T_p are respectively

$$C(0)=B(0,T_p)\left(E_Q\left[(S(T_m)-K)^+\middle|\mathfrak{F}_0\right]-\alpha E_Q\left[(S(T_m)-K)^+1_{\{\tau_D\le T_p\}}\middle|\mathfrak{F}_0\right]\right) \tag{3.4}$$

$$P(0)=B(0,T_p)\left(E_Q\left[(K-S(T_m))^+\middle|\mathfrak{F}_0\right]-\alpha E_Q\left[(K-S(T_m))^+1_{\{\tau_D\le T_p\}}\middle|\mathfrak{F}_0\right]\right) \tag{3.5}$$

Since the option's underlying asset $S(t)$ is a martingale under the T_p-forward measure Q, and the evolution of $S(t)$ follows

$$dS(t)=\sigma_S S(t)dW_S(t) \tag{3.6}$$

where W_S is a standard Brownian motion under the T_p-forward measure Q. If assuming the option writer's asset $V(t)$ is tradable, then the evolution of the writer's forward asset value

$$V_F(t)=V(t)/P(t,T_p) \tag{3.7}$$

is a martingale and its evolution follows

$$dV_F(t)=\sigma_V V_F(t)dW_V(t) \tag{3.8}$$

where W_V is a standard Brownian motion under the T_p-forward measure Q, which is correlated with W_S and has the instantaneous correlation ρ. The time-0 values $C(0)$ and $P(0)$ are derived explicitly as follows.

Lemma 3.1. Under the framework (3.6)-(3.8), the time-zero prices $C(0)$ and $P(0)$ of a vulnerable European call and put options with maturity and payment dates at T_m and T_p, $T_p>T_m$, are respectively

$$\begin{aligned}C(0)=&\ P(0,T_p)\int_{-\infty}^{\infty}h_1(f)g(f)df\\ &-\alpha P(0,T_p)\int_{-\infty}^{\ln D}h_1(f)\times\left[1-Pr\{U(T_m)>\ln D\mid L_F=f\}\right]g(f)df\\ &-\alpha P(0,T_p)\int_{\ln D}^{\infty}h_1(f)Pr\{U(T_p)\le\ln D\mid U(T_m)>\ln D, L_F=f\}\times Pr\{U(T_m)>\ln D\mid L_F=f\}g(f)df\end{aligned}$$

$$
\begin{aligned}
P(0) = {} & P(0,T_p)\int_{-\infty}^{\infty} h_2(f)g(f)df \\
& - \alpha P(0,T_p)\int_{-\infty}^{\infty} h_2(f)\times\left[1 - Pr\{U(T_m) > \ln D \mid L_F = f\}\right]g(f)df \\
& - \alpha P(0,T_p)\int_{\ln D}^{\infty} h_2(f)Pr\{U(T_p) \le \ln D \mid U(T_m) > \ln D, L_F = f\}\times Pr\{U(T_m) > \ln D \mid L_F = f\}g(f)df
\end{aligned}
$$

where $g(f)$ if the probability density function of a normal distribution with mean

$$\mu(f) = \ln S(0) - \sigma_S^2 T_m / 2 + \rho\sigma_S[f - \ln V(0) + \ln P(0,T_p) + \sigma_V^2 T_m / 2]/\sigma_V$$

and variance $\sigma_m^2 = \sigma_S^2(1-\rho^2)T_m$. The functions

$$
\begin{aligned}
h_1(f) = {} & E_Q\left[(S(T_m) - K)^+ \mid L_F = f\right] \\
& = e^{\mu(f)+\sigma_m^2/2}\Phi\left(\frac{-\ln K + \mu(f) + \sigma_m^2}{\sigma_m}\right) - K\Phi\left(\frac{-\ln K + \mu(f)}{\sigma_m}\right) \\
h_2(f) = {} & E_Q\left[(K - S(T_m))^+ \mid L_F = f\right] \\
& = -e^{\mu(f)+\sigma_m^2/2}\Phi\left(\frac{\ln K - \mu(f) - \sigma_m^2}{\sigma_m}\right) + K\Phi\left(\frac{\ln K - \mu(f)}{\sigma_m}\right)
\end{aligned}
$$

Proof. In Appendix A and B.

4. CREDIT VALUATION ADJUSTMENT OF CAP/FLOOR

The standard model of credit valuation adjustment (CVA) was first proposed by Sorensen and Bollier (1994) for vanilla swap contracts, in which the fixed-rate paying party, namely A, pays a stream of fixed-rate coupons and receives payments indexed to a reference floating interest rate such as EURIBOR or LIBOR. For a general derivative, let T be the maturity and α be the constant lose given default. Then

$$CVA = \alpha\int_0^T Y(t)h(t)dt \tag{4.1}$$

where $h(t)$ is the probability density function of the counterparty's time τ to default, $Y(t) = E[max\{v(t),0\} \mid \tau = t]$ is the time-t conditional expected value of the exposure, where $v(t)$ is the time-t value of the derivative. Here the probability density function $h(t)$ of the counterparty's time to default is usually estimated from the counterparty's credit spreads observed in the market.

For a cap contract, the holder of the cap, say party A, can be considered as the fixed rate payer, while the writer of the cap can be considered as the fixed-rate receiving party B. Suppose the cap has n caplets with n payment dates $T_1 < \cdots < T_n$, and B defaults during the times T_{j-1} and T_j, that is, $T_{j-1} < \tau_B \le T_j < \cdots < T_n$, where τ_B is the default time of B. In such a case, the exposure to loss of party A at time τ_B will be the sum of the values of the $(n-j+1)$ caplets with payment dates $T_j < \cdots < T_n$, i.e.,

$$FE_j^A(\tau_B) = \Delta \sum_{i=j}^{n} P(\tau_B, T_i) E_{\tau_B}\left[max\{f(T_{i-1}, T_{i-1}, T_i) - K, 0\}\right] \tag{4.2}$$

where $f(t, T_{i-1}, T_i)$ is the forward EURIBOR or LIBOR rate at time t, $P(t, T)$ is the time-t price of a discount zero-coupon bond paying \$1 at time T. By the Black 76 model, (4.2) is the sum of the prices of $(n-j+1)$ non-vulnerable European call option with strike K and underlyings $f(t, T_{i-1}, T_i)$, $j \le i \le n$. The time-0 CVA is

$$\begin{aligned} \text{CVA} &= \alpha\Delta \sum_{j=1}^{n}\left[\int_{T_{j-1}}^{T_j} P(0,\tau_B) FE_j^A(\tau_B) h(\tau_B) d\tau_B\right] \\ &= \alpha\Delta \sum_{i=1}^{n} P(0,T_i)\left[\int_0^{T_i} E_{\tau_B}\left[max\{f(T_{i-1}, T_{i-1}, T_i) - K, 0\}\right] h(\tau_B) d\tau_B\right] \end{aligned} \tag{4.3}$$

where α is the loss given default, $h(\tau_B)$ is the probability density function of the default time τ_B. In (4.3), the CVA can be decomposed as the losses corresponding to n vulnerable European call options, with the loss of the i^{th} option as

$$\alpha\Delta P(0,T_i)\left[\int_0^{T_i} E_{\tau_B}\left[max\{f(T_{i-1}, T_{i-1}, T_i) - K, 0\}\right] h(\tau_B) d\tau_B\right] \tag{4.4}$$

where T_{i-1} is the exercise date and T_i is the payment date T_i, $1 \le i \le n$. For the i^{th} vulnerable European option, $1 \le i \le n$, suppose default occurs as soon as the option writer's total asset $V(t)$ is less than the discounted aggregate liability $P(t, T_i)D$, where D is the aggregate liabilities at the payment date T_i. Then (4.4) can be rewritten as

$$\alpha\Delta P(0,T_i) E\left[max\{f(T_{i-1}, T_{i-1}, T_i) - K, 0\} \times 1_{\{\tau_B < T_i\}}\right] \tag{4.5}$$

Compared to (3.4), by letting $T_{i-1} = T_m$ and $T_i = T_p$, one can see that (4.5) is the difference between the time-0 price of a non-vulnerable European call and $C_i(0)$, i.e.,

$$\Delta P(0,T_i)E\left[max\left(f\left(T_{i-1},T_{i-1},T_i\right)-K,0\right)\right]-C_i(0)$$

where $C_i(0)$ is the price of a vulnerable European call option with deferred payment given in Lemma 3.1. Together with (4.2), it is concluded that CVA is the difference between the time-0 prices of a non-vulnerable cap and the corresponding vulnerable cap, respectively. Similarly, the CVA of a floor can be obtained as the difference between the time-0 prices of the non-vulnerable floor and vulnerable floor, respectively. In the following, numerical examples will be given to illustrate the calculation of the cap's CVA.

5. NUMERICAL EXAMPLE OF VULNERABLE CAP/FLOOR

This Section uses numerical examples to illustrate the calculation of the CVAs of two caps and two floors with the floating EURIBOR as the underlying. The reset frequencies (tenors) of the two caps (floors) are 6-month and 1-month, respectively. The starting date of the 6-month cap (floor) and 1-month cap (floor) are July 3, 2013 and Jan 3, 2013, respectively. Both caps (floors) have the same starting reset date as of July 3, 2013, strike rate K=1%, and the notional amount of 100. The payment dates of the 6-month tenor cap (floor) are Jan. 2, 2014, July 2, 2014, Jan. 2, 2015, July 2, 2015, Jan. 4, 2016, July 4, 2016, Jan. 2, 2017, July 3, 2017, respectively. The payment dates of the 1-month tenor cap (floor) are Aug. 2, 2013, Sep. 2, 2013, Oct. 2, 2013, Nov. 4, 2013, Dec. 2, 2013, Jan. 2, 2014, respectively. The 6-month and 1-month forward EURIBOR rates and discount rates derived from the forward curve starting from July 3, 2013 are given in Table 1. The volatilities of the 6-month caplet/floorlet and the 1-month caplet/floorlet, calibrated by a Stochastic Alpha, Beta, Rho model (SABR) model (Hagan et al. 2002) using Bloomberg EUR Caps/Floors implied volatility surface on 06/28/2013, are given in Panel A and B, respectively, of Table 2.

The writer's initial asset value and the ratio of bankruptcy cost are assumed to be $V(0)$=100,00 and α=0.5, respectively. Four aggregate liabilities D are assumed:

D=2000, D=4000, D=6000, and D=8000, respectively. Three different volatilities of the writer's asset $V(t)$ are considered: σ_V=0.15, σ_V=0.30, σ_V=0.45, σ_V=0.60, respectively. The correlation ρ between the cap/floor underlying, i.e., the forward EURIBOR and the writer's asset $V(t)$ is set to -0.9, -0.6, -0.3, 0.0, 0.3, 0.6, 0.9, respectively.

Tables 1-2 provide the CVAs of the aforementioned 6-month and 1-month caps, respectively, under various combinations of the three parameters: aggregate liabilities Ds, volatilities of the writer's asset σ_Vs, and correlations ρs between the cap's underlying, i.e., the forward EURIBOR rate, and the writer's asset $V(t)$. For a cap contract, the CVA increases as the correlation ρ decreases. This is due to the fact that a negative correlation ρ between the forward rate and the writer's asset value implies a positive relationship between the forward rate and the writer's default probability. As higher forward rate implies higher exposure of the cap contract, together with the higher default probability, one can thus conclude that negative correlation ρ leads to a higher CVA. Figures 1-2 illustrate this negative relationship for the 6-month and 1-month caps under four aggregate liabilities D=2000, D=4000, D=6000, and D=8000, respectively. Note the volatility σ_V of the writer's asset is held fixed at σ_V=0.45. Note Figures 1-2 also indicate a positive relationship between the CVAs and the aggregate liabilities D. For the 1-month cap in Figure 2, the CVAs are negligible at the lower levels of aggregate liabilities: as D=2000, the CVAs are all negligible, while the CVAs are negligible for higher correlations with as D=4000. To the contrary, the CVAs of the 6-month cap in Figure 1 are all significant. This indicates the shorter the tenor, the l+ess sensitivity of the CVAs to the aggregate liabilities D. This also holds for the 1-month floor as illustrated in Figure 4.

Tables 3-4 provide the CVAs of the aforementioned 6-month and 1-month floors, respectively, under various combinations of the three parameters: aggregate liabilities Ds, volatilities of the writer's asset σ_Vs, and correlations ρs between the cap's underlying, i.e., the forward EURIBOR rate, and the writer's asset $V(t)$. To the contrary of the cap contracts, the relationship between the CVAs and the correlation ρ is positive for the floor contracts. This is due to the fact that a positive correlation ρ between the forward rate and the writer's asset value implies a negative relationship between the forward rate and the writer's default probability. As a lower forward rate implies higher exposure of the floor contract, together with the higher default probability, one can thus conclude that a positive correlation ρ leads to a higher CVA.

The CVAs of the 1-month cap in Figure 2 are the most sensitive to the correlation ρ, as compared to the 6-month cap in Figure 1, and the 6-month and the 1-month floors in Figures 3-4, respectively. This is due to the fact that the 1-month cap is an out-of-money cap with all its caplets out-of-money. The price of an out-of-money caplet (floorlet) is more sensitive to a negative (positive) correlation ρ as a significant increase (decrease) in the underlying is required to increase the value of the cap (floor), which significantly increases the default probability simultaneously. For this reason, the reduction in the value of a cap (floor), i.e., the CVA, will be significant for an out-of-money cap (floor).

Figures 5-8 illustrate the positive relationship between CVAs and the volatility σ_V of the writer's asset for the 6-month and 1-month caps and floors under seven correlations -0.9, -0.6, -0.3, 0.0, 0.3, 0.6, 0.9, respectively. Note the writer's aggregate liabilities D is held fixed at $D=4000$. From Figures 5-8, certain degrees of interaction effects between the correlation ρ and the volatility σ_V are exhibited. This can be seen from Figures 5-8 that the effect of the correlation ρ on the CVAs is most prevalent as the volatility $\sigma_V=0.60$, while the effect of the correlation ρ are negligible as the volatility $\sigma_V=0.15$. For a cap contract, the effect of the volatility σ_V is most (least) significant as the correlation $\rho=-0.9$ $(=0.9)$. On the other hand, for a floor contract, the effect of the volatility σ_V is most (least) significant as the correlation $\rho=0.9$ $(=-0.9)$.

For higher aggregate liabilities D (D>4000), the positive relationship between the CVAs and the volatility σ_V for all the four contracts is more significant. At the same time, the corresponding interaction effect between the correlation ρ and the volatility σ_V is also more significant.

6. SUMMARY AND CONCLUSION

A structural model with analytic pricing formulas is derived for the valuation of the Credit Value Adjustment (CVA) of the caps and floors, which play important roles in the interest rate derivatives market. The proposed structural model improves the existing structural models for vulnerable European options by allowing the payments made one period of time (tenor) after the exercise of the options. Four parameters in the proposed structural model in determining the CVAs are identified, they are: the cap's/floor's tenor, the correlation ρ between the cap's/floor's underlying and the writer's asset, the volatility σ_V of the writer's asset, and the writer's aggregate liabilities D. Compared to the market practice of calculating the CVAs based on the reduced-form models, the four crucial parameters of CVAs are the unique features of the proposed structural model. It is hoped the proposed structural model can be extended for more complicated interest rate derivatives in the market, e.g., swap contracts. This will be the future work of this study.

Table 1. Forward EURIBOR and discount rates

Start date	End date	Discount factor Start	Discount factor End	Forward rate

The differences ($\times 10^4$) between the prices of the vulnerable floor and the non-vulnerable floor by Black (1976), which is 0.4163, under various correlation ρ between the option's underlying and the writer's total assets, various aggregate liabilities D of the writer, and various volatility σ_V of writer's total asset are shown.

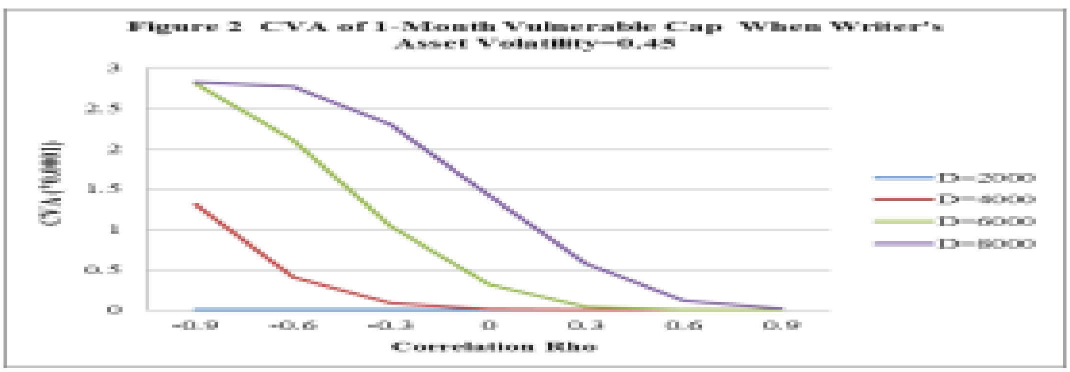
Note. This figure illustrate the relationship between CVA and the correlation ρ (Rho) between the option's underlying and the writer's assets under four different aggregate liabilities D of the writer for a 6-month cap with strike 1%. The writer's initial asset value $V(0)$=10,000, and the asset volatility σ_V =0.45.



Note. This figure illustrate the relationship between CVA and the correlation ρ (Rho) between the option's underlying and the writer's assets under four different aggregate liabilities D of the writer for a 1-month cap with strike 1%. The writer's initial asset value $V(0)$=10,000, and the asset volatility σ_V =0.45.

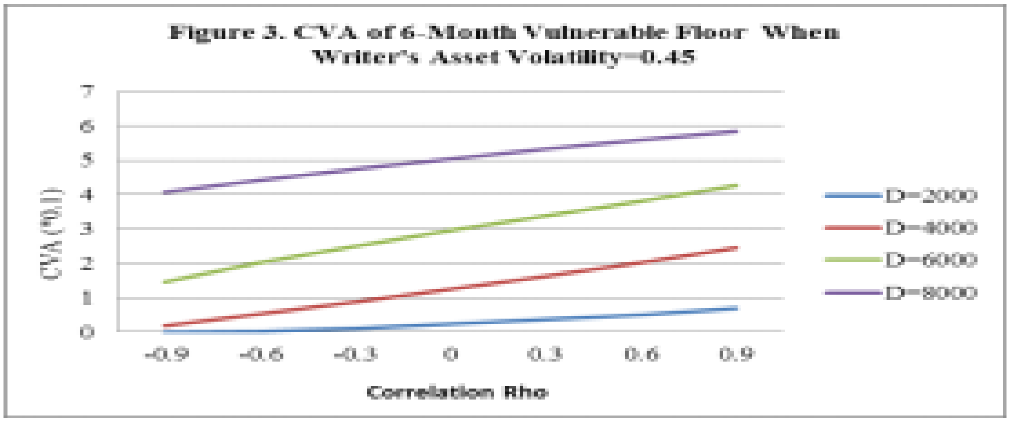


Figure 3. CVA of 6-Month Vulnerable Floor When Writer's Asset Volatility=0.45

Note. This figure illustrate the relationship between CVA and the correlation ρ (Rho) between the option's underlying and the writer's assets under four different aggregate liabilities D of the writer for a 6-month floor with strike 1%. The writer's initial asset value $V(0)$=10,000, and the asset volatility σ_V =0.45.

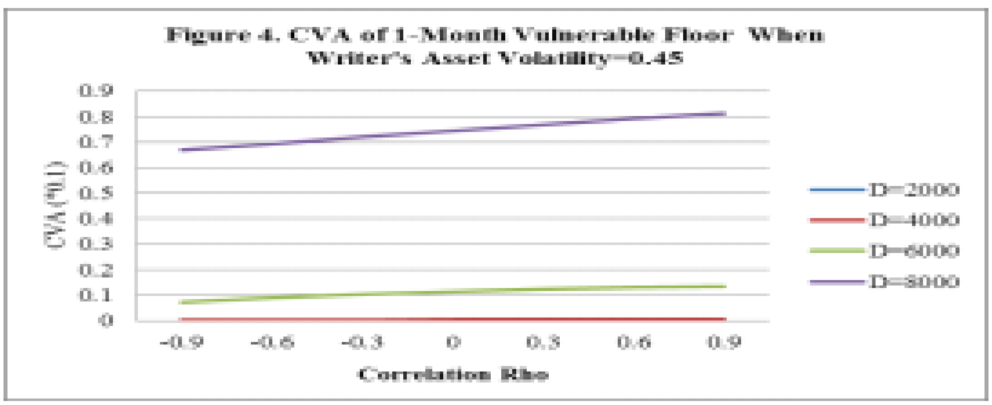

Figure 4. CVA of 1-Month Vulnerable Floor When Writer's Asset Volatility=0.45

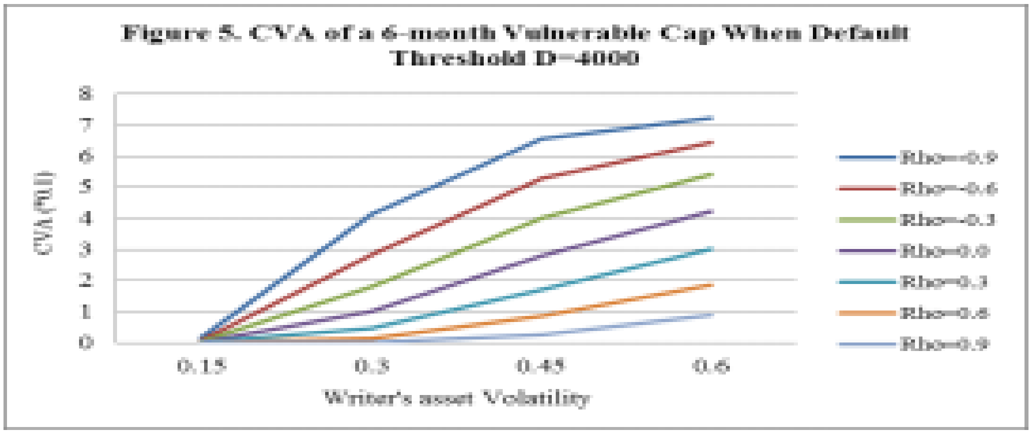
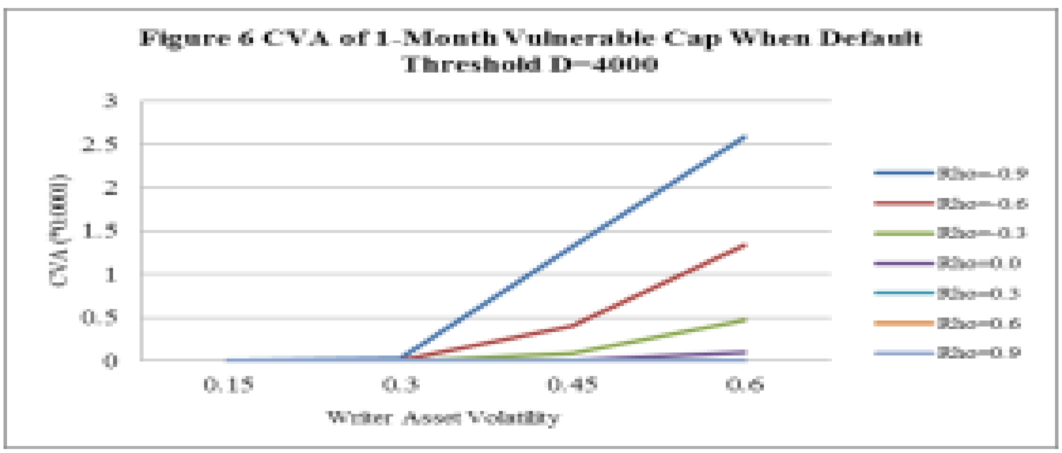
Note. This figure illustrate the relationship between CVA and the correlation ρ (Rho) between the option's underlying and the writer's assets under four different aggregate liabilities D of the writer for a 1-month floor with strike 1%. The writer's initial asset value $V(0)$=10,000, and the asset volatility σ_V =0.45.

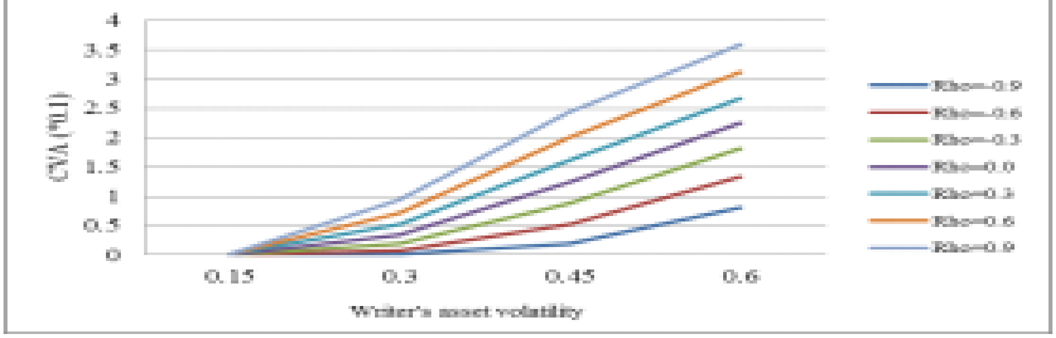


Note. This figure illustrate the relationship between CVA and the volatility of the writer's asset under seven different correlation ρ (Rho) between the option's underlying and the writer's assets of the writer for a 6-month cap with strike 1%. The writer's initial asset value $V(0)$=10,000, and the aggregate liabilities D=4000.



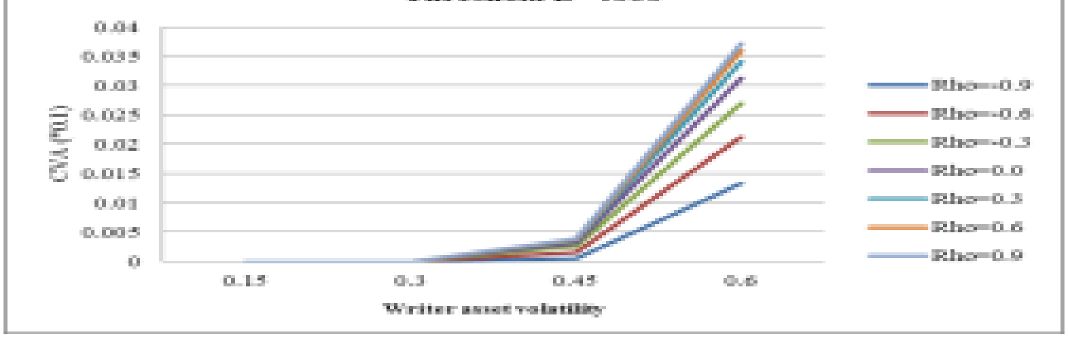
Note. This figure illustrate the relationship between CVA and the volatility of the writer's asset under seven different correlation ρ (Rho) between the option's underlying and the writer's assets of the writer for a 1-month cap with strike 1%. The writer's initial asset value $V(0)$=10,000, and the aggregate liabilities D=4000.

Figure 7. CVA of 6-Month Vulnerable Floor When Default Threshold D=4000



Note. This figure illustrate the relationship between CVA and the volatility of the writer's asset under seven different correlation ρ (Rho) between the option's underlying and the writer's assets of the writer for a 6-month floor with strike 1%. The writer's initial asset value $V(0)$=10,000, and the aggregate liabilities D=4000.

Figure 8.CVA of 1-Month Vulnerable Floor When Default Threshold D=4000



Note. This figure illustrate the relationship between CVA and the volatility of the writer's asset under seven different correlation ρ (Rho) between the option's underlying and the writer's assets of the writer for a 1-month floor with strike 1%. The writer's initial asset value $V(0)$=10,000, and the aggregate liabilities D=4000.

APPENDIX A

Suppose the initial asset value $V(0)$ exceeds the discounted default threshold D, i.e., $V(0)>P(0,T_F)D$. For the discussion hereto, set $L_F=lnV_F(T_m)$, where $V_F(t)$ is the option writer's time-t forward asset value defined in (3.7). Define the auxiliary random process associated with $V_F(t)$ as

$$U(t)=min\{\ln V_F(u): 0\le u\le t\}\ ,\ t>0 \tag{A1}$$

Lemma A.1 Given $L_F=f$, the logarithm of the underlying asset's value $lnS(T_m)$ is independent of the auxiliary random process $\{U(t): 0\le t\le T_F\}$ and is normally distributed with mean

$$\mu(f)=lnS(0)-\sigma_S^2T_m/2+\rho\sigma_S[f-lnV(0)+lnP(T_m,T_F)+\sigma_V^2T_m/2]/\sigma_V$$

and variance $\sigma_m^2=\sigma_S^2(1-\rho^2)T_m$.

Proof. By the evolution (3.8) of the forward asset value $V_F(t)$, the logarithm $lnV_F(t)$ can be expressed as

$$lnV_F(t)=lnV(0)-lnP(t,T_F)-\sigma_V^2t/2+\sigma_VW_V(t) \tag{A2}$$

Given the constraint $L_F=f$, it implies that

$$W_V(T_m)=[f-lnV(0)+lnP(T_m,T_F)+\sigma_V^2T_m/2]/\sigma_V \tag{A3}$$

Consider an orthogonal decomposition of the standard Brownian motion W_S, which drives the option's underlying asset value $S(t)$ in (3.6),

$$W_S(t)=\rho W_V(t)+\sqrt{1-\rho^2}\ W_0(t) \tag{A4}$$

where W_0 is a standard Brownian motion that is independent of W_V. Plugging in (A3) into (A4), one has

$$W_S(T_m)=\rho[f-lnV(0)+lnP(T_m,T_F)+\sigma_V^2T_m/2]/\sigma_V+\sqrt{1-\rho^2}\ W_0(T_m) \tag{A5}$$

Set $c=\rho[f-lnV(0)+lnP(T_m,T_F)+\sigma_V^2T_m/2]/\sigma_V$. (A5) implies that given $L_F=f$, the random variable $W_S(T_m)$ is the sum of a constant c and the random variable $\sqrt{1-\rho^2}\ W_d(T_m)$. Since the underlying asset value $S(t)$ is a martingale (from (3.6)), therefore the logarithm $lnS(T_m)$ satisfies

$$lnS(T_m) = lnS(0) - \sigma_S^2 T_m / 2 + \sigma_S W_S(T_m) \tag{A6}$$

Plugging in (A5) into (A6), one has

$$lnS(T_m) = lnS(0) - \sigma_S^2 T_m / 2 + \sigma_S c + \sqrt{1-\rho^2}\ \sigma_S W_d(T_m) \tag{A7}$$

Set $\mu(f) = lnS(0) - \sigma_S^2 T_m / 2 + \sigma_S c$

$$= lnS(0) - \sigma_S^2 T_m / 2 + \sigma_S \rho[f - lnV(0) + lnP(0, T_p) + \sigma_v^2 T_m / 2]/\sigma_V$$

It follows that given $L_p = f$, $lnS(T_m)$ is the sum of a constant $\mu(f)$ and the random variable $\sqrt{1-\rho^2}\ \sigma_S W_d(T_m)$. As $W_d(T_m)$ is normally distributed with mean zero and variance T_m, from (A7), thus $lnS(T_m)$ normally distributed with mean $\mu(f)$ and variance σ_m^2.

The logarithm of the underlying asset value $lnS(T_m)$ and the auxiliary process $\{U(t)\text{: } 0<t\leq T_p\}$ and are independent conditional on $L_p = f$ is due to the following. From (3.8), the logarithm of the forward asset value $\{\ln V_p(t)\text{: } 0<t\leq T_p\}$ is driven by the Brownian motion $\{W_v(t)\text{: } 0<t\leq T_p\}$, so is the auxiliary random process $\{U(t)\text{: } 0<t\leq T_p\}$, where $U(t) = min\{\ln V_p(u)\text{: } 0\leq u\leq t\}$. Recall the Brownian motions W_v and W_d are independent, it follows the auxiliary process $\{U(t)\text{: } 0<t\leq T_p\}$ is independent of $\{W_d(t)\text{: } 0<t\leq T_p\}$. Recall that given $L_p = f$, $lnS(T_m)$ is the sum of a constant d and the random variable $\sqrt{1-\rho^2}\ \sigma_S W_d(T_m)$, it follows the auxiliary process $\{U(t)\text{: } 0<t\leq T_p\}$ is independent of $lnS(T_m)$ given $L_p = f$. □

Lemma A.2. For any Brownian motion W with drift μ and diffusion σ, the joint distribution function of $W(t)$ and the minimum $M(t) = min\{W(u)\text{:}0\leq u\leq t\}$ is

$$\Pr\{W(t) = w,\ M(t) > a\} = \frac{1}{\sigma\sqrt{t}}\phi\left(\frac{w-\mu t}{\sigma\sqrt{t}}\right)\left(1 - e^{-\left(2a^2 - 2wa\right)/\sigma^2 t}\right) \quad \text{for } w\geq a,\ a\leq 0$$

The distribution function of the minimum $M(t)$ is

$$\Pr\{M(t)\le a\}=1-\Phi\left(\frac{-a+\mu t}{\sigma\sqrt{t}}\right)+e^{2a\mu/\sigma^2}\Phi\left(\frac{a+\mu t}{\sigma\sqrt{t}}\right)\quad \text{for } a\le 0$$

where ϕ is the standard normal density, and Φ is the corresponding distribution function.

***Proof*.** The results follow from (He et al. (1995), p3-4) directly. □

LemmaA.3. Given $L_y=f\ge lnD$, the conditional probability

$$\Pr\{U(T_m)>lnD|L_y=f\}=\left(1-e^{-(2(lnD-f)\times(lnD-lnV(0)+lnP(T_m,T_y)))/\sigma_V^2T_m}\right)$$

***Proof*.** Recall from (A2), the logarithm of the forward asset value

$$lnV_F(t)=lnV(0)-lnP(t,T_y)-\sigma_V^2t/2+\sigma_VW_1(t)$$

Set $W(t)=lnV_F(t)-lnV(0)+lnP(t,T_y)$, then the process $\{W(t): 0\le t\le T_m\}$ obeys a Brownian motion with drift $\mu=-\sigma_V^2/2$ and diffusion σ_V. Define $M(t)=min\{W(u):0\le u\le t\}$, and

$$a=lnD-lnV(0)+lnP(T_m,T_y) \tag{A8}$$

$$w=f-lnV(0)+lnP(T_m,T_y) \tag{A9}$$

By the assumption the initial asset value $V(0)$ exceeds the discounted default threshold D, it follows that $V(0)>P(T_m,T_y)D$ and $a<0$. Also $f\ge lnD$ implies $w\ge a$. Using lemma A.2, for $w\ge a$ and $a<0$, one has the joint probability

$$\Pr\{W(T_m)=w, M(T_m)\ge a\}$$

$$=\frac{1}{\sigma_V\sqrt{T_m}}\phi\left(\frac{w+\sigma_V^2T_m/2}{\sigma_V\sqrt{T_m}}\right)\left(1-e^{-(2a^2-2wa)/\sigma_V^2T_m}\right)$$

As $\{W(t): 0\le t\le T_m\}$ obeys a Brownian motion with drift $\mu=-\sigma_V^2/2$ and diffusion σ_V, thus $W(T_m)$ is normally distributed with mean $-\sigma_V^2T_m/2$ and standard deviation $\sigma_V\sqrt{T_m}$.

It follows the conditional probability is

$$\Pr\{M(T_m)>a\,|W(T_m)=w\}=\left(1-e^{-(2a^2-2wa)/\sigma_V^2T_m}\right)$$

Plugging in a and w in (A8)-(A9), respectively, one has

$$\Pr\{U(T_m)>\ln D|L_p=f\}=\left(1-e^{-(2(\ln D-f)(\ln D-\ln V(0)+\ln P(T_m,T_p)))/\sigma_V^2 T_m}\right)$$

The Lemma is proved. □

LemmaA.4. For $f\geq\ln D$, the conditional probability $\Pr\{U(T_p)\leq\ln D|\Xi\}$ is

$$1-\Phi\left(\frac{-2b-\sigma_V^2(T_p-T_m)}{2\sigma_V\sqrt{T_p-T_m}}\right)+e^{-b}\Phi\left(\frac{2b-\sigma_V^2(T_p-T_m)}{2\sigma_V\sqrt{T_p-T_m}}\right)$$

where the event $\Xi=\{U(T_m)>\ln D,\ L_p=f\}$ and $b=\ln D-f$.

Proof. Define the process $R(t')=\ln V_p(t'+T_m)-L_p$ for $0<t'\leq T_p-T_m$. By the logarithm of the forward asset value $\ln V_p(t)$ in (A2), one has

$$R(t')=-t'\sigma_V^2/2+\sigma_V\{W_p(t'+T_m)-W_p(T_m)\} \tag{A10}$$

By the characteristics of a Brownian motion, the increment $W_p(t'+T_m)-W_p(T_m)$ is independent of the information set $\mathfrak{F}_{T_m}$ up to the maturity date T_m for all $t'>0$. Thus the process $\{R(t'): 0<t'\leq T_p-T_m\}$ is independent of $\mathfrak{F}_{T_m}$ and the minimum

$$M(T_p-T_m)=min\{R(t'): 0<t'\leq T_p-T_m\}$$

is also independent of $\mathfrak{F}_{T_m}$. By the definition of the event Ξ and the random variable $L_p=\ln V_p(T_m)$, one has $\Xi\in\mathfrak{F}_{T_m}$. In addition, conditional on the event $\Xi=\{U(T_m)>\ln D,\ L_p=f\}$, where $f\geq\ln D$, the event $\{U(T_p)\leq\ln D\}$ implies that $M<b$, where $b=\ln D-f$. As $M(T_p-T_m)$ is independent of $\mathfrak{F}_{T_m}$, thus

$$\Pr\{U(T_p)\leq\ln D|\Xi\}=\Pr\{M(T_p-T_m)<b\}$$

where $b=\ln D-f<0$. From (A10), $\{R(t'): 0<t'\leq T_p-T_m\}$ is a Brownian motion with drift $\mu=-\sigma_V^2/2$ and diffusion σ_V. Using Lemma A.2, the probability

$$\Pr\{M(T_p-T_m)<b\}=1-\Phi\left(\frac{-b+\mu t}{\sigma\sqrt{t}}\right)+e^{2b\mu/\sigma^2}\Phi\left(\frac{b+\mu t}{\sigma\sqrt{t}}\right)$$

Plugging in $b=\ln D-f$, $\mu=-\sigma_V^2/2$ and diffusion $\sigma=\sigma_V$, the Lemma follows directly.

APPENDIX B

By the definition of a default event, τ_D is the first passage time the asset value $\{V(s)\colon 0<s\le T_p\}$ first reaches the default boundary $P(t, T_p)D$, that is, the forward asset value $V_p(\tau_D)=lnD$.

Three possibilities are associated with the default time τ_D: (a) No default occurs, i.e., $\tau_D>T_p$; (b) Default occurs prior to or at the maturity date T_m, i.e., the default time $\tau_D\le T_m$; and (c)Default occurs after the maturity but before the payment date, i.e., $T_m<\tau_D\le T_p$. By the definition of the auxiliary process $\{U(t)\colon 0\le t\le T_p\}$ in (A1), the events $\{\tau_D\le T_m\}$ and $\{T_m<\tau_D\le T_p\}$ are equivalent to the events $\{U(T_m)\le \ln D\}$ and $\{U(T_m)>\ln D, U(T_p)\le \ln D\}$, respectively. The time-zero option values $C(0)$ and $P(0)$ in (3.4)-(3.5) can now be rewritten as

$$
\begin{aligned}
X(0) = {} & P(0,T_p)E_Q\left[G(T_m)\middle|\mathfrak{F}_0\right] - \alpha P(0,T_p)E_Q\left[G(T_m)1_{\{U(T_m)\le \ln D\}}\middle|\mathfrak{F}_0\right] \\
& - \alpha P(0,T_p)E_Q\left[G(T_m)1_{\{U(T_m)>\ln D, U(T_p)\le \ln D\}}\middle|\mathfrak{F}_0\right]
\end{aligned}
\qquad \text{(B1)}
$$

where $X(0)=C(0)$ and $G(T_m)=(S(T_m)-K)^+$ for the call option; and $X(0)=P(0)$ and $G(T_m)=(K-S(T_m))^+$ for the put option. In the following, the dependency on the information set $\mathfrak{F}_0$ is omitted and rewrite (B1) as

$$
\begin{aligned}
X(0) = {} & P(0,T_p)\int_{-\infty}^{\infty} E_Q\left[G(T_m)\middle|L_F = f\right]g(f)df \\
& - \alpha P(0,T_p)\int_{-\infty}^{\infty} E_Q\left[G(T_m)1_{\{U(T_m)\le \ln D\}}\middle|L_F = f\right]g(f)df \\
& - \alpha P(0,T_p)\int_{lnD}^{\infty} E_Q\left[G(T_m)1_{\{U(T_m)>\ln D, U(T_p)\le \ln D\}}\middle|L_F = f\right]g(f)df
\end{aligned}
\qquad \text{(B2)}
$$

where $L_F=lnV_F(T_m)$ and $g(f)$ is the probability density function of $L_F=f$. Since

$$lnV_F(T_m)=lnV(0)-lnP(T_m, T_p)-\sigma_V^2T_m/2+\sigma_V W_F(T_m)$$

Thus $g(f)$ is the $p.d.f.$ of a normal distribution with mean $lnV(0)-lnP(T_m, T_p)-\sigma_V^2T_m/2$ and variance $\sigma_V^2T_m$. By Lemma A.1, conditional on $L_F=f$, the logarithm of the underlying asset $lnS(T_m)$ is independent of the process $\{U(t)\colon 0\le t\le T_p\}$. Thus (B2) can be expressed as

$$
\begin{aligned}
X(0) &= P(0,T_p)\int_{-\infty}^{\infty} h_i(f)g(f)df \\
&- \alpha P(0,T_p)\int_{-\infty}^{\infty} h_i(f) Pr\{U(T_m) \le \ln D | L_F = f\} g(f)df \\
&- \alpha P(0,T_p)\int_{\ln D}^{\infty} h_i(f) Pr\{U(T_m) > \ln D, U(T_p) \le \ln D | L_F = f\} g(f)df
\end{aligned} \tag{B3}
$$

where i=1 for the call option with $h_1(f)= E_Q\left[(S(T_m)-K)^+ \middle| L_F = f\right]$, and i=2 for the put option with $h_2(f)= E_Q\left[(K - S(T_m))^+ \middle| L_F = f\right]$. Now the conditional probability

$$\Pr\{U(T_m)>\ln D,\ U(T_p)\le\ln D|L_F=f\} = \Pr\{U(T_p)\le\ln D|\Xi\} \times \Pr\{U(T_m)>\ln D\ |L_F=f\}$$

where $\Xi=\{U(T_m)>\ln D,\ L_F=f\}$. Thus, (B3) can be rewritten as

$$
\begin{aligned}
X(0) &= P(0,T_p)\int_{-\infty}^{\infty} h_i(f)g(f)df \\
&- \alpha P(0,T_p)\int_{-\infty}^{\infty} h_i(f)\times\left[1 - Pr\{U(T_m) > \ln D | L_F = f\}\right] g(f)df \\
&- \alpha P(0,T_p)\int_{\ln D}^{\infty} h_i(f) Pr\{U(T_p) \le \ln D | \Xi\}\times Pr\{U(T_m) > \ln D | L_F = f\} g(f)df
\end{aligned} \tag{B4}
$$

$\Pr\{U(T_p)\le\ln D|\Xi\}$ and $\Pr\{U(T_m)>\ln D|L_F=f\}$ can be obtained using Lemmas A.3-A.4. The functions $h_1(f)$ and $h_2(f)$ are derived in the following Lemma.

Lemma B.1. The functions

$$h_1(f)= E_Q\left[(S(T_m)-K)^+ \middle| L_F = f\right]= e^{\mu(f)+\sigma_m^2/2}\Phi\left(\frac{-\ln K + \mu(f) + \sigma_m^2}{\sigma_m}\right) - K\Phi\left(\frac{-\ln K + \mu(f)}{\sigma_m}\right)$$

$$h_2(f)= E_Q\left[(K - S(T_m))^+ \middle| L_F = f\right]= -e^{\mu(f)+\sigma_m^2/2}\Phi\left(\frac{\ln K - \mu(f) - \sigma_m^2}{\sigma_m}\right) + K\Phi\left(\frac{\ln K - \mu(f)}{\sigma_m}\right)$$

where $\mu(f)$ and σ_m^2 are given in Lemma A.1.

Proof. By Lemma A.1, given L_F=f, $lnS(T_m)$ is normally distributed with mean $\mu(f)$ and variance σ_m^2. Therefore,

$$h_1(f)= E_Q\left[(S(T_m)-K)^+ \middle| L_F = f\right]= \int_{\ln K}^{\infty}(e^u - K)\frac{1}{\sqrt{2\pi}\sigma_m}exp\left(-\frac{(u-\mu(f))^2}{2\sigma_m^2}\right)du$$

$$h_2(f)= E_Q\left[(K - S(T_m))^+ \middle| L_F = f\right]= \int_{-\infty}^{\ln K}(K - e^u)\frac{1}{\sqrt{2\pi}\sigma_m}exp\left(-\frac{(u-\mu(f))^2}{2\sigma_m^2}\right)du$$

The Lemma is proved. □

Using put-call futures parity violations to measure asynchronous adjustments in asset prices, this study explores how arbitrage trading affects equity liquidity and which trader types provides liquidity in the period of arbitrage exploitation in Taiwan index option market. Our results show that an increasing in limit order submission improves liquidity during times of before violating PCFP but increases bid-ask spread to deteriorate liquidity during times of after violating PCFP. Individual traders play an important role to drive option prices to violate the PCFP and then market makers provide liquidity during law of one price breaking down. Our results suggest that market markers do their formal market making obligation as the TXO market demand unexpected liquidity.

JEL Classification: G10; G11; G14.

1. Introduction

The impact of arbitrage on liquidity supply has received considerable attention within the recent literature. Because financial liberalization and growth in cross-border capital movements lead to increase financial markets variation, arbitrageurs play an important role and in enforcing the law of one price in the financial market. Increasing computerized trading technology and high frequency trading in the recent year eases arbitrage to buy the cheaper asset and selling the expensive one when law of one price breaks down. However, how arbitrage affects equity liquidity is still unclear.

Gromb and Vayanos (2010) argue from a theoretical perspective that if arbitrage opportunities arise from non-fundamental demand shocks, such as fire sales by funding constraint, arbitrage trading could correct missing price and improve liquidity to the market and thereby causing a positive relation between arbitrage and equity liquidity. However, arbitrage opportunities are due to different information sets (Domowitz, Glen, and Madhavan, 1998) and asynchronous price adjustments to information (Focault, Kozhan, and Tham, 2015), arbitrageurs have an information advantage and arise adverse selection cost for market makers, leading to deteriorate liquidity.

This study considers a simple no-arbitrage relation, the well-known put-call futures parity (PCFP) that the payoff of a futures contract can be synthetically replicated using call options, put options, and bonds. The option market relies heavily on arbitrage to ensure that prices do not deviate substantially from fair value for long period of time. However, the PCFP violations caused by asynchronous adjustments in option prices should occur more frequently as new information shocks since options with a lot of distinct exercise prices and contract months are traded simultaneously in the marketplace.[1] Although option market is

[1] Most literature on price discovery, documented by the speed at which prices react to new information, finds that index futures lead both index options and the spot index (e.g., Stoll & Whaley, 1990; Fleming, Ostdiek, & Whaley, 1996).

dynamically efficient,[2] previous empirical literature finds that PCFP violations are frequent and substantial violations at short-lived term.[3] Because different markets receive different information over time, lags in the transmission information and interpretation of prices lead to PCFP violations. If arbitrage traders interpret price information faster than market makers, then arbitrage is possible and thereby increasing adverse selection cost and decreasing equity liquidyt (Kumar and Seppi, 1994; Focault et al., 2015). Given above reasons, PCFP violations provide us an opportunity to capture asynchronous adjustments in asset prices with new information.

Understanding liquidity provision is very important as traders in limit order markets encounter the choice of order type every time they trade since the electonic limit order market is one of the major trading venues in equity and futures exchanges around the world. In this trading platform, market orders come with execution certainty, but traders pay an implicit price for immediacy. On the other hand, limit orders allow traders to set a limit price at which the order can be filled, but traders run the risk of nonexecution and adverse selection risk. Prior literature on the study of arbitrage focuses primarily on the size of profits and its impact on liquidity. In contrast, such research in liquidity supply as violating the LOP is still lacking. Furthermore, most studies regarding the supply of liquidity mainly examine the stock, foreign exchange, and futures markets[4] while the liquidity supply in option market is less well addressed. This paper attempts to fill this gap by exploring the liquidity provision of option market in the period of arbitrage exploitation.

---

[2] Lee and Nayar (1993), and Fung and Chan (1994) find that both the S&P 500 option and futures markets, in general, are efficient by testing put-call-futures parity using S&P 500 index options and futures contracts. Based on put-call-futures parity, Fung and Fung (1997), and Fung, Cheng, and Chan (1997) report that markets are dynamically efficient by using Hong Kong' Hang Seng Index futures and options.

[3] Many empirical studies show that despite the put-call parity usually holds, there are frequent, substantial violations of put-call parity (Stoll, 1969; Gould and Galai, 1974; Klemkosky and Resnick, 1979; Evnine and Rudd, 1985; Kamara and Miller, 1995). For put-call-futures parity tests, Fung and Mok (2001) find significant arbitrage profitability by using the quotes of Hang Seng Index options and futures.

[4] See, for example, Biais, Hillion, and Spatt (1995), Chung, Van Ness, and Van Ness (1999), Ahn, Bae, and Chan (2001), Anand, Chakravarty, and Martell (2005), Bjonnes, Rime, and Solheim (2005), Bloomfield, O'Hara, and Saar (2005), Menkhoff, Osler, and Schmeling (2010), and Chiu, Chung, and Wang (2014).

In addition to the theoretical studies previously discussed, recent empirical studies reveal an increased focus on the relation between arbitrage and equity liquidity. Roll, Schwartz, Subrahmanyam (2007) consider no-arbitrage relations between stock market and futures index and explore the joint dynamic structure of the futures-cash basis and stock market liquidity. Their empirical results show that deviations from no-arbitrage relations can increasing bid-ask spread and help in predicting market liquidity on subsequent days. In addition, the deviations from the law of one price are forecasted by liquidity. Their results suggest that liquidity plays an important role in moving markets toward an efficient outcome. Hence, the deviations from no-arbitrage relations could provide information to investors, leading to be valuable in affecting equity liquidity.

Using triangular arbitrage opportunities in the FX market, Focault et al. (2015) examine how arbitrage affects liquidity. Foucault et al. (2015) argue that asynchronous price adjustments in asset prices following new information arrival can cause toxic arbitrage opportunities due to created adverse selection costs for liquidity providers. This is because as enforcing these toxic opportunities, arbitrageurs expose the liquidity providers to the risk of trading at stale quotes, i.e., being picked off. As a result, the liquidity providers with stale quotes will incur a loss on the trade as if they have been trading with better informed investors. Their results suggest that arbitrage opportunity from asynchronous price adjustments in asset price leads to decreasing equity liquidity. Moreover, Rosch (2015) examines how arbitrage opportunity from Depositary Receipts (DRs) affects liquidity from the U.S. and five different home markets. His results show that around 70% of the arbitrage opportunities in DRs are due to non-fundamental demand shocks and an increasing in arbitrage activity is associated with a reduction in market order imbalance and increase in liquidity. His empirical results suggest a theoretical perspective of Gromb and Vayanos (2010).

Using a unique data set that identifies order submission by trader types, this study investigates how arbitrage opportunity from PCFP violation affects liquidity provision and which trader types provides liquidity in the period of arbitrage exploitation in Taiwan index option market. We first examine whether the PCFP violation is due to asynchronous adjustments in option prices. We examine whether the futures price and order flow change at the origin of this opportunity reverts after the opportunity terminates. We then divide traders into four groups (individual traders, foreign institutional firms, domestic institutional traders and market makers) to examine who drives option prices to violate the PCF parity. We finally invistiage how arbitrage opportunity from PCFP violation affects bid-ask spread and which trader types provides liquidity in the period of arbitrage exploitation in Taiwan index option market.[5] To the best of our knowledge, the literature focus on the differences among foreign institutional investors and other types of traders in the liquidity provision at arbitrage opportunity is very small. Understanding the liquidity supply of option market by different trade types in arbitrage shocks is of high importance because of increased investor interest and regulator concern for this toxic arbitrage.

(Results & contributions)

Our empirical results provide evidence that option price violations related to the PCFP are mainly driven by individual traders. In terms of initially violating PCFP, the orders on the opposite side of arbitrageurs are submitted most by market makers, followed by individual traders, and least by foreign and domestic institutional traders. The market makers respond most limit orders centralized on best 5 quotes, but least market orders. In contrast, individual traders use most of market orders.

[5] This study only sheds light on option market because the futures market is more liquid and high pricing efficiency relative to option market. The liquidity, transaction costs, pricing efficiency, and price discovery in the TXO market have been explored by Roope and Zurbruegg (2002), Hsieh (2004), Huang (2004), and Chou and Wang (2006). Generally, evidence confirms that the market of index futures is good in quality in every perspective.

For liquidity providing by trader types, we find that market makers dominate the response of liquidity supply in arbitrage shocks whereas individual traders and domestic institutional traders respond less. This result is robust even using aggressive orders with highly executed probability instead of orders submitted. However, our results provides evidence that market markers do their formal market making obligation as option market demands unexpected liquidity. It also supports the results of Mayhew (2002), and Eldor, Hauser, Pilo, and Shurki (2006) who find the contribution of market makers to the liquidity in the option market.

In terms of before and after violating PCFP, the effect of submitted limit orders on liquidity is different. Overall, an increase in submitted limit orders improves option liquidity during times of before violating PCFP, consistent with Chung et al. (1999) who find a negative relation between the number of outstanding limit orders and spread. Inversely, more limit orders reduce liquidity during times of after violating PCFP, reflecting an unaggressive order submission by market traders. The evidence supports the result of Kamara and Miller (1995), Kumar and Seppi (1994), Roll et al. (2007), and Foucault et al. (2014) that arbitrage deteriorates liquidity. Also, for most of different trader types we find negative relations between submitted limit orders and liquidity during period of after violating PCFP.

Our results are related to a recent strand of literature that shows the difference in supply and use of market liquidity between informed and liquidity traders (or patient and impatient traders) in the limit order book. These studies are analyzed by both theoretical model such as Glosten (1994), Chakravarty and Holden (1995), Seppi (1997), Hariss (1998), and Kaniel and Liu (2006) and by empirical work like as Keim and Madhavan (1995), Bloomfield et al. (2005), and Foucault, Kadan, and Kandel (2005). In addition, Chiu et al. (2014) find that institutional traders use more limit orders than market orders in the Taiwan index futures market. Bjonnes et al. (2005) explore the liquidity supply of non-financial customers in the foreign exchange market (Swedish Krona market).

Our study is organized as follows. Section 2 describes the Taiwan option market structure and presents our data source. Section 3 estimates PCFP violation and investigates how option price and order flow change during the PCFP violation. Section 4 examines the relation between PCFP violations and equity liquidity. Section 5 provides the concluding remarks.

2. Market structure and data set

2.1. Taiwan Index Options market structure

The TXO option market is a hybrid market like as the NYSE and Amex, in which both market makers and limit order traders establish prices. The Taiwan Stock Exchange (TWSE) was one of the major exchanges in the world. Furthermore, the Taiwan index options (hereafter TAIEX options), the underlying asset of which is the TWSE Capitalization Weighted Stock Index, are ranked the fourth most frequently traded index option on a global scale. The designated market makers in the TXO option market must reflect in their quotes the highest bid price and the lowest ask price posted in the limit-order book as they provide the bid and ask price quotations in response to inquiries by market participants.[6]

The TXO with European style and Taiwan stock index futures (TX) both traded in Taiwan Futures Exchange (TAIFEX) share the same underlying asset, the Taiwan Stock Exchange Capitalization Weighted Stock Index (TAIEX)[7], and expiration date, the third Wednesday of the delivery month of each contract[8]. The preopen session of TXO and TX is from 8:30 a.m. to 8:45

---

[6] Upon receiving the quote request message, a quote is a two-way (bid and ask) limit order placed by a market maker. His bid-ask spread must be within the range stipulated by TAIFEX, and the quantity ordered (i.e. the minimum quantity ordered) must comply with relevant requirements as well. In addition, a market maker can also give a quote without being asked.

[7] The TAIEX is a value-weighted index of all common stocks.

[8] For the delivery months, the futures contracts are spot month, the next calendar month, and the next three quarterly months, and the option contracts are spot month, the next two calendar months, and the next two quarterly months.

a.m. During this period, investors can submit orders to the electronic limit-order book, and the exchange uses the single-price action system to establish the opening prices of regular trading hours. The regular trading hours conducted on weekdays excluding public holidays are from 8:45 a.m. to 1:45 p.m. (Taipei time). In real time, the TAIEX disseminates order and transaction prices to the public. Investors can observe on the screen the specific anonymous best five bid and best five ask prices with the number of contracts.

2.2. Data source and sample selection

In our analysis, we use intraday tick-by-tick data of the TXO and TX obtained from the TAIFEX. The data cover the period from January 1, 2007 to December 31, 2008 and contain detailed information on consolidated transactions, quotes and order flows, and order book. For each order, the date and time of order submission, order type and quantity, trade direction (buy or sell), limit price, and trader identification are recorded. The trader identification enables us to categorize four types of traders: market makers (MM), individual traders (IT), foreign institutional traders (FIT), and domestic institutional traders (DIT). In addition, the three month time deposit of the postal saving system, retrieved from TEJ, is used to be a proxy for the risk-free interest rate. The source files are checked whether there are typographical problems to avoid large pricing problem. We also eliminate price limit day, time periods without limit order information, and days with missing trading data.[9]

3. PCFP violation and asynchronous adjustments in option prices

3.1. PCFP violation and its arbitrage profits

We follow the data-matching procedure adopted by Fung and Mok (2001) to match the futures and options prices within 15-second time interval. Firstly, every bid (ask) quote of call option is matched with ask (bid) quote of the put option with same exercise price and

[9] Futures data are missing for eight days in June 2008 and three days in December 2008.

maturity. Next, the option pair is then matched with ask (bid) quote of futures contract. To reduce the impact of illiquid trade on our test results, this study only use the data of spot month contract. The options and futures with time to maturity less five trade days are switched from first deferred contracts to nearby contracts.

Tucker (1991) documents that if the European options and futures contracts share the same underlying asset and expiration, the payoff of a futures position can be synthesized by a call option and a put option with the same exercise. However, PCFP needs to hold exactly at any point in time, otherwise investors may benefit from arbitrage trading until the mispricing is eliminated. The arbitrage profits incorporating the costs are given in Equations (1) and (2), which separately represent the ask price of futures ($F_{ask,t}$) under the bid price of synthesized futures ($F_{bid,t}^{syn}$) and the bid price of futures ($F_{bid,t}$) over the ask price of synthesized futures ($F_{ask,t}^{syn}$).

$$F_{bid,t}^{syn} - F_{ask,t} = [(C_{bid,t} - P_{ask,t}).e^{r\tau} + K] - F_{ask,t} - \Psi_t - M_t \tag{1}$$

$$F_{bid,t} - F_{ask,t}^{syn} = F_{bid,t} - [(C_{ask,t} - P_{bid,t}).e^{r\tau} + K] - \Psi_t - M_t \tag{2}$$

in which $C_{bid,t}$ and $C_{ask,t}$ ($P_{bid,t}$ and $P_{ask,t}$) denote the bid and ask prices of calls (puts) at time t. $F_{bid,t}$ and $F_{ask,t}$ are the bid and ask prices of futures at time t. K is the option exercise price. τ denotes the time to maturity. r is the risk-free interest rate. M and Ψ denote the opportunity costs of margin deposits and trade costs.

The total costs for establishing arbitrage portfolio (i.e., arbitrage costs) consist of opportunity costs of margin deposits (M)[10], and trade costs (Ψ)[11]. We consider the

[10] Fung and Fung (1997) find that the effect is small when differential borrowing and lending rates are used.

opportunity costs (*M*) since cash is primarily used for margin deposits of options and futures. Following Fung and Fung (1997), the financing cost on margin deposits is calculated as $TMD.(e^{rt}-1)$, in which *TMD* is the total margin deposits. The trade costs for arbitrage (Ψ) constructed on the hold-to-expiration strategy involve the opening trade costs for one pairs of call and put options and a futures contract, and the settlement costs for a futures contract and an option (call or put)[12]. No charge is levied for out of the money options on expiration.

Equation (1) also implies that a call option is overvalued, a put option is undervalued, or both. The arbitrage profit in Equation (1) is equivalent to the difference between a bid price of call and a ask price of synthesized call, and the difference between a bid price of synthesized put and a ask price of put.[13] Moreover, in practice, the speed at which futures prices react to new information is faster than that of option (Stoll & Whaley, 1990; Fleming, Ostdiek, & Whaley, 1996). Consequently, the call's bid price over the ask price of synthesized call and the put's ask price under the bid price of synthesized put reflect an overvalued call or an undervalued put, or both. Similarly, Equation (2) implies an undervalued call or an overvalued put, or both. In this paper, we analyze the liquidity providing in these four categories of PCFP violations, i.e., call and put options with overvalued and undervalued prices.

---

[11] In the TXO market, transaction tax is 0.025% for the futures contract value, and 0.125% for the option premium. At expiration, an in-the-money option is subject to 0.025% tax of the settlement value if it is closed out by settlement instead of by offsetting trading. An out-of-the money option is not taxed because no transaction would be made. In addition, since settlement price is not available in time t, here we use futures price instead of settlement price.

[12] Because the multipliers for the futures and option contracts are NT$200 and NT$50 per index point, respectively, every four pairs of calls and puts, thus, can be hedged by one futures (FITX) contract. For simplification, this study represents the arbitrage profits by NT$50 per index point, consistent with the option's multiplier. Therefore, one pair of call and put options is only hedged by one FITX contract. However, despite the difference in multiplier values, the PCFP condition still holds.

[13] Based on the PCFP, a call can be synthesized by long a put, long a futures contract, and short a risk free bond. Similarly, a put can be synthesized by long a call, long a risk free bond, and short a futures contract.

Table 1 reports the statistics of arbitrage profits involved trading costs. Using the option and futures data from January 1, 2007 to December 31, 2008, there is 0.14% percentage of option prices to violate the PCFP in all samples. We further divide options violating PCFP into three groups by call option's moneyness (*myn*): (1) for in-the-money options with *myn* below 0.975 (ITM), (2) at-the-money options with *myn* above 0.975 and below 1.025 (ATM), and (3) out-of-the-money options with *myn* below 1.025 (OTM). The moneyness is calculated as $K/(S*e^{r\tau})$, in which K is exercise price, S is the underlying index price, τ is time to maturity, and r is risk-free interest rate. The measure unit for arbitrage gain is an index point, with each index point valued at NT$50. As shown in Table 1, the arbitrage profit averages 3.5244. On average, the arbitrage profit for OTM options is slightly above those in ITM and ATM options by about 2 index point, respectively with average profits of 5.6227, 3.3920, and 3.4083. They are positively skewed and exhibit leptokurtosis. Given the above empirical results, investors could get potential profits by rapidly submitting orders to build their arbitrage portfolios when PCFP is violation and law of one price breaks down.

[TABLE 1 ABOUT HERE]

3.2. PCFP violation and option price

In order to examine whether PCFP violation could be due to asynchronous price adjustments in asset price following new information arrival or reflect non-fundamental demand shocks, we tract option price during the PCFP violation period. According to Schultz and Shive (2010), we posit that arbitrage opportunities as situations in which asynchronous adjustment in option prices are eventually followed by permanent shifts in futures option prices.[14] We posit that if

[14] As an illustration, suppose that liquidity providers in the futures market receive a string of buy orders due to good information arrival and raise their bid and ask quotes. If this price move is large enough and liquidity providers in the option market are slow to adjust their quotes to reflect this information, then an arbitrage opportunity in PCFP violation appears. When arbitrage opportunity vanishes, the futures prices do not revert to

arbitrage opportunities reflect non-fundamental demand shocks, the futures option price change at the origin of this opportunity reverts after the opportunity terminates.

Figure 1 shows the plot of correlation coefficients between the return of index futures at 15-second (30-second) time interval of just violating PCFP at time t=0 and the cumulative index futures return from time t=0 to the tth time interval of after violating PCFP, in which t=1, 2, …, 12 (2, 4, …, 12) for 15-second (30-second) time intervals. A positive (negative) correlation coefficient indicates that the price in index futures moves in the same (opposite) direction before and after violating PCFP. Our results show that both the correlation coefficients for 15- and 30-second time intervals are all positive with significance at 1% level. During times of arbitrage shocks, the correlation coefficients for 15-second (30-second) time intervals range from 0.41 to 0.80 (0.5 to 0.79), suggesting that arbitrage opportunities in PCFP violations are inclined to be generated by asynchronous adjustments in option prices.

In addition, for each PCF violation, we compare the futures option prices at the onset of arbitrage opportunity (time t=0) and at time t=1, 2, 3, and 4. If the move direction of future price is same, we regard it as a toxic arbitrage opportunity. Our analysis reveals that on average, the fractions of toxic arbitrage opportunities over all PCFP violations are 67.07%, 63.39%, 60.58%, and 58.00% (72.83%, 69.29%, 62.00%, and 59.67%) in 1st, 2nd, 3rd, and 4th time intervals of 15 seconds (30 seconds) of after violating PCFP. Overall, our empirical results show that option prices are not easy to revert after violating the PCFP 6 minutes, indicating that arbitrage opportunities from PCFP violation could not reflect non-fundamental demand shocks and could be the asynchronous adjustment in option prices.

[FIGURE 1 ABOUT HERE]

---

their position before the arbitrage opportunity because the initial shock is a shock to fundamentals.

3.3. PCFP violation and order submission

Our prior empirical results show that investors could get potential profits and option prices are not easy to revert by rapidly submitting orders to build their arbitrage portfolios when PCFP is violation. Using complete limit order book information, we investigate the new order submission after violating PCFP. If order imbalance occurs after violating PCFP, market makers raise higher inventory risk and thereby decreasing equity liquidity.[15]

Based on the best five bid and ask prices recorded in the limit order book exposed to the screen, we use the following rules to classify five levels (categories) of increasing order aggressiveness: (a) Market Orders (MO) = market orders that demand liquidity and are executed immediately at the best prices currently standing in the market (i.e., most aggressive); (b) Better Best 1 (BB1Q) = marketable limit orders and prices of limit orders are submitted at better than best one quote; prices of buy (sell) orders are greater (less) than the best bid (ask) quote; (c) Best 1 (B1Q) = limit orders that are submitted to the best one quote; that is, submission of limit buy (sell) orders is equal to the best bid (ask) quote; (d) Best 2–5 (B2-5Q) = limit orders that are submitted behind the best one quote but at or before the best five quotes; and (e) Behind Best 5 (BB5Q) = limit orders that are submitted behind the best five quotes (i.e., least aggressive).

We first calculate the average number of new order submission and cumulative average number of new order submission at five order aggressive levels after violating PCFP 15 and 30 second time intervals. We then calculate the ratios of the cumulative average number of submitted bid orders to ask orders. We divided PCFP into four types: overvalued call, overvalued put, undervalued call, and undervalued put. We could expect that

---

[15] See O'Hara and Oldfield (1986), Chordia et al. (2002), and Roll, et al. (2007).

As exhibited in Panel A of Table 2, in 15-second time interval of initial arbitrage shocks, the ratios of cumulative average number of submitted bid orders to ask orders by quote types (A/B) are almost less than one for overvalued calls and puts, but almost greater than one for undervalued options. This provides empirical evidence in favor of that arbitrage introduces newly submitted bid-ask order imbalances.

More specifically, the largest difference between cumulative bid and ask orders, reported in columns of Cum. (A) and Cum. (B), occurs at best quote, B1Q (e.g., with the averages of -2.56 and -33.83 contracts separately for overvalued calls and puts). The asymmetric number of bid-ask orders clustering on the prices better than the best 2–5 quotes reflects that market participants place unaggressive orders in the side of liquidity supply during times of arbitrage shocks. Besides, on the side of arbitrageurs we find more aggressive ask (bid) orders in MO and BB1Q for overvalued (undervalued) options. These aggressively asymmetric quotes may create order imbalances on trade since these two quote types of MO and BB1Q are almost executed immediately. Similarly, Panel B reported a 30-second time interval of initially violating PCFP also obtain same results.

[TABLE 2 ABOUT HERE]

Overall, Table 2 find that overvalued (undervalued) options generates more ask (bid) orders than bid (ask) orders and results in order imbalances. We further estimate the average excess order imbalances (AEOIB) of mispriced options during the 12 successive time intervals of 15 seconds after violating PCFP (at time t=0). The PCFP violations are divided into four categories: overvalued calls, overvalued puts, undervalued calls and undervalued puts. For the AEOIB of each category in each 15-second interval, we first calculate the AEOIB and then average them. The AEOIB is calculated as order imbalance less the mean of order imbalances in 360 successive time intervals of 15 seconds prior to the occurrence of arbitrage opportunity. We use the algorithm proposed by Lee and Ready (1991) to determine whether the transactions are buyer or seller initiated. The algorithm classifies a trade as a buyer (seller) initiated trade if the traded price is higher (lower) than the midpoint of the bid and ask price. We assign a value of +1 (-1) to each transaction to indicate that the trade is buyer (seller) initiated and multiply the assigned value by trading dollar.

In Figure 2, we find negative (positive) AEOIB for overvalued (undervalued) options after PCFP is violated. The magnitude of AEOIB increases at first 15-second time interval, and decreases until the fourth 15-second time interval, then level off. This suggests that arbitrage generates persistent order imbalances due to completing with others for the same trade. The negative (positive) AEOIB for overvalued (undervalued) options reflects a trade direction on sell (buy) side, consistent with that of arbitrageurs. Also, it suggests that liquidity suppliers absorbed imbalances on buy (sell) side cannot adjust their inventories easily during period of arbitrage shocks.[16]

[FIGURE 2 ABOUT HERE]

3.4. Who drives option prices to violate the PCF parity?

An interesting and important question arising from temporary mispricing of options is who drives option prices to violate the PCFP. Bollen and Whaley (2004), Ni, Pan, Poteshman (2008), and Gârleanu, Pedersen, and Poteshman (2009) document that the net buy (sell) demand drives option price upward (downward). Following their argument, we use the net buy volume of options by each trader type to investigate this issue. We estimate net buy volume for 24 successive time intervals of 15 seconds before and after violating PCFP (at time t=0). For each time interval, we calculate average net buy volumes of mispriced options,

[16] The order imbalances can be used to measure both direction and degree of buying or selling pressure (Chordia et al., 2002; Chordia & Subrahmanyam, 2004).

measured by buy volume less sell volume, by each of trade types. The results are exhibited in Figure 3.

[FIGURE 3 ABOUT HERE]

Figure 3 shows the plot of average net buy volume of options by trader types around PCFP violations. Figures A and D (C and B) represent the average net buy volumes by each trader type separately for overvalued (undervalued) calls and puts. For overvalued options (shown in Figures A and D), we find an increasing net buy volume for individual traders but an increasing net sell volume for market makers prior to PCFP violations. Inversely, individual investors for undervalued options (shown in Figures C and B) have an increasing net sell volume, while market makers have an increasing net buy volume. For individual traders, the corresponding t-values from t=-4 to t=2 are 2.02, 2.00, 5.34, 10.46, 18.50, 16.72, and 3.13 (-5.40, -3.66, -3.89, -13.44, -15.57, -11.60, and -3.20) on the overvalued (undervalued) calls, and 6.83, 7.33, 7.58, 9.00, 10.48, 9.62, and 6.13 (-19.49, -19.98, -21.86, -23.08, -26.74, -27.88, and -22.05) on the overvalued (undervalued) puts, respectively.[17] Besides, regardless of overvalued options and undervalued options, the net buy volumes of foreign and domestic institutional investors are almost invariant around PCFP violations.

The finding that the process of option price to violate the PCFP accompanies with increased net buy (or sell) volume of non-market makers is consistent with Bollen and Whaley (2004), Gârleanu et al. (2009), and Ni et al. (2008) who document that option net buy (sell) demand of non-market makers increases (decreases) its price. However, these results provide evidence supporting that individual traders drive option prices to violate the PCFP.

[17] For market makers, the corresponding t-values from t=-2 to t=2 are 9.33, 8.44, 5.42, 1.37, -7.21, -3.93, and 8.13 (7.45, 6.14, 5.18, 12.14, 14.42, 11.38, and 3.8), respectively, for overvalued (undervalued) calls, and -7.35, -7.55, -7.97, -10.19, -11.35, -11.02, and -7.49 (10.73, 8.67, 11.94, 15.15, 20.75, 22.53, and 14.50) for overvalued (undervalued) puts.

4. PCFP violations and equity liquidity

4.1. The impact of PCFP on bid-ask spread

However, in practice, the bid-ask spread is an indicator of liquidity and directly associated with transaction costs of all market participants. We further examine the variation in liquidity of options established by submitted limit orders (*NLO*) of different trader types around PCFP violations. We employ the following unbalanced panel regression as an empirical investigation on the impact of limit orders on liquidity. For each trade type and each type of PCFP violations, we estimate the panel regression controlling on trade volume of option ($OVol$) and liquidity at prior time interval. $D_{M,t}$ is a dummy variable that equals 1 if it is in 12 successive time intervals of 15 seconds of after violating PCFP.

In addition, the negative (positive) β_1 indicates that liquidity rises (falls) following increased limit orders during times of before violating PCFP. A negative (positive) sum of β_1 and β_2 shows that increased limit orders narrow (widen) the percentage spread during times of after violating PCFP.

$$\begin{aligned} Liq_{i,t} &= \alpha + \beta_1 * NLO_{i,t} + \beta_2 * D_{M,t} * NLO_{i,t} + \beta_3 * OVol_{i,t} + \beta_4 * Liq_{i,t-1} + \varepsilon_t \\ &, i = 1,2,3,\ldots,N, t = -a,\ldots,0,\ldots,b, \text{ and } a,b \in [3,12] \end{aligned} \tag{3}$$

where Liq_t is the liquidity of option at the end of time interval t, which is measured as bid-ask spread divided by the midpoint of quote. N is the number of PCFP violations. NLO_t is the number of newly submitted limit bid and ask orders during time t interval (i.e., the sum of bid and ask orders in quote types of B1Q, B2-5Q, and BB5Q). $OVol_t$ is the option trade volume during time t interval.

The coefficients in Equation (3) are estimated using the two stages least square (2SLS) panel regression due to possibly endogenous problem between liquidity, submitted limit orders, and trade volume.[18] In the process of calculating the estimates, we use lagged values of number of submitted limit orders (*NLO*), trade volume (*OVol*), realized volatility (*RV*), net buy pressure (*NBP*), arbitrage size (*ArbSz*), and return of futures (*FRet*) as instrument variables.

Table 3 gives the results of the impact of limit orders (*NLO*) on liquidity by each trader type around violating PCFP. Panels A-D report the results for overvalued calls, overvalued puts, undervalued calls, and undervalued puts, respectively. During times of before violating PCFP, our results reveal that, in general, an increase in limit orders submitted by all market traders improves liquidity evidenced by the significantly negative coefficients of *NLO* (respectively with t-values of -4.04, -6.18, and -4.10 for overvalued puts and undervalued calls and puts), except for overvalued calls. This result supports the finding of Chung et al. (1999) who find a negative relation between the number of outstanding limit orders and spreads.

Furthermore, the effect of limit orders submitted by different trade types on liquidity is likely to be distinct in different types of PCFP violations. In four types of PCFP violations, we find that both market makers and domestic institutional traders have three significant and negative coefficients of *NLO* while individual and foreign institutional traders have two significantly negative coefficients of *NLO*, respectively. This suggests that market makers and domestic institutional traders play a crucial role to narrow the spread of options during times of before violating PCFP.

In the time intervals of after violations of PCFP, we find that the coefficients of *D*NLO* for market traders are all positive and significance at 1% level in four types of PCFP violations. Specifically, the sum of coefficients for *NLO* and *D*NLO* are all positive with

[18] Chung et al. (1999) argue that there exists an endogenous problem between the limit order spread, the quantity of limit orders, and the execution rate of limit orders.

0.00005 and 0.00013 (0.00009 and 0.00007) for overvalued (undervalued) callas and puts, showing that liquidity of option is reduced as increasing limit orders. These results also reflect an unaggressive order submission strategy by market traders. However, this evidence provides support for the results of Copeland and Galai (1983), Kumar and Seppi (1994), Kamara and Miller (1995), Roll et al. (2007), and Foucault et al. (2014) that arbitrage deteriorates liquidity. In addition, we also find that the negative relation between liquidity and newly submitted limit orders almost holds for four trader types during times of after violating PCFP. Only the limit orders placed by individual and foreign institutional traders are found to reduce the width of spreads when call or put options are overestimated.

[TABLE 3 ABOUT HERE]

4.2. Liquidity providing in PCFP violations by trader types

4.2.1 The percentage of change in the number of submitted orders

Prior to the analysis of liquidity supply by the change ratios of submitted orders and the panel regression, we first take a look at Table 2 about orders submitted on the side of liquidity supply in terms of initially violating PCFP. In Panel A, we find that, on the whole, investors who face arbitrage shocks in initial interval of 15 seconds favor to use orders with prices at best 5 quotes while using a little market orders. This is evidenced by submitted orders clustering at best 2–5 quotes or best quotes, but least for market orders. For instance, the ratios of orders submitted at best 5 quotes (market orders) to all quoted orders are 59.82% and 53.28% (1.64% and 0.59%) for overvalued calls and puts.

Regarding the orders submitted by trader types, the untabulated results reveal that the orders on the side of liquidity supply are submitted most by market makers, followed by individual traders, and least by foreign and domestic institutional traders. For example, the submitted bid orders of overvalued calls (puts) average 18.15, 9.15, 2.19, and 0.42 (49.12, 4.33, 3.11, and 2.50) respectively for MM, IT, FIT, and DIT. In contrast, the market orders are submitted most by IT, but rarely used by MM and FIT.

Also, we compare the order aggressiveness of trader types by calculating the ratio of orders over best quote to all orders which are submitted by each trader type itself. We find that IT are aggressive relative to MM. This is because IT have the largest ratios respectively with the ratios being 29.56% and 40.74% (33.04% and 39.24%) for overvalued (undervalued) calls and puts whereas the ratios are small for MM with 17.29% and 7.96% (9.69% and 26.61%) for overvalued (undervalued) calls and puts, respectively.

In addition, Panel B reported a 30-second time interval of initial arbitrage shocks also obtains similar results. The same findings in Panels A and B that market makers place most orders within the best 5 quotes but least market orders suggests that market makers seemly act like a role of liquidity trader who favors to place limit orders.

At the beginning, we use the ratios of change in submitted orders on the opposite side of arbitrageurs to measure the liquidity supply in arbitrage shocks. For each type of PCFP violations and each trader type, we compute the ratios of change in submitted orders accumulated by quote types, which are defined as the difference between average numbers of submitted orders accumulated by quote types to average numbers of all orders submitted at prior time interval of violating PCFP. More specifically, we first calculate the differences between cumulative numbers of submitted orders by quote types in two time intervals of just before and after violating PCFP and average them. Then, they are divided by the average number of all orders submitted in one time interval of just before violating PCFP. However, the advantages of using this measure do not only reflect the change of liquidity supply but also order aggressiveness.

The results are reported in Table 4. Panel A and Panel B respectively present the results of mispriced options in two 15-second time intervals and in two 30-second time intervals of just before and after violating PCFP.

Panel A shows that the ratios at BB5Q, i.e., indicating a percentage change in the number of all submitted orders, for MM are almost positive with values of 1.1%, 2.29%, and 0.09% separately for overvalued puts, and undervalued calls and puts, except the overvalued calls with value of -0.54%. But, the ratios at BB5Q for IT, FIT, and DIT are almost negative, especially for IT. In contrast to other trader types, the increased ratio for MM indicates that more orders on the side of liquidity supply are placed by MM in arbitrage shocks.

Specifically, the ratios for maker makers raise in quote types with high level of execution probability and switch to decrease afterward. The largest ratios of an increase in submitted orders occurs at best quote (B1Q) with values of 1.52% and 10.97% for overvalued calls and puts and with values of 10.14% and 2.45% for undervalued calls and puts. This indicates that market makers place more orders with highly executed probability relative to those submitted at the prior time interval of violating PCFP. The evidence of an increase in use of aggressively-priced orders supports that market makers provide liquidity to option market in arbitrage shocks.

The results in Panel B for a 30-second time interval of initial arbitrage shocks are also similar to those in Panel A. Market makers still place more aggressive orders, but individual traders cut down their submitted orders. Consequently, we conclude that market makers dominate the response of liquidity supply to arbitrage shocks while individual traders respond little.

[TABLE 4 ABOUT HERE]

To further test whether market markers do their formal market making obligation as violating PCFP, we divide the options violating the PCFP into three groups based on the moneyness of option : for OTM, ATM, and ITM options. Then, for each of PCFP violations and each trader type, we recalculate the change ratios of submitted orders by each moneyness group. Here, only the results during period of initial 15-second arbitrage shocks are plotted in Figure 4: Figures A-C for overvalued calls (OC), Figures D-F for undervalued calls (UC), Figures G-I for overvalued put (OP), and Figures J-L for undervalued puts (UP). In the x-axis, the number 1, 2, 3, 4, and 5 respectively correspond to the MO, BB1Q, B1Q, B2-5Q, and BB5Q of quote types, which are arranged in highly executed probability order.

Figure 4 exhibits the plot of the change ratios of orders submitted by trader types for different moneyness groups. A visual inspection shows that the ratios for market makers vary enormously, but the variations in orders submitted by other trader types are relatively small. The change ratios for market makers in three moneyness groups and four types of PCFP violations are all positive at best quote (corresponding to the number 3 in the x-axis) and almost positive at behind best 5 quote (corresponding to the number 5 in the x-axis). More specifically, the OTM and ATM options have large change ratios of submitted orders. In contrast, the orders submitted by individual traders are generally reduced more in initial arbitrage shocks, especially for ATM options.

The similar results are obtained in the initial 30-second time interval of arbitrage shocks (unreported). However, regardless of option moneyness and types of PCFP violations, the finding that market makers place more orders on the opposite side of arbitrageurs and with highly executed probability provides in support of liquidity supply by market makers as option market demands unexpected liquidity.

[FIGURE 4 ABOUT HERE]

4.2. 2. Liquidity providing in PCFP violations by trader types

Arbitraging in PCFP violations decreases liquidity. A liquidity provider should be who provides more bid (ask) quotes in the option order book when option prices are overvalued (undervalued). This is because that more orders placed on the opposite side of arbitrageurs may raise the execution probability of orders (Chung et al., 1999), i.e., increasing liquidity supply. As a result, we define the supply of liquidity during times of arbitrage shocks as an increase in bid (ask) orders for overvalued (undervalued) options.

This study particularly interests in liquidity supply of option during period of arbitrage exploitation. However, in practice, arbitrage opportunity is short-lived. For each violation, we select the option data within before and after 3-minute time period of violating PCFP (i.e., 24 successive time intervals of 15 second) as data set to test liquidity supply by different trader types.[19] Furthermore, the violations with less than three successive time intervals of 15 seconds in before or after of violating PCFP are excluded from the sample (i.e., violations occurs in before 8:45:30 a.m. or after 1:44: 30 p.m.).

Our empirical analysis for liquidity supply to option market are in two ways. First, we analyze the percentage of change in the number of orders submitted by each trader type on the opposite side of arbitrageurs just before and after violating PCFP.

Second, we adopt an unbalanced panel regression to analyze the variation in the number of bid (ask) orders, NLM_t, of overvalued (undervalued) options. For each trader type and each type of PCFP violations, options (calls and puts) with overvalued and undervalued prices, we individually use the panel regression to investigate the supply of liquidity. In addition, the Hausman test statistic (1978) with asymptotical chi-squared distribution (χ^2) is used to differentiate between fixed effect model and random effect model in panel data. A rejection

[19] Cheng, Fung and Pang (1998) find that arbitrage profitability, based on the PCFP, declines and subsequently disappears within 5 minutes. Fung and Draper (1999) analyze the mispricing of the Hong Kong Seng Index. They find that arbitrage profit opportunities exist within 5 minutes and become smaller or disappear as the time lags increase. Consequently, here we use the average value of 3 minutes.

of the null hypothesis indicates that the fixed effect model is suitable for the panel data. The empirical model is specified as

$$
\begin{aligned}
NLM_{i,t} &= \alpha + \beta_1 * NBP_{i,t-1} + \beta_2 * RV_{t-1} + \beta_3 * ArbSz_{i,t-1} + \beta_4 * FRet_{t-1} + \beta_5 * OVol_{i,t-1} \\
&+ \beta_6 * OSpd_{i,t-1} + \beta_7 * TolBid_{i,t-1} + \beta_8 * TolAsk_{i,t-1} + \beta_9 * Myn_{i,t} + \gamma_j * \sum_{j=1}^{12} D_{jt} + \varepsilon_t \qquad (4) \\
&, i = 1,2,3,\ldots,N, t = -a,\ldots,0,\ldots,b, \text{ and } a,b \in [3,12]
\end{aligned}
$$

The dependent variable, NLM_t, denotes the number of bid (ask) orders submitted on the opposite side of arbitrageurs for overvalued (undervalued) options during t time interval. N is the number of PCFP violations. The time interval $t=0$ indicates the occurrence of violating PCFP. ε_t is the error term. Myn_t is option moneyness at time t. $D_{j,t}$ is a dummy variable that equals 1 if it is in jth time interval of after violating PCFP, j=1,2,3,…, 12. This variable captures the intraday variation in the number of submitted orders with respect to the time of after violating PCFP. The coefficient of γ_i represents the difference between the mean of ith time interval and the mean of around the violations of PCFP. The other independent variables associated with market characteristics are specified as following.

NBP_{t-1} indicates option net buy pressure during $t-1$ time interval, which is measured in terms of the degree and direction of transaction (Chordia et al., 2002; Chordia & Subrahmanyam, 2004). The more NBP is often accompanied by a buy transaction due to its persistence (Chordia et al, 2002), suggesting that investors tend to submit bid orders rather than ask orders following a positive and large NBP. We calculate the NBP as the buyer-initialed trades less the seller-initialed trades during the $t-1$ time interval, in which every transaction is assigned using the Lee and Ready (1991) algorithm.

RV_{t-1} is the realized volatility of futures, which is calculated as the square root of the sum of squared return during *t-1* time interval. Handa and Schwattz (1996), Foucault (1999), Ahn et al. (2001), Bae et al. (2003), Goettler et al. (2005), and Menkhoff et al. (2010) find that price volatility affects order placement and execution. A rise in volatility is followed by an increase in the order placement and execution. We use the realized volatility to control the dynamic impact of volatility on order submission.

$ArbSz_{t-1}$ is the size of arbitrage profits, shown in Equations (1) and (2), at time *t-1*. In practice, large arbitrage profits can attract more arbitrageurs, thereby generating more imbalance between newly submitted bid orders and ask orders. This suggests that the size of deviations from PCFP is associated with order placement strategy. We thus use this variable to control the impact of PCFP deviation on order submission.

$OSpd_{t-1}$ denotes the average best bid-ask spread of options during *t-1* time interval, which the literature finds significant response of order placement to changes in spreads (Bae et al., 2003; Biais et al., 1995; Chung et al., 1999; Menkhoff et al., 2010). It is used to control for the effect of option spreads on order submission.

$TolBid_{t-1}$ and $TolAsk_{t-1}$ are the average of bid and ask volume submitted at the best 5 quotes during the *t-1* time interval, respectively. Numerous studies document that changes on depth in the buy and sell sides of the book affects order submission (Menkhoff et al, 2010; Ranaldo, 2004). A rise in the same side depth of the trade discourages the limit order at the same side depth while encouraging the limit order in the opposite side. Thereby, we use this variable to control the impact of market depth in the book on order submission.

$FRet_{t-1}$ and $OVol_{t-1}$ are the return of futures and trade volume of option during *t-1* time period, respectively. We include these two variables due to the probable influence on order submission.

The second way to analyze the supply of liquidity is the panel regression in Equation (3), which examines the variation in number of submitted orders by incorporating dummy variables. The dummy variables are used to capture the intraday variation in number of submitted orders with respect to the time intervals of after violating PCFP. A positive coefficient γ_j of dummy variable represents an increase in number of submitted orders on the jth time interval of arbitrage shocks. Inversely, the negative coefficient indicates less orders submitted. The regression results for overvalued and undervalued options (calls and puts) are reported in Tables 6-7, respectively.

[TABLE 5 ABOUT HERE]

[TABLE 6 ABOUT HERE]

Table 6 presents the regression results of liquidity supply on buy side by each trader type separately for overvalued calls and puts, controlling on market shocks such as net buy pressure, volatility, arbitrage size, option spreads, futures return, and depth in the book. The results of the Hausman test (1978) reported in the second row of Tables 6 shows that the fixed effect model is suitable for the panel data in every trader type. For the liquidity supply by all traders, in Table 6 we find significant evidence in support of an increase in number of submitted orders on the overvalued puts in first two time intervals of arbitrage shocks (with t-values of 4.59 and 2.92, respectively), whereas no evidence in Table 6 supports an increase in the number of submitted orders for overvalued calls.

For the liquidity providing in overvalued calls by trader types, however, in Table 6 we find significant and positive coefficient of D_1 for market makers (t-value = 2.06), but almost significantly negative coefficients for individual traders. In panel B of Table 6, we also find that market makers have two positive coefficients of D_1 and D_2 for overvalued puts with significance at 1% level in first two time intervals of arbitrage shocks (t-values = 5.79 and 2.88, respectively). For individual traders, we find only a significantly positive coefficient of D_2 (t-value =1.86) but significantly negative coefficients in the latter time intervals of arbitrage shocks. These results indicate that market makers submit more orders of calls and puts and then switch to usual or less orders afterwards in response to initial arbitrage shocks. In contrast, individual traders submit less orders except increased orders of puts in the second time interval of after violating PCFP.

In addition, both the coefficients of dummy variables for foreign and domestic institutional traders are insignificant (see Table 6) or significantly negative (see the results in panel B of Table 6 for domestic institutional traders). Therefore, we conclude that market makers dominate the liquidity supply during times of after violating PCFP.

We further specify the effect of market shocks on order submission by each of trader types from Tables 6. For option net buy pressure (NBP), all the coefficients are positive and most of them are statistically significant at 1% level, indicating that more bid orders are submitted by investors following an increased NBP. This evidence provides in support of the results of Chordia et al. (2002) and Chordia and Subrahmanyam (2004) that large NBP often accompanies with a buy transaction due to its persistence. Overall, we find that more orders are placed following a rising volatility evidenced by that the coefficients of realized volatility (RV) for all traders and most trader types are positive and highly significant at the 1% level. This finding is consistent with results in Handa and Schwattz (1996), Foucault (1999), Ahn et al. (2001), Bae et al. (2003), Goettler et al. (2005), and Menkhoff et al. (2010).

For the potential arbitrage profits ($ArbSz$), the coefficients with negative and highly significant at the 1% level show that large arbitrage profits stemming from overestimated options (calls and puts) attract market traders to place more ask orders, thus leading less bid orders submitted, i.e., on the opposite side of arbitrageurs.

Regarding the depth at best 5 quotes of bids ($TolBid$) on same side of liquidity supply, most of the coefficients for overvalued calls and puts lagged one period are found to have significant and negative signs. The result indicates that most traders place fewer orders on buy side when the state of the buy side order book is thicker and more orders when the buy side order book is thinner. This provides evidence in support of the crowding-out effect proposed by Parlour (1998) who documents that a rise in the same side depth discourages the orders submitted at the same side depth. This is because the orders with time priority already in the book lessens the execution probability of a new order on the same side. In contrast, the effect of the sell side order book ($TolAsk$) on order submission is ambiguous.

On the whole, lagged one-period return of futures ($FRet$) as well as trade volume of option ($OVol$) has a positive impact on bid order placement. One possible explanation is that investors favor to buy calls and hedgers tend to buy puts when a price of underlying futures rises, and large trade volume reflecting the quantity of option contracts bought and sold at the same time accompanies with more quotes in the book (Cohen, Maier, Schwartz, & Whitcomb, 1981; Chung et al., 1999). As a consequence, this leads to an increase in bid orders of calls and puts. Furthermore, for all traders and most trader types, we find significantly negative relation between option spread ($OSpd$) and order placement, indicating that traders place less orders on the same side of liquidity supply when intraday spread is wide.

In addition, order submission is associated with option moneyness. One possibility is that options with different degree of moneyness have distinct financial leverage (risk), hedging ratio, and liquidity risk (transaction costs) which in turn are correlated with the trading activity. In general, the newly submitted orders decreases with increased option moneyness (Myn). An out-of-the-money option (calls and puts) tends to decrease orders submitted while an in-the-money option (calls and puts) increases order submission.

The empirical analysis of liquidity supply on sell side of undervalued calls and puts, reported in Table 6, obtains several similar results with those in Tables 5. In brief, market makers still provide the liquidity to option market in the session of arbitrage shocks. Our finding supports the result of Mayhew (2002), and Eldor et al. (2006) who find the contribution of market makers to the liquidity in the option market.

4.3. Robustness results

In practice, the duration of arbitrage opportunities is short-lived and arbitrageurs face execution risk in forming their arbitrage portfolios (Kleidon, 1992; Kumar & Seppi, 1994; Holden, 1995; Kozhan & Tham, 2012). A high speed of trade execution is beneficial for traders to build their arbitrage portfolios and lowers their execution risk. Therefore, more active orders placed on the opposite side of arbitrageurs and with high execution probability may stimulate arbitrage activity and in turn remove mispricing.

To test the robustness of our empirical results, we redefine a provider of liquidity as a trader who places more active orders with highly executed probability on the opposite side of arbitrageurs. We use the number of submitted orders available at over best quote, i.e., market order (MO) and better best quote (BB1Q), instead of the number of all submitted orders. These orders are executed rapidly in the marketplace. Further, we also re-perform the unbalanced panel regression in Equation (3) to investigate the supply of liquidity by each trader type.

To save space, we only report the coefficients of dummy variables for mispriced options in Table 8. Panels A-D represent the results separately for overvalued calls, overvalued puts, undervalued calls, and undervalued puts.

[TABLE 7 ABOUT HERE]

For overvalued calls and puts, as reported in Panels A and B, we find that the significance of dummy variables (D_1–D_{12}) for market markets are comparable to the results in Table 5, with calls being significant for D_7 and D_8 and puts being significant for D_1, D_2, D_6,

D_9, and D_{10}. Results support that market makers respond more active orders during times of after violating PCFP. Similarly, in Panels C and D we also find similar results for undervalued calls and puts. We thus conclude that market makers play a significant role in providing liquidity when option market demands unexpected liquidity, supporting that they fulfill their exchange obligation of liquidity provision.

5. Conclusion

Arbitraging in put-call futures parity (PCFP) violations impairs liquidity due to created adverse select costs and order imbalances. This study investigates the liquidity supply of option providing in arbitrage exploitation. We use a unique data set of the Taiwan index option to separately examine the liquidity supply by market makers, individual traders, and foreign and domestic institutional traders. The data set includes order codes of identification, trading activity, and the real-time information in order book. Thus, our study is not subject to the trader-type error.

Our conclusions are specified as follows. First, individual traders play an important role in driving option prices to violate the PCFP. Second, in terms of initially violating PCFP, the orders on the side of liquidity supply are submitted most by market makers, followed by individual traders, and least by foreign and domestic institutional traders. Third, we find that market makers dominate the response of liquidity supply during times of after violating PCFP while individual and domestic institutional traders respond less. This finding provides evidence that market markers fulfill their obligation of liquidity supply when option market demands liquidity unexpectedly.

Next, for the effect of limit orders on liquidity, we find that on the whole, increased limit orders improves liquidity during period of before violating PCFP, consistent with Chung et al. (1999). Inversely, more submitted limit orders reduce liquidity during times of arbitrage exploitation. This evidence provides in favor of the results of Kamara and Miller (1995), Kumar and Seppi (1994), Roll et al. (2007), and Foucault et al, (2014) that arbitrage deteriorates liquidity. Finally, the characteristics of market and underlying asset affect the order placement strategy by different trader types.

Notes: The table reports the statistics of arbitrage profits as violating the put-call futures parity (PCFP). The data cover the period from January 1, 2007 to December 31, 2008. The total costs for building the arbitrage portfolio consist of trade costs and opportunity costs of margin deposits. The transaction costs include the pairs of call and put options and a futures contract. We further separate the options violating the PCFP into three groups by call option's moneyness: for in-the-money options, at-the-money options, and out-the-money options. The option moneyness (*myn*) is calculated as $K/(S*e^{r\tau})$, in which K is exercise price, S is the underlying asset price, τ is time to maturity, and r is risk-free interest rate.

Table 2. Submitted orders after violating the put-call futures parity

Panel A: In a 15-second time interval just after violating the put-call futures parity											
	Overvalued call						Overvalued put

Notes: The table presents the ratios of the cumulative average number of submitted bid orders to ask orders by quote types in the initial arbitrage shocks. The results in first 15-second and 30-second time intervals of arbitrage shocks are reported in Panel A and Panel B, respectively. The quoted orders are divided into the following categories: MO (market order), BB1Q (better best quote), B1Q (best 1 quote), B2-5Q (best 2–5 quotes), and BB5Q (behind best 5 quotes). They are arranged in highly executed probability order. For each type of arbitrage opportunities (with 24976 observations for overvalued calls and undervalued puts, and with 2827 observations for undervalued calls and overvalued puts), we compute the ratio of submitted bid orders to ask orders (A/B) by each quote type. The ratios for quote types are calculated as the cumulative average number of submitted bid orders (A) to the cumulative average number of submitted ask orders (B). Vol. denotes the average number of submitted orders in all violations. Cum. (A) is the cumulative average number of submitted orders by quote types.

Table 3. **Regression results of limit orders on liquidity**

	Overvalued calls		Overvalued puts		Undervalued calls		Undervalued puts	
	Coeff.	*t-stat.*	*Coeff.*	*t-stat.*	*Coeff.*	*t-stat.*	*Coeff.*	*t-stat.*
NLO_t	0.02	3.68***	-0.03	-4.04***	-0.02	-6.18***	-0.01	-4.10
D_{Mt}*NLO_t	0.03	5.79***	0.16	6.23***	0.11	6.04***	0.08	8.26 ***

Notes: The table presents the unbalanced panel regression results of limit orders on liquidity by each trader type around PCFP violations. We estimate the coefficients in Equation (4) using the two stages least square (2SLS) panel regression. The lagged values of number of submitted limit orders (*NLO*), trade volume (*OVol*), realized volatility (*RV*), net buy pressure (*NBP*), arbitrage size (*ArbSz*), and futures return (*FRet*) are used as instrument variables. The results for overvalued calls, overvalued puts, undervalued calls, and undervalued puts are reported in Panels A-D, respectively. In addition, the Hausman test (1978) is used to judge which the fixed effect model or the random effect model is suitable for the panel data. The empirical model is specified as

$$\begin{aligned} & Liq_{i,t} = \alpha + \beta_1 * NLO_{i,t} + \beta_2 * D_{Mt} * NLO_{i,t} + \beta_3 * OVol_{i,t} + \beta_4 * Liq_{i,t-1} + \varepsilon_t \\ & i = 1,2,3,\ldots,N, t = -a,\ldots,0,\ldots,b, \text{and } a,b \in [3,12] \end{aligned} \tag{4}$$

The dependent variable, Liq_t , is the liquidity of option at the end of time interval t, which is measured as bid-ask spread divided by the midpoint of quote. N is the number of violating PCFP. The time interval $t=0$ indicates the occurrence of violating PCFP. The limit orders (NLO_t) are calculated as the number of submitted bid and ask orders available at under better best quote during time t interval (i.e., the sum of bid and ask orders in quote types of B1Q, 2-5Q, and BB5Q). D_{Mt} is a dummy variable that equals 1 if it is during the period of after violating PCFP. $OVol_t$ is option trade volume during t time interval. Liq_{t-1} is lagged liquidity. In addition, for brevity, we only report the coefficients of *NLO* and D_{Mt}*NLO*. Both the coefficients are multiplied by 1000. ***, **, and * indicate that the t-values are significant at the 0.01, 0.05, and 0.1, respectively.

Notes: The table presents the change ratios of submitted orders accumulated by quote types during times of before and after violating PCFP. Panel A and Panel B report the results in two 15-second time intervals and two 30-second time intervals just before and after PCFP violations, respectively. For each type of PCFP violations and each trader type, we compute the ratios of change in number of submitted orders accumulated by quote types. The ratios for quote types are calculated as the differences between average numbers of submitted orders accumulated by quote types to average number of all submitted orders at prior time interval. More specifically, we first calculate the differences between cumulative numbers of submitted orders by quote types in two 15-second (or 30-second) time intervals of just before and after violating PCFP and average them. Then, they are divided by the average number of all submitted orders in 15-second (or 30-second) time interval of just before violating PCFP. In addition, the quoted orders are selected on the opposite trade direction of arbitrageurs and divided into the following categories: MO (market order), BB1Q (better best quote), B1Q (best 1 quote), B2-5Q (best 2–5 quotes), and BB5Q (behind best 5 quotes). The order types are arranged in highly executed probability order.

Notes: The table presents the unbalanced panel regression results of liquidity supply on buy side by trade types for overvalued calls (in panel A) and overvalued put (in panel B) after violating PCFP. The second row reports the results of Hausman test (1978) for different trader types. The results indicate which the fixed effect model or the random effect model is suitable for these panel data. The empirical model is specified as

$$
\begin{aligned}
NLM_{i,t} = {} & \alpha + \beta_1 * NBP_{i,t-1} + \beta_2 * RV_{t-1} + \beta_3 * ArbSz_{i,t-1} + \beta_4 * FRet_{t-1} + \beta_5 * OVol_{i,t-1} \\
& + \beta_6 * OSpd_{i,t-1} + \beta_7 * TolBid_{i,t-1} + \beta_8 * TolAsk_{i,t-1} + \beta_9 * Myn_{i,t} + \gamma_j * \sum_{j=1}^{12} D_{j,t} + \varepsilon_t \qquad (3) \\
& i = 1,2,3,\ldots,N, t = -a,\ldots,0,\ldots,b, a,b \in \{3,12\}
\end{aligned}
$$

The dependent variable, NLM_t, denotes the number of submitted buy orders during t time interval. N is the number of violating PCFP. The time interval $t=0$ indicates the occurrence of arbitrage opportunity. $D_{j,t}$ is a dummy variable that equals 1 if it is in jth interval, j=1,2,3,…, 12. This dummy variable captures the intraday variation in the number of submitted bid orders with respect to the time of violating the PCFP. For control variables, NBP_{t-1} is option net buy pressure during $t-1$ time interval, which is measured in terms of its persistence on buy side. RV_{t-1} is the realized volatility of futures during $t-1$ time interval, which controls the impact of volatility on order placement. $ArbSz_{t-1}$ is the profit for arbitrage trade at time $t-1$. $OVol_{t-1}$ and $OSpd_{t-1}$ denote option trade volume and its average best bid-ask spread during $t-1$ time interval, which control for the effect of option volume and spread on order placements. $TolBid_{t-1}$ and $TolAsk_{t-1}$ are the average of option bid and ask volume at the best 5 quotes during the $t-1$ time interval, respectively. $FRet_{t-1}$ is the futures return during $t-1$ time period. Myn_t is option moneyness at time t. In addition, both coefficients of *TolBid* and *TolAsk* are multiplied by 100 and the coefficient of *FRet* is divided by 100. ***, **, and * indicate that the t-values are significant at the 0.01, 0.05, and 0.1, respectively.

Table 6. Regression results of liquidity provision by trader types for undervalued calls and puts

Notes: The table presents the unbalanced panel regression results of liquidity supply on sell side by trade types for undervalued calls (in Panel A) and undervalued puts (in Panel B) after violating PCFP. The second row reports the results of Hausman test (1978) for different trader types. The results indicate which the fixed effect model or the random effect model is suitable for these panel data. The empirical model is specified as

$$
\begin{aligned}
NLM_{i,t} = {} & \alpha + \beta_1 * NBP_{i,t-1} + \beta_2 * RV_{t-1} + \beta_3 * ArbSz_{i,t-1} + \beta_4 * FRet_{t-1} + \beta_5 * OVol_{i,t-1} \\
& + \beta_6 * OSpd_{i,t-1} + \beta_7 * TolBid_{i,t-1} + \beta_8 * TolAsk_{i,t-1} + \beta_9 * Myn_{i,t} + \gamma_j * \sum_{j=1}^{12} D_{j,t} + \varepsilon_t \qquad (3) \\
& i = 1,2,3,\ldots,N, t = -a,\ldots,0,\ldots,b, a,b \in [3,12]
\end{aligned}
$$

The dependent variable, NLM_t, denotes the number of submitted buy orders during t time interval. N is the number of violating PCFP. The time interval $t=0$ indicates the occurrence of arbitrage opportunity. D_{jt} is a dummy variable that equals 1 if it is in jth interval, j=1,2,3,…, 12. This dummy variable captures the intraday variation in the number of submitted bid orders with respect to the time of violating the PCFP. For control variables, NBP_{t-1} is option net buy pressure during $t-1$ time interval. RV_{t-1} is the realized volatility of futures during $t-1$ time interval. $ArbSz_{t-1}$ is the profit for arbitrage trade at time $t-1$. $OVol_{t-1}$ and $OSpd_{t-1}$ denote option trade volume and its average best bid-ask spread during $t-1$ time interval. $TolBid_{t-1}$ and $TolAsk_{t-1}$ are the average of option bid and ask volume at the best 5 quotes during the $t-1$ time interval, respectively. $FRet_{t-1}$ is the futures return during $t-1$ time period. Myn_t is option moneyness at time t. In addition, both coefficients of *TolBiid* and *TolAsk* are multiplied by 100 and the coefficient of *FRet* is divided by 100. ***, **, and * indicate that the t-values are significant at the 0.01, 0.05, and 0.1, respectively.

Notes: The table presents the unbalanced panel regression results of liquidity actively providing in the opposite side of arbitrageurs during times of after violating PCFP. We use the number of submitted orders available at over best quote (i.e., market order, MO, and better best quote, BB1Q) instead of the number of all submitted orders. These orders are executed rapidly in the marketplace. The results for overvalued calls, overvalued puts, undervalued calls, and undervalued puts are reported in Panels A-D, respectively. The Hausman test (1978) is used to judge which the fixed effect model or the random effect model is suitable for the panel data. The empirical model is specified as

$$NLM_{i,t} = \alpha + \beta_1 * NBP_{i,t-1} + \beta_2 * RV_{t-1} + \beta_3 * ArbSz_{i,t-1} + \beta_4 * FRet_{t-1} + \beta_5 * OVol_{i,t-1}$$

$$+ \beta_6 * OSpd_{i,t-1} + \beta_7 * TolBid_{i,t-1} + \beta_8 * TolAsk_{i,t-1} + \beta_9 * Myn_{i,t} + \gamma_j * \sum_{j=1}^{12} D_{j,t} + \varepsilon_t \qquad (3)$$

$$i = 1,2,3,\ldots,N, t = -a,\ldots,0,\ldots,b, a,b \in [3,12]$$

The dependent variable, NLM_t, is the number of submitted orders available at over best quote during t time interval. N is the number of violating PCFP. The time interval t=0 indicates the occurrence of violating PCFP. D_{jt} is a dummy variable that equals 1 if it is in jth interval, j=1,2,3,…, 12. This dummy variable captures the intraday variation in the number of submitted bid orders with respect to the time of violating the PCFP. For control variables, NBP_{t-1} is option net buying pressure. RV_{t-1} is the realized volatility of futures. $ArbSz_{t-1}$ is the profit for arbitrage trade at time t-1. $OVol_{t-1}$ and $OSpd_{t-1}$ denote option trade volume and its average best bid-ask spread during t-1 time interval. $TolBid_{t-1}$ and $TolAsk_{t-1}$ are the average of option bid and ask volume at the best 5 quotes during the t-1 time interval, respectively. $FRet_{t-1}$ is the futures return during t-1 time period. Myn_t is option moneyness at time t. In addition, ***, **, and * indicate that the t-values are significant at the 0.01, 0.05, and 0.1, respectively.

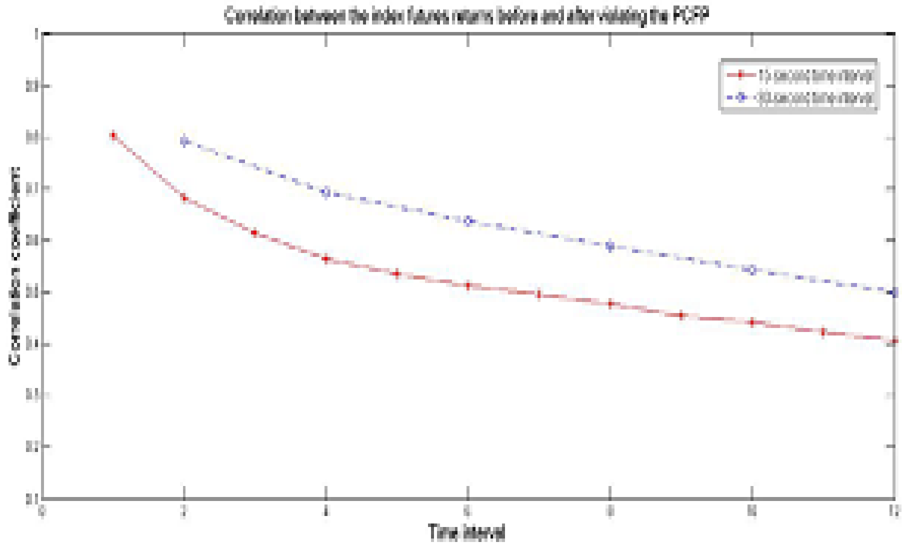

Figure 1. Correlation between the returns of index futures before and after violating PCFP. This figure depicts the correlation coefficient between the return of index futures at 15-second (30-second) time interval of just violating PCFP at time t=0 and the cumulative index futures return from time t=0 to the *j*th time interval of after violating PCFP, in which *j*=1, 2, …, 12 (2, 4, …, 12) for 15-second (30-second) time intervals. The correlation coefficients are used to judge whether the price in index futures moves in the same direction before and after violating PCFP.

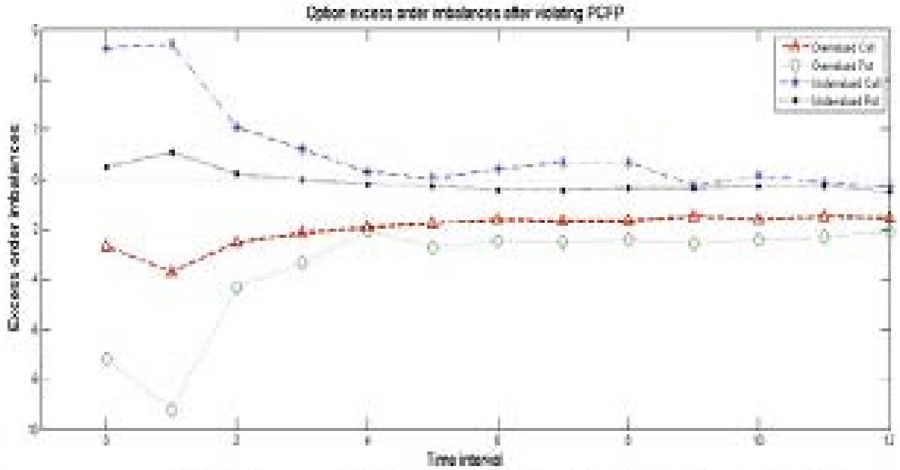

Figure 2. Average excess order imbalances of options after violating PCFP. This figure depicts the average excess order imbalances (AEOIB) of mispriced options during the 12 successive intervals of 15 seconds after violating PCFP (at time t=0). The PCFP violations are divided into four categories: for overvalued calls, overvalued puts, undervalued calls and undervalued puts. For the AEOIB in each time interval of 15 seconds for overvalued calls (overvalued puts, undervalued calls, and undervalued), we first calculate the AEOIB and then average them by each time interval. The AEOIB is calculated as the order imbalance less the mean of order imbalances in 360 successive time intervals of 15 seconds prior to the occurrence of arbitrage opportunity. We compute the order imbalances over all trades within each time interval. Following the Lee and Ready's (1991) algorithm, the order imbalance is measured as buyer-initiated trades less seller-initiated trades.

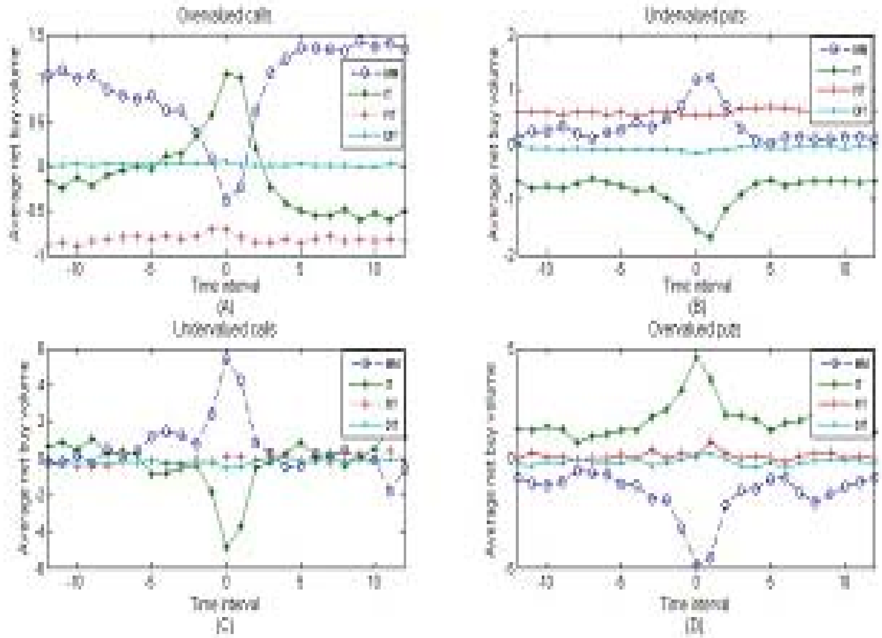

Figure 3. Average net buy volume of options around PCFP violations. This figure depicts the average net buy volumes of calls and puts by trader types within before and after 3-minute time intervals (24 successive 15-second time intervals) as arbitrage opportunities occur (at time t=0). The PCFP violations are divided into four classes, overvalued call and put options and undervalued call and put options. Figures A and D (C and B) show the average net buy volumes of overvalued (undervalued) calls and puts, respectively, around PCFP violations. For each of 24 time intervals, the average net buy volumes, defined as buy volume less sell volume, are calculated by trader types.

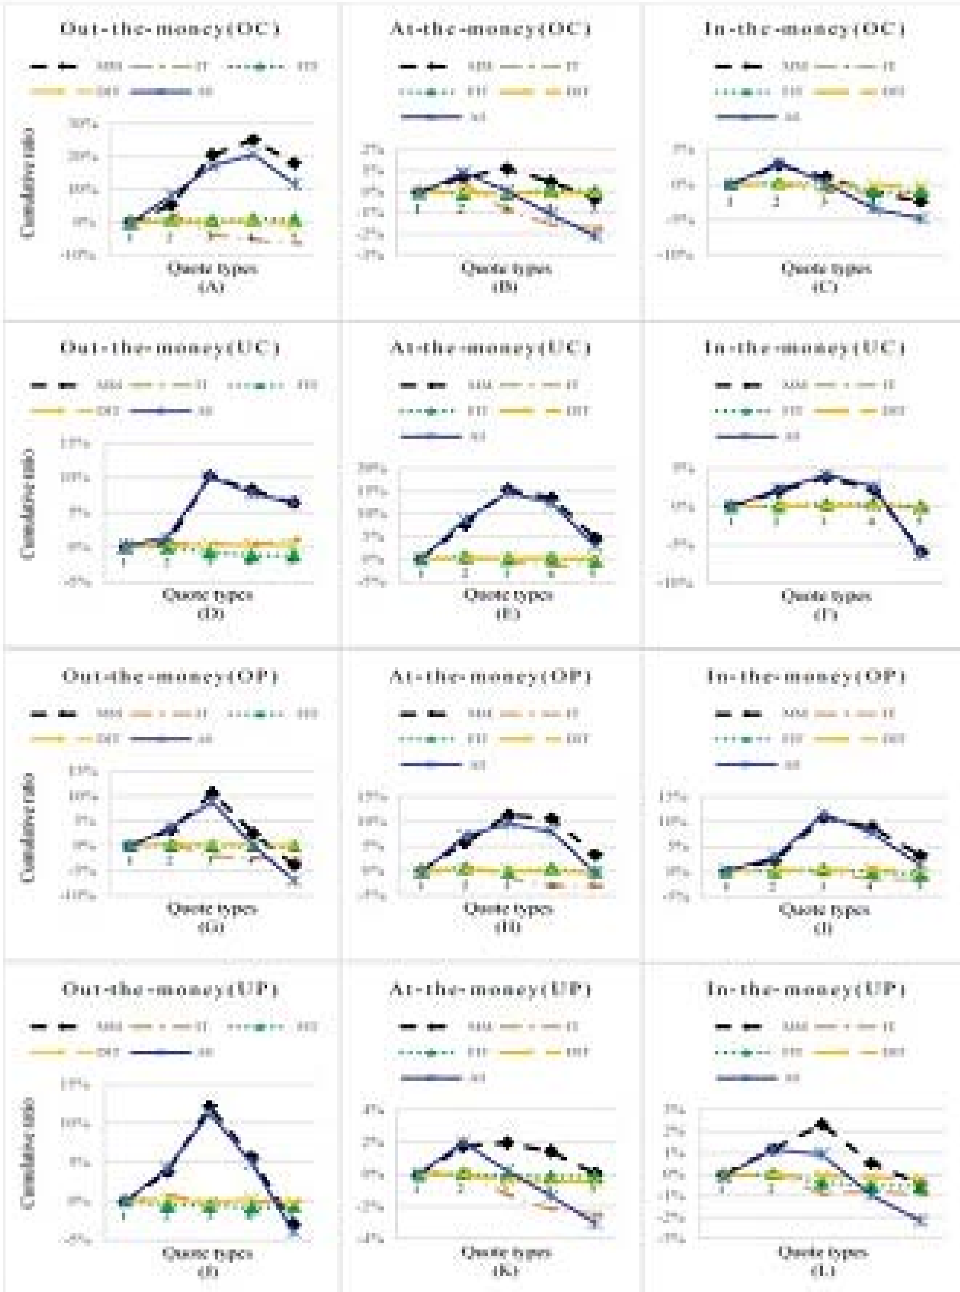

Figure 4. Change ratios of order submission for different moneyness groups. This figure depicts the ratios of change in submitted orders accumulated by quote types for different moneyness groups during two 15-second time intervals of just before and after violating PCFP. The numbers 1, 2, 3, 4, and 5 in the x-axis respectively correspond to the MO, BB1Q, B1Q, B2-5Q, and BB5Q of quote types. The quoted orders are selected on the opposite trade direction of arbitrageurs and divided into the following categories: MO (market order), BB1Q (better best quote), B1Q (best 1 quote), B2-5Q (best 2–5 quotes), and BB5Q (behind best 5 quotes). The order types are arranged in highly executed probability order. For each of overvalued calls (OC), undervalued calls (UC), overvalued puts (OP), and undervalued puts (UP), they are divided into three groups by option moneyness, including in-the-money options, at-the-money options, and out-the-money options. For each of PCFP violations and each trader type, we compute the change ratios of submitted orders each moneyness group.

Using a battery of look-ahead-bias free measures of accruals quality (AQ), we find a strong and long-lasting negative relation between future returns and AQ. In decile portfolios that rank on AQ, a hedge portfolio that goes long in the lowest decile and short in the highest decile generates an annualized, risk-adjusted return of 4–12% over one-month to five-year horizons, depending on the AQ measure and the portfolio weighting scheme. The return premiums associated with AQ are, i) robust to a wide range of AQ measures, ii) robust to a battery of return-informative variables, and iii) not driven by low-priced or small stocks, earnings shocks, or the fourth-quarter effect. The documented premiums are consistent with the information uncertainty effect where firm uncertainty is negatively related to future returns.

Keywords: Accruals quality, Stock returns, Return premium, Information uncertainty

1 Introduction

Whether the quality of accounting information or its commonly used proxy, namely, accruals quality, is a priced risk factor has been a subject of much debate in recent years. Prior studies in this literature typically use the annual accrual-residual volatility of Dechow and Dichev (2002) (hereafter, "AQ") as the inverse accruals quality measure. In two widely cited papers, Francis, LaFond, Olsson, and Schipper (2004, 2005) (hereafter, "FLOS") show that AQ is positively associated with contemporaneous returns and argue that it is a priced factor. However, their interpretation is questioned by Core, Guay, and Verdi (2008) (hereafter, "CGV"), who demonstrate that poor accruals quality does not induce a positive return premium and that an accruals-quality mimicking factor[1] fails to explain the cross-section of asset returns such as returns on portfolios sorted on size and book to market. Nevertheless, the existence of an accruals quality pricing risk has been assumed in a large number of subsequent studies since FLOS (e.g., Ecker et al. 2006; Chen et al. 2007; Krishnan et al. 2008; Kravet and Shevlin 2010, to name just a few).

In this paper we revisit the pricing of accruals quality by examining whether there are robust return premiums associated with accruals quality. To ensure that investment strategies formed on AQ do not suffer from look-ahead biases, different from the prior literature, we construct AQ measures using information prior to portfolio formation. By examining return premiums associated with AQ, we are able to sharpen our focus on own-firm returns arising from a firm characteristic. If, as FLOS and others propose, high AQ (i.e., low accruals quality) increases information risk and decreases current firm value, AQ should be positively associated with returns in the future.

We, however, find that AQ is negatively associated with future returns. Importantly, we find that the relation between AQ and future returns is economically significant (in an order of 10% annually after risk-adjustment), spans return horizons over one month to five years, and survives a wide-range of robustness tests. Since a larger value of AQ implies lower accruals quality, our results indicate that higher accruals quality predicts higher returns. As a practical matter, our findings

[1]The mimicking factor is estimated as the difference in monthly excess returns of the top two quintiles and the bottom two quintiles of a sample of firms rank-ordered by AQ (FLOS 2005, p313).

suggest that firms that are able to produce higher accruals quality are subsequently rewarded by markets.

While our findings that there are positive return premiums associated with accruals quality seem at odds with the information risk literature used in FLOS that predicts the opposite (e.g., Easley and O'Hara 2004), they are nevertheless consistent with a recent stream of literature that documents an "information uncertainty" effect (Zhang 2006). In this literature, a number of historical information uncertainty proxies are shown negatively associated with future returns. These information uncertainty proxies include analyst forecast dispersion (Diether et al. 2002), idiosyncratic return volatility (Ang et al. 2006), and earnings volatility and cash flow volatility (Berkman et al. 2009; Huang 2009).[2] Since AQ is a standard deviation of accrual residuals, it is by design similar to these information uncertainty proxies. Given that "accruals are the product of judgments, estimates, and allocations (of cash flow events in other periods)" (FLOS 2005, p301), a larger accrual residual volatility, or larger value of AQ, indicates greater estimation errors and thus signals higher information asymmetry at the firm level. In fact, Chen et al. (2012) argue that AQ incorporates managerial discretion in the recognition of accruals and thus measures information quality, and Callen et al. (2012) show that measures of accounting quality such as AQ are negatively associated with the speed that stock prices adjust to information arrivals. A negative association between AQ and future returns is, therefore, consistent with the information uncertainty effect.

We assemble evidence of the negative AQ-future return association at both the firm and portfolio levels. At the firm level, we corroborate the return premiums to AQ using Fama and MacBeth (1973) cross-sectional regressions that control for not only the traditional Fama-French four factors of beta, size, market-to-book, and price momentum (hereafter "FF-4 factors"), but also a number of other related variables. These other control variables include illiquidity (to control for the liquidity risk of Pastor and Stambaugh (2003)), earnings surprise (to control for the earnings-surprise-driven

[2]The findings of these information uncertainty effects appear to be robust across different studies. For example, Ang et al. (2009) document that idiosyncratic volatility negatively predicts returns in international markets; and Huang (2009), similar to us, documents that cash flow volatility is negatively related to future stock returns over the horizons of one-month to five years.

accruals-quality effect), and earnings yield (to control for the level of earnings which may cause the pricing of accruals quality). The effect of AQ lasts for periods extending one month to five years ahead. Importantly, over these return horizons, the economic significance of AQ remains relatively stable: One decile increase in AQ leads to an annualized return reduction in the order of 40–80 basis points. At the portfolio level, the decile portfolio with the smallest AQ (highest accruals quality) outperforms the decile portfolio with the largest AQ by 4–12% a year in returns after controlling for the FF-4 factors, depending on the AQ measure and the portfolio weighting scheme. In addition, when the sample portfolios are partitioned into halves, the smoother AQ half outperforms the more volatile half by the order of 4% a year after adjusting for the FF-4 factors.

Our results hold with a number of accruals quality measures. We consider measures estimated from both annual and quarterly accounting data. For annual measures, we use two traditional FLOS measures: one following the definition used in FLOS, and the other adjusted for potential look-ahead bias using an out-of-sample approach. For quarterly measures, we use the counterpart of our out-of-sample annual measure, as well as a number of measures that are adjusted for quarterly seasonality (e.g., Brown 1993). These latter measures employ industry-mean adjustment for seasonality, or employ scaling by sales, which displays similar seasonality as quarterly working capital in the AQ calculation. We also consider absolute abnormal accruals to proxy for accruals quality (Warfield et al. 1995; Rajgopal and Venkatachalam 2011). Notwithstanding somewhat weaker results for the FLOS annual measure, our findings remain strong for all of the other measures.

We evaluate the robustness of our results to a number of alternative explanations provided in the AQ literature. In order to re-establish the findings of Francis et al. (2005), Kim and Qi (2010) argue that the presence of low-priced stocks causes the disappearance of the pricing of accruals quality, while Ogneva (2012) attributes such disappearance to negative earnings shocks experienced by firms. Our results are robust to controls of both low stock price and earnings surprise. Specifically, our conclusions do not change when we remove from our sample stocks that have prices less than \$5 (Kim and Qi 2010), or stocks that are at the bottom 30 percentiles of earnings surprise (Ogneva

2012). Furthermore, our findings are not driven by small firms, as the results are robust to removing firms at the bottom 30 percentiles of market capitalization. Our results are also robust to the so-called accrual anomaly that abnormal accruals negatively predict returns (Sloan 1996; Xie 2001): We control for abnormal accruals and find our results continue to hold.

We find evidence that the pricing of accruals quality is consistent with the information uncertainty literature. Information uncertainty measures such as idiosyncratic return volatility and cash flow volatility are not only highly correlated with AQ, but they also greatly reduce the pricing effect associated with AQ. We find that in some cases, the pricing of AQ is subsumed by a combination of information uncertainty measures such as idiosyncratic return volatility and cash flow volatility, a manifestation that the relation between AQ and returns is embedded in the overall firm information uncertainty.

This paper contributes to the literature by providing a novel insight into the contentious debate about the pricing of accruals quality. We examine the predictive ability of accruals quality for future returns. Different from the extant literature, we explicitly emphasize return-predictability of AQ by examining look-ahead-bias free AQ measures. One strength of this paper is that we provide evidence of strong, robust, and long-lasting return premiums related to accruals quality. If accruals quality reduces information risk and if information risk is a priced factor then AQ is predicted to be positively related to future returns. Our results are not consistent with this prediction. Rather, our results are consistent with the recent empirical regularity of the information uncertainty literature, where higher volatility tends to lead to lower returns.

The rest of the paper is organized as follows. Section 2 discusses the related literature. Section 3 describes the variable definitions, and Section 4 demonstrates the return premiums related to accruals quality. Section 5 evaluates explanations drawn from the accruals quality literature and the information uncertainty literature. Section 6 concludes.

2 Related Literature and Background

As previously discussed, our paper is related to two growing areas of the literature: the pricing of accruals quality and the pricing of information uncertainty. In this section we provide a further background review and discuss the relative positioning of our paper.

2.1 The Pricing of Accruals Quality

According to the information risk literature (e.g., O'Hara 2003; Easley and O'Hara 2004), investors bear an information risk when they have to rely on private information in the absence of adequate public information, and thus they must be compensated with higher returns. Following this line of argument, if a firm's accruals quality is poor, investors will have greater difficulty in forecasting its future performance and thus incur greater information risk. Motivated by this observation, FLOS examine the relation between the Dechow and Dichev (2002) accruals quality measure (AQ) and a number of return proxies, and find that firms with poorer accruals quality tend to have higher contemporaneous returns, costs of debt and equity market betas. FLOS conclude that their empirical evidence is consistent with the view that the risk related to accruals quality is a priced factor. FLOS's interpretation, however, is questioned by CGV. Using two-stage asset pricing tests based on Fama and MacBeth (1973) and Cochrane (2005), CGV show that the FLOS accruals-quality factor does not explain the cross-section of returns on various portfolios, such as the Fama-French 25 size/book-to-market portfolios. They conclude that there is no evidence that accruals quality serves as a risk factor. Despite the findings of CGV, a large number of subsequent studies have assumed the existence of an accruals quality price risk (e.g., Ecker et al. 2006; Chen et al. 2007; Krishnan et al. 2008; Kravet and Shevlin 2010).

Two recent papers attempt a reconciliation of FLOS and CGV. Ogneva (2012) constructs an accruals quality mimicking risk factor from returns orthogonal to earnings surprise, and Kim and Qi (2010) exclude low-priced stocks in their derivation of the accruals quality factor. Both studies show that the accruals quality factor explains returns on various accruals-quality portfolios.

However, the power of these tests can be an issue; for example, Lewellen et al. (2010) point out that pricing tests of a factor using assets based on the same factor characteristic tend to produce biases. In fact, Du (2011) finds that the pricing results of such an accruals quality factor is not due to accruals quality being a risk factor, but due to mispricing that arises from a spurious correlation between accruals quality characteristic and accruals quality beta in the fashion of Daniel and Titman (1997).

The risk-factor studies above typically construct an accruals quality mimicking risk factor and relate the factor to the cross section of returns on a wide-range of portfolios. In this paper, we choose to focus on own-firm returns arising from the firm characteristic of AQ. For the information risk factor to hold, a positive correlation between future returns and AQ must exist. Extant literature, which typically correlates one-year-ahead returns with annual accounting data, does not provide evidence of such a positive correlation (e.g., CGV, Kim and Qi 2010, Ogneva 2012). For example, Tables 7 and 8 of CGV provide mixed evidence by showing that AQ can be positively or negatively associated with future returns.[3]

Brousseau and Gu (2013), in a contemporaneous piece, report findings similar to ours, and attribute the observed accruals quality and return relation to large firms. Brousseau and Gu (2013) focus on equal-weighted, quintile portfolios sorted on FLOS's AQ measure predicting one-month-ahead returns. They show that the FLOS AQ-return relation in these portfolios is driven by smallest firms. Removing the smallest 20% of firms would result in a finding similar to ours. They further argue that liquidity and short-sale constraints are responsible for their findings. Our results appear to be more robust than those in Brousseau and Gu (2013). In particular, different from Brousseau and Gu (2013), we attempt i) one-month- to five-year-ahead returns, ii) equal- and value-weighted

[3]Table 7 of CGV presents 12 cases of portfolio-sorting test of the association between AQ and future returns; out of the 12 cases, the association is significant and positive for 6 cases, and significant and negative for one case. Table 8 of CGV presents two cases of regression test of the association between AQ and two to five-years-ahead buy-and-hold returns, and reports that the association is significant and negative for one case, and insignificant and negative for the other case. CGV do not examine if the relation is robust to controls but suggest that these results "are unlikely to be explained by noise in realized returns." We instead show that the negative association documented in this paper is very robust and survives controls of a large number of potentially confounding effects and a variety of accrual quality measures.

portfolios, iii) firm-level cross sectional regressions, iv) annual AQ measures with and without look-ahead bias, and v) a wide range of of quarterly AQ measures. Importantly, we show that our results survive after we remove the smallest 30% of firms, and also survive the controls of short-sale constraints proxied by measures such as liquidity and idiosyncratic volatility. Thus, the explanation proposed by Brousseau and Gu (2013) does not appear to compromise our results.

2.2 Information Uncertainty

A popular measure used to test the information risk suggested by O'Hara (2003) is the probability of informed trading (PIN) used in Easley et al. (2002). Empirical evidence on the pricing of PIN is mixed: for example, Easley et al. (2002) find supporting evidence, while Mohanram and Rajgopal (2009) and Duarte and Young (2009) question the robustness of this finding to factors such as sample period, additional risk factors, and limits to arbitrage. In fact, a growing literature on information uncertainty reports that a wide range of information uncertainty proxies negatively predict future returns (Zhang 2006). Such a negative relation exists for analyst forecast dispersion (Diether et al. 2002), idiosyncratic return volatility (Ang et al. 2006, 2009), cash flow volatility and earnings volatility (Berkman et al. 2009; Huang 2009), and accruals volatility (Bandyopadhyay et al. 2012).[4] These information uncertainty measures and AQ share a common feature that they are all standard deviation measures of firm-level variables.

The literature also establishes a positive link between idiosyncratic return volatility and managerial discretion-induced information quality. Chen et al. (2012) argue that the AQ measure reflects part of the quality of the information arising from managerial discretion, and relates it to the trends of idiosyncratic return volatility in the past four decades. Callen et al. (2012) show that accounting quality, as measured by AQ and a number of other variables, is negatively associated with the speed that prices adjust to information arrivals. These papers collectively show that AQ measures a firm's information asymmetry. Given that AQ is positively related to information

[4] Some of these results are debated. For example, Fan (2009) questions the findings of Ang et al. (2006), and shows that idiosyncratic return volatility estimated as out-of-sample forecasts of EGARCH models positively predicts future stock returns.

uncertainty, we expect that AQ would negatively predict future returns based on the information uncertainty effect (Zhang 2006). Our findings are consistent with this prediction; furthermore, we show that the return premiums to AQ may be subsumed by a combination of information uncertainty measures.

3 Sample and Variable Definitions

3.1 Accruals Quality Measures Using Annual Data

We follow the literature (e.g., FLOS, CGV, and Rajgopal and Venkatachalam (2011)) to derive the Dechow and Dichev (2002) accruals quality ("AQ") measure using annual accounting data. We select all NYSE/NASDAQ/AMEX-listed firms on the merged CRSP/Compustat database and extract annual accounting items. Specifically, *AQ_FLOS* involves estimating the following regression by fiscal year for each industry:

$$\begin{aligned} TCA_{i,j,y} = \quad & \beta_{0,j} + \beta_{1,j}CFO_{i,j,y-1} + \beta_{2,j}CFO_{i,j,y} + \beta_{3,j}CFO_{i,j,y+1} \\ & + \beta_{4,j}\Delta Sales_{i,j,y} + \beta_{5,j}PPE_{i,j,y} + \varepsilon_{i,j,y} \end{aligned} \tag{1}$$

where TCA is total current accruals (that is, operating accruals or change in working capital);[5] CFO is cash flow from operations, defined as earnings before extraordinary items minus TCA plus depreciation and amortization; PPE is property, plant and equipment; $\Delta Sales$ is the change in sales relative to the prior year; i indexes firm; j indexes industry; and y indexes fiscal year. Both sides of Equation (1) are scaled by total assets; and hence we remove observations with negative total assets. Equation (1) is estimated every fiscal year for each of the 48 Fama and French (1997) industries that has at least 20 observations. The residual obtained from Equation (1) is the so-called discretionary accruals (DA). A firm's *AQ_FLOS* is its five-year rolling standard deviation of DA

[5] Working capital is defined as (Current assets − Cash and short-term investment) − (Current liabilities − Debt in current liabilities).

from years $y-4$ to y. Larger values of *AQ_FLOS* indicate lower accruals quality. As is standard in the literature, we match *AQ_FLOS* to returns three months after fiscal year end. For example, *AQ_FLOS* for a firm with fiscal year-end of March is matched to returns from July of the same year. Our sample of *AQ_FLOS* covers the period of 1970–2012, in which the starting period of 1970 follows FLOS.

This paper examines whether there are return premiums to accruals quality. As such, it is important to ensure that investment strategies formed on AQ do not suffer from the so-called look-ahead bias. The construction of *AQ_FLOS* in Equation (1) and its association with returns could suffer from potential look-ahead bias in two ways. First, the alignment of firms by fiscal year ignores fiscal year end differences across firms, which may result in return realizations preceding accounting information when *AQ_FLOS* is matched to returns. Second, Equation (1) uses one-year-ahead *CFO* to estimate *AQ_FLOS*, which is in turn matched to returns of only three months ahead. To address these issues, we design an out-of-sample estimate of AQ. We first align accounting observations across firms by calendar month and assign the same annual observation to each month within the fiscal year. Once we create the monthly data, we modify Equation (1) to:

$$\begin{aligned} TCA_{i,j,t} = \quad & \beta_{0,j} + \beta_{1,j}CFO_{i,j,t-12} + \beta_{2,j}CFO_{i,j,t} + \beta_{3,j}CFO_{i,j,t+12} \\ & + \beta_{4,j}\Delta Sales_{i,j,t} + \beta_{5,j}PPE_{i,j,t} + \varepsilon_{i,j,t} \end{aligned} \tag{2}$$

where t denotes month. We use the same five-year window to estimate Equation (2) by industry. Specifically, for each month t, we estimate Equation (2) over month $t-60$ to $t-1$; we then substitute the slope coefficient estimates into Equation (2) for month t and calculate the predicted residual value at month t. Once we derive the time-series estimate of the residual, we estimate our second AQ measure, called *AQ_annual*, as the monthly rolling standard deviation of the predicted residual over the past five years. We further lag the estimate of *AQ_annual* by a year, and match returns three months thereafter. This out-of-sample estimate of *AQ_annual* ensures that when we use it to predict returns, the conditioning information (i.e. *AQ_annual*) is known to the market.

3.2 Accruals Quality Measures Using Quarterly Data

We also create a number of quarterly *AQ* measures based on quarterly accounting data from Compustat. We follow the same out-of-sample approach of Equation (2) to estimate the quarterly measures, except that, consistent with the extant literature (see, e.g., Dechow et al. 2011), we change lagged and lead *CFO*s to *CFO*s to those of the past and next quarters. Quarterly changes of variables, such as change in working capital, are defined relative to the same quarter of last year. We choose an estimation window of 16 quarters to estimate AQ for the quarterly data.[6] Quarterly data items that are necessary for computing accruals are reported in large scale in Compustat only from 1976; and allowing for four years of AQ estimation, our quarterly AQ measures start from 1980.

Compared to the low-frequency annual data, using quarterly data has the apparent advantage of increasing the data frequency by fourfold, and hence is more suitable for estimating time-series standard deviations. However, quarterly accounting items such as accruals exhibit seasonality (e.g., Brown 1993). Our data confirms the existence of quarterly seasonality. In our sample, the one-year apart autocorrelation of annual *DA* in Equation (2) is 0.05; however, the autocorrelation jumps to 0.19 for quarterly *DA*.

We adopt two ways to adjust for seasonality: (i) adjusting for industry mean (assuming that seasonality is common within the industry), and (ii) applying a scalar that is believed to display similar seasonality as quarterly working capital. For the first method, we keep total assets as the scalar, deduct the industry mean from each term in Equation (2), and estimate the industry-adjusted *DA* accordingly. For the second method, we choose sales instead of total assets as the scalar. Sales satisfies two criteria: (i) it has been used in the prior literature as a measure of firm size (e.g., Berk 1997), so it serves the purpose of scaling for cross-firm comparison, and (ii) it co-varies with earnings, cash flows and thus, working capital. The one-year apart autocorrelation for industry-adjusted quarterly *DA* reduces slightly to 0.18; and the autocorrelation of sales-deflated quarterly *DA* significantly reduces to 0.09, which is similar to the 0.05 autocorrelation of the assets-deflated

[6] Chen et al. (2012) use three, four and five years in their quarterly data to derive a similar measure; we choose a middle ground of four years. Our results are robust to estimation windows of three and five years. We require that at least half of the observations within this estimation window are not missing.

annual *DA* reported earlier. Thus, deflating by sales seems to be an effective way of addressing quarterly seasonality in our case. We hence use the sales-deflated quarterly AQ measure, called *AQ_qtr*, as our primary quarterly measure. We denote the corresponding quarterly measure deflated by total assets *AQ_qtr_A*, and the quarterly measure deflated by total assets and industry-adjusted *AQ_qtr_Ind*.

In robustness tests, we also address the fourth-quarter effect in quarterly data. There is evidence that fourth quarters demonstrate an elevated level of earning management activities relative to interim quarters (e.g., Francis et al. 1996; Dhaliwal et al. 2004; Das et al. 2009). If elevated earnings management in the fourth quarter biases the estimate of accruals quality, or if the return response to accruals is different in the fourth quarter, any empirical evidence that we glean could be driven by the fourth quarter effect. To address this concern, we remove all fourth-quarter observations from our estimation of *AQ_qtr*; we denote the AQ measure so estimated as *AQ_no4q*.

Our last AQ measure is the absolute value of accruals. The literature also uses absolute abnormal accruals to measure accruals quality (e.g., Warfield et al. 1995; Rajgopal and Venkatachalam 2011). We estimate abnormal accruals as the residual of the following performance-matched Jones (1991) model of Kothari et al. (2005):

$$ACC_{i,j,t} = \beta_{0,j} + \beta_{1,j}\Delta Sales_{i,j,t} + \beta_{2,j}PPE_{i,j,t} + \beta_{3,j}\text{Earnings}_{i,j,t} + v_{i,j,t} \tag{3}$$

where *ACC* is total accruals, scaled by sales as with *AQ_qtr*. We use the same out-of-sample technique of Equation (2) to estimate Equation (3) by each industry j using the past four years' data and take the predicted value of $v_{i,j,t}$, denoted as Abs(*AbAcc*), to be the abnormal accruals of firm i at month t. Similar to our other AQ measures, higher values of absolute Abs(*AbAcc*) indicate lower accruals quality.

3.3 Correlations

Tables 1 and 2 provide, respectively, the descriptive statistics and the time-series means of the cross-sectional correlations of the AQ measures. The different measures of AQ are all highly correlated. Within the annual measures, *AQ_FLOS* and *AQ_annual* have a correlation of 0.79; and within the quarterly measures, *AQ_qtr* has a correlation of around 0.50 with *AQ_qtr_A* and with *AQ_qtr_Ind*. Finally, *AQ_annual* and *AQ_qtr* have a correlation of 0.33.

[Tables 1 and 2 about here.]

We further validate the link between annual and quarterly AQ measures by examining the degree of potential misclassification of firm accruals quality as measured by these two families. We use *AQ_annual* and *AQ_qtr* as an illustration. Each month, we classify firms into deciles based on, respectively, *AQ_annual* and *AQ_qtr*. We then examine the degree of overlapping among these deciles. We find that 16.3% of firms are placed in exactly the same decile between *AQ_annual* and *AQ_qtr*. Further, 42.0% of the the firms have an *AQ_qtr*-decile one decile away from *AQ_annual*-decile, and 61.1% of the firms have an *AQ_qtr*-decile within two deciles away from *AQ_annual*-decile. These statistics further indicate that the probability of misclassification of accruals quality arising from our use of annual and quarterly AQ is likely to be small in our sample.

Since our accruals quality measures are estimated over a relatively long horizon, it is desirable to examine its relation to not only the one-month-ahead return, as is typical in the literature, but also longer-horizon returns. Following CGV, the longest horizon return that we examine is 5-year-ahead return. We thus examine future returns over horizons of one and six month(s), and one, two, and five year(s) as well. We control for the delisting survivorship bias by adjusting for delisting returns as per Shumway (1997) and Shumway and Warther (1999), and calculate returns of all horizons using monthly returns from CRSP. In order to reduce the effects of outliers, all returns are winsorized at the 1st and 99th percentiles over the full sample (see also, e.g., Skinner and Sloan 2002; Zhang 2007).[7] Table 2 shows that all of our AQ measures are negatively and significantly

[7]Our results remain qualitatively the same if we do not winsorize returns, or winsorize returns at extreme tails such as at the 0.1st and 99.9th percentiles.

correlated with returns of these horizons. These results provide first evidence that accruals quality positively predicts returns.

4 The Return Premiums to Accruals Quality

In this section we present evidence that accruals quality predicts future returns related to using both annual and quarterly data. We find that firms with poorer accruals quality suffer from lower returns subsequently, from one-month to five-year-ahead horizons. The negative return due to accruals quality is robust to the control of a battery of common risk factors.

4.1 Evidence from the Annual Accounting Data

4.1.1 Firm-Level Evidence from Cross-Sectional Regressions

We estimate return regressions at the firm level using the Fama and MacBeth (1973) cross-sectional methodology. Specifically, we first estimate the regression every month, and then average the monthly coefficient estimates to get the full-sample estimates and corresponding t-statistics. The independent variables include the traditional risk adjustments of Fama-French three factors of market, size and value, and Carhart's (1997) momentum factor. The cross-sectional multiple-regression for every month t is therefore:

$$R_{i,t+1} = \alpha_{i,t} + \gamma_{1,t} beta_{i,t} + \gamma_{2,t} \ln(ME)_{i,t} + \gamma_{3,t} \ln(BEME)_{i,t} + \gamma_{4,t} PMOM_{i,t} + \gamma_{5,t} \mathrm{AQ}_{i,t} + v_{it} \quad (4)$$

where the subscript i indexes stock, the subscript t indexes month, R is stock's return, ME is lagged market equity, $BEME$ is book-to-market equity, and $PMOM$ is price momentum (the past-12-month stock return). Note that the subscript $t+1$ in Equation (4) denotes future returns of one month to five years.[8]

[8]The t-statistics for longer-horizon return regressions are adjusted for the Newey and West (1987) autocorrelation with the number of lags corresponding to the degree of overlapping in returns. That is, standard errors in the regressions of six-month returns are adjusted for five lags, and so on and so forth upto the adjustment of 59 lags for the regressions

Table 3 presents the regression results of Equation (4) using one-month to five-year-ahead returns on *AQ_FLOS* and *AQ_annual*. The signs on the control variables in Table 3 are unremarkable. Briefly, beta is insignificant (e.g., Fama and French 1992); size is insignificant (consistent with the disappearing size effect after the 1980s); and the coefficients of book-to-market and price momentum are significantly positive most of the times, as expected. Importantly, we observe that both *AQ_FLOS* and *AQ_annual* negatively predict future returns over one month to five years. Note that part of the *AQ_FLOS* results are also reported in the literature; for example, CGV (Table 8) also report that buy-and-hold returns from year two to year five are negatively related to *AQ_FLOS* decile.

[Table 3 about here.]

In Table 4, we offer two schemes of robustness checks for the results in Table 3, namely subperiod analysis and adding a number of control variables. In Panels A and B of Table 4, we examine the pricing of AQ in a number of sample subperiods. We divide the full sample into two subperiods of 1970–1990 and 1991–2012. We also carve out a subperiod of 1980–2012, which corresponds to the sample period used in our subsequent quarterly analyses. We note that while *AQ_FLOS* loads significantly across all return horizons in the subperiod of 1980–2012 and across longer return horizons in other subperiods, it is not significant or only marginally significant (with a significance level of only 10%) in predicting one- and six-month returns for the subperiods of 1970–1990 and 1991–2012. The weaker results of *AQ_FLOS* in these subperiods perhaps explain why the negative relation between *AQ_FLOS* and returns previously documented in the literature (e.g. CGV) are somewhat obscured. In contrast, *AQ_annual* loads significantly in all three subperiods across all return horizons.

[Table 4 about here.]

In Panel C of Table 4 we add a number of return-informative variables to Equation (4). The additional variables that we include are earnings surprise (Chan et al. 1996), earnings yield (Haugen

of five-year returns.

and Baker 1996), and illiquidity (Amihud 2002; Pastor and Stambaugh 2003), as these variables are also widely used in return predictions. We present the results with *AQ_annual* since it is free of look-ahead bias. Compared with Table 3, the magnitude of the coefficient estimate of *AQ_annual* is about halved with the addition of these variables; however, the significance of *AQ_annual* is not lost. In sum, the evidence of Table 3 shows that AQ, in particular, *AQ_annual*, is negatively associated with future returns.

4.1.2 Portfolio-Level Evidence of *AQ_annual*

To examine return premiums, the literature also frequently uses the portfolio sorting approach to form hedging portfolios. Following the literature, we rank the sample firms based on the value of *AQ_annual* and then form 10 portfolios based on the ranks. After forming the portfolios, we examine one-month- to five-year-ahead buy-and-hold returns of these portfolios, based on either equal-weighting, or value-weighting by the beginning-of-the-month market value of equity.

We form two hedge portfolios from the decile portfolios. Our first hedge portfolio is long on the smallest decile portfolio and short on the largest decile portfolio. This hedge portfolio, however, ignores the returns of intermediate deciles. We address this issue in the second hedge portfolio, which is long on the smallest five decile portfolios and short on the largest five decile portfolios, with each decile portfolio receiving an equal weight. We consider risk-adjusted returns, or Jensen's alpha. We employ risk adjustments by the Fama-French four factors (i.e., market, size, value, and momentum). The monthly market return, risk free rate, and factor returns are all taken from Kenneth French's website.[9] To match returns of longer horizons, factors for horizons longer than one month are calculated as buy-and-hold returns based on the monthly factors.

Table 5 presents the alphas of the decile portfolios. In the table, the column labeled "D1 – D10" shows the spread between the smallest decile portfolio (D1) and the largest decile portfolio (D10), and the column labeled "D1:5 – D6:10" shows the spread between the simple average return of deciles 1 to 5 and the simple average return of deciles 6 to 10. We first observe a large, positive

[9] The website's URL address is: http://mba.tuck.dartmouth.edu/pages/faculty/ken.french/.

D1 − D10 spread of alpha in both equal- and value-weighted portfolios. In Panel A, the D1 − D10 equal-weighted alpha spread is 0.73% (t = 4.15) per month for the one-month-ahead returns, corresponding to an annualized spread of 9% (≈ 0.73% × 12);[10] and in Panel B, the corresponding value-weighted return spread is 0.33% (t = 1.87) per month, corresponding to an annualized spread of 4% (≈ 0.33% × 12). Furthermore, the *AQ* effect identified in the case of one-month-ahead return does not abate over longer horizons. Over six-month to five-year horizons, the annualized D1 − D10 alpha spreads are about 8–10% for equal-weighted portfolios, and in the range of 4-10% for value-weighted portfolios. Lastly, the D1:5 − D6:10 alpha spreads are all significant; and the annualized D1:5 − D6:10 alpha spreads are about 4% for equal-weighted portfolios and 2% for value-weighted portfolios.

[Table 5 about here.]

4.2 Evidence from the Quarterly Accounting Data

We now turn to the evidence from the quarterly data for the period of 1980–2012. Table 6 reports the cross-sectional regressions of returns on *AQ_qtr*, our primary measure of quarterly AQ. Similar to the return regressions on *AQ_annual*, *AQ_qtr* significantly and negatively predicts returns from one month to five years, whether the control variables are the Fama-French four-factor variables or the augmented set that also includes *SUE*, *EY*, and *ILLIQ*.

[Table 6 about here.]

As previously discussed, we also consider other measures of quarterly accruals quality. Collectively, we consider the following alternative measures: *AQ_qtr_A* (out-of-sample measure of AQ using total assets as the scalar), *AQ_qtr_Ind* (out-of-sample measure of AQ using total assets as the scalar, and all quarterly data items used in the estimation are industry-mean-adjusted), *AQ_no4q* (similar as *AQ_qtr* except that all fourth-quarter observations are removed), and Abs(*AbAcc*) (ab-

[10] We define annualize spread as the spread of a given return horizon divided by the number of the years of the horizon.

solute level of abnormal accruals). Table 7 reports the regression results of returns on the Fama-French four-factor variables and one of these four alternative measures. We continue to observe negative significance of AQ on future returns over one month to five years across these alternative measures.

[Table 7 about here.]

Lastly, we replicate the portfolio sorting results for *AQ_qtr*, and present the results in Table 8. Here we observe that both D1 − D10 and D1:5 − D6:10 alpha spreads are highly significant for both equal- and value-weighted portfolios across all of the return horizons that we examined. The annualized D1 − D10 alpha spread is about 10% for equal-weighted portfolios, and about 8% for value-weighted portfolios. Compared with the case of annual AQ in Table 5, these spreads are higher, in particular, in cases of shorter-horizon returns. This is also true for D1:5 − D6:10 spreads. The increased spread of *AQ_qtr* relative to *AQ_annual* suggests that the information set contained in *AQ_qtr* is more timely relative to that contained in *AQ_annual*, and hence *AQ_qtr* is accompanied by a stronger market reaction.

[Table 8 about here.]

4.3 Economic Significance of the AQ Return Premium

Our portfolio sorting results earlier suggest the existence of a 4–10% alpha (abnormal return) annualized spread difference between extreme AQ deciles, depending on the AQ measure and the portfolio weighting scheme. We now show that this magnitude of spread difference is to a large extent corroborated in cross-sectional return regressions, despite the fact that the portfolio sorting performance is subject to how the portfolio is constructed. To this end, every month we transform *AQ_annual* and *AQ_qtr* into decile ranks and re-estimate Equation (4) with the decile variable replacing its continuous counterpart. Table 9 reports the results. We observe that the coefficients of *AQ_annual* decile or *AQ_qtr* remain significant and negative for all of the return horizons. *AQ_annual* decile has a coefficient of −0.04 on one-month-ahead returns (in percentage point); in other words, a decrease in *AQ_annual* by one decile rank would lead to an annualized return impact of 0.04% × 12 or about 50 basis points. The most extreme decile change of nine decile change would therefore result in approximately 4.5 percent return a year. This magnitude of economic significance is in the same order as the D1 – D10 alpha spread of *AQ_annual* in portfolio sorting in Table 5. We further observe that the annualized impact of *AQ_annual* remains roughly at the same order of magnitude for future returns of six months to five years, again similar to the longer-horizon portfolio sorting results in Table 5.

[Table 9 about here.]

The remainder of Table 9 presents the economic significance of *AQ_qtr*. We note that the annualized impact of one decile change in *AQ_qtr* is about 75 bps; this is equivalent to an 8% difference in an extreme decile movement. This is at par with the portfolio sorting results in Table 8. As with the case of portfolio sorting, the results in Table 9 suggest that *AQ_qtr* has a higher economic significance than *AQ_annual*, perhaps due to better information timeliness embedded in the former measure.

5 Evaluating Explanations

5.1 Evaluating Existing Explanations

In an attempt to re-establish the results of Francis et al. (2005), Kim and Qi (2010) argue that low-priced stocks cause the loss of pricing power of the accruals quality factor, and Ogneva (2012) argues that the loss is due to negative earnings shocks. Based on these findings, it is possible that our results are driven by low-priced stocks or negative earnings surprise. To address these concerns, we remove observations that are associated with low stock prices or negative earnings surprises. Panel A of Table 10 presents the results. We follow Kim and Qi (2010) and remove the observations with the beginning-of-the-month price less than \$5.[11] We then re-estimate Regression

[11] We also follow Kim and Qi (2010) to create a dummy variable for low-priced stocks and include it in regression Equation (4). Doing so barely changes our results.

(4) with these observations removed from the sample. For the negative earnings shocks, we create Ogneva's (2012) earnings surprise measure, *SURP_TS*, remove the observations with the bottom 30% of *SURP_TS* (i.e., the most negative earnings surprise), and re-estimate Regression (4) with this reduced sample. The results in Panels A of Table 10 shows that AQ continues to load negatively, with an order of magnitude comparable to those of the main results reported in Tables 3 and 6. Thus, our results are unlikely to be driven by low-priced stocks or negative earnings surprise.

[Table 10 about here.]

One common feature shared by low-priced firms and firms that experience negative earnings shocks is that they tend to be smaller firms. Brousseau and Gu (2013) show that the FLOS results, if any, are completely driven by smallest firms in the sample. Earlier in our portfolio sorting results, we showed that value-weighted alpha spreads in the AQ decile portfolios are generally smaller than their equal-weighted counterparts. Thus, size can be a driving factor for our results. To address this concern, in Panel A of Table 10 we also provide evidence that our results are not driven by small firms. There, we remove observations at the bottom 30 percentiles of the beginning-of-the-month market capitalization. We again observe negative coefficients for both *AQ_annual* and *AQ_qtr* in return regressions, with a similar magnitude to those of the main results reported earlier.

5.2 Robustness of the AQ Effect to the Accrual Anomaly

A large literature, pioneered by Sloan (1996), documents the existence of an accrual anomaly where large accruals lead to lower future returns. Fama and French (2008) confirm that the accrual anomaly is among the most persistent asset pricing anomalies. Xie (2001) finds that the accrual anomaly is largely concentrated in abnormal accruals. Given the mean reverting nature of accruals over the long run, a higher level of accruals implies higher accrual volatility and accrual volatility-related measures such as AQ. Therefore, the negative relationship between AQ and future returns documented earlier may merely be a rediscovery of the well-known accrual anomaly phenomenon. We now show that this is not the case.

Following the accrual anomaly literature (e.g., Sloan 1996; Xie 2001), we use the value of abnormal accruals (i.e., signed accruals, *AbAcc*) estimated earlier in Equation (3) to denote the level of accruals. We augment Equation (4) with *AbACC* and present the results in Panel B of Table 10. The results there first confirm that the accrual anomaly holds after controlling for AQ in our sample: Accruals are negatively related to future returns over one-month to five-year horizons in most cases. Importantly, the regression results in Panel B show that the accrual anomaly and the AQ effect exist side by side: All of the coefficients on *AQ_annual* and *AQ_qtr* remain significantly negative from one-month to five-year returns. In sum, the AQ effect is distinct from the accrual anomaly.

5.3 Information Uncertainty and Accruals Quality

We now relate the AQ effect to the recent literature on information uncertainty, which reports that future returns are negatively related to information uncertainty proxies. In particular, these information uncertainty measures include idiosyncratic return volatility (Ang et al. 2006), cash flow volatility (Huang 2009), and analyst forecast dispersion (Diether, Malloy and Scherbina 2002). These phenomena can be collectively referred to as the "information uncertainty" effect as in Zhang (2006).

Information uncertainty, in general, can be viewed as an attribute of publicly available information that reflects the degree of information asymmetry between the firm insiders (such as managers) and outside investors and other market participants. Arguably, earnings is among the most important performance measures used by market participants such as investors, analysts, senior executives, and board of directors. Accruals add noise to the earnings stream by imparting transitory components in the process of converting cash flows to earnings (Leuz et al. 2003; Schipper and Vincent 2003). Chen et al. (2012), for instance, show that managerial discretion-induced information quality such as accruals volatility drives the trend in idiosyncratic return volatility over the past four decades. Since accruals quality indicates the extent of uncertainty of the firm's financial information, it follows that AQ is related to information uncertainty.

We first examine the correlation between AQ and information uncertainty proxies used in the literature. We define idiosyncratic return volatility (*IRV*) as per Ang et al. (2006); and cash flow volatility (*CFV*) either as the standard deviation of cash flow to assets over the past five years to match *AQ_annual*, or the standard deviation of cash flow to sales over the past 16 quarters to match *AQ_qtr*. For ease of comparison with respect to economic significance, we transform all of these variables into deciles cross-sectionally. Over our sample period, the times-series mean of cross-sectional correlations between *AQ_annual* decile and, respectively, *IRV* and *CFV* deciles are 0.42 and 0.74; and those between *AQ_qtr* decile and, respectively, *IRV* and *CFV* deciles are 0.28 and 0.82. These correlations indicate that AQ is indeed highly correlated with information uncertainty.[12]

We then augment regression Equation (4) with information uncertainty proxies. In Panel A of Table 11, we use *AQ_annual* decile alongside i) *IRV* decile, ii) *CFV* decile, and iii) both *IRV* and *CFV* decile. In cases i) and ii), we note that while *AQ_annual* decile remains significant in predicting one month to five year returns, its economic significance is markedly reduced. For example, earlier in Table 9 the coefficient estimate of *AQ_annual* decile was −0.04 for one-month return and −0.19 for six-month return; and with the addition of *IRV* decile, these numbers reduce to −0.03 and −0.15 respectively. In untabulated results, we can report that these reductions are statistically significant. Adding *CFV* to the regression induces similar reductions. In case iii) when we add both *IRV* and *CFV* deciles, the coefficient estimate of *AQ_annual* decile is about halved over one-month to five-year horizons.

[Table 11 about here.]

Panel B of Table 11 replicates the results in Panel A but with *AQ_qtr*. Compared with Table 9, the coefficient estimate of *AQ_qtr* is only slightly reduced with the addition of *IRV* as an regressor.

[12]We also consider analyst forecast dispersion of earnings as per Diether et al. (2002) using data from I/B/E/S (available only from 1982). The correlation between forecast dispersion decile and *AQ_annual* decile is 0.16, and between forecast dispersion decile and *AQ_qtr* decile is 0.22. These correlations are lower than AQ's correlations with *IRV* and *CFV*. Nonetheless, our results remain robust to using forecast dispersion as the information uncertainty proxy.

The smaller reduction of the AQ coefficient relative to the case of *AQ_annual* is likely due to the fact that *AQ_qtr* is less correlated with *IRV* than is *AQ_annual*. *AQ_qtr*, however, is even more highly correlated with *CFV* than is *AQ_annual*. It turns out that when *CFV* decile is added to the regression, the significance of *AQ_qtr* decile is subsumed, as shown in the remainder of Panel B. Collectively, the results in Table 11 indicate that commonly used information uncertainty proxies can either greatly reduce or completely subsume the pricing effect of AQ. The evidence suggests that the pricing effect of AQ is part of the information uncertainty phenomenon.

6 Conclusions

Recent literature debates whether an accruals quality mimicking portfolio is a priced risk factor. A number of studies argue that investors are compensated with returns for holding risk reflected in AQ, the standard deviation of residuals from current accruals regressed on cash flows (Francis, LaFond, Olsson, and Schipper 2005; Kim and Qi 2010; Ogneva 2012). The validity of these findings and their methodologies are questioned by studies such as Core, Guay, and Verdi (2008) and Du (2011), who show that an accruals quality mimicking portfolio is not a risk factor. Accordingly, we examine the relation between future returns and accruals quality. We construct look-ahead-bias free measures of AQ to ensure return-predictability of these measures, and document strong and positive return premiums associated with accruals quality over both short- and long-terms. Firms with higher accruals quality (lower AQ measure) generate higher returns in the future.

The return premiums associated with accruals quality undergo extensive robustness checks in our study. In decile portfolios that rank on AQ, a hedge portfolio that goes long in the lowest decile and short in the highest decile generates an annualized, risk-adjusted return in the order of 4–12% from one-month to five-year horizons. The return premiums associated with AQ are: i) robust to a battery of return-informative variables, including the Fama-French three factors, price momentum, illiquidity, earnings momentum, and earnings yield; ii) economically significant to be ignored; and iii) robust to a number of accruals quality measures estimated from both annual and quarterly accounting data.

Our findings add to the recent literature that historical information uncertainty, as proxied by measures such as idiosyncratic return volatility and cash flow volatility, negatively predicts future returns. AQ measures firms' financial reporting quality and therefore reflects firms' information asymmetry. The return premiums to AQ are consistent with the information uncertainty literature; and we further show that these return premiums may be subsumed by a combination of information uncertainty measures.

Abs(*AbAcc*)	1,191,404	0.16	0.31	0.00	0.06	2.02
1-month return (%)	2,402,115	1.00	14.79	-38.89	0.00	57.35
6-month return (%)	2,375,501	6.47	38.41	-75.00	2.97	164.00
1-year return (%)	2,348,931	13.80	57.80	-87.57	6.45	267.50
2-year return (%)	2,294,974	28.30	87.40	-95.65	13.51	426.70
5-year return (%)	2,120,882	75.83	175.65	-99.03	32.18	954.97

The data covers all NYSE, NASDAQ, and AMEX-listed firms from COMPUSTAT from January 1970 to December 2012 for all variables except the quarterly measures of *AQ_qtr*, *AQ_qtr_A*, *AQ_qtr_Ind*, *AQ_no4q*, and Abs(*AbAcc*), whose coverage are from January 1980 to December 2012. The AQ measures using annual data are: *AQ_FLOS* (AQ measure following FLOS), and *AQ_annual* (a modified, out-of-sample measure of AQ). The AQ measures using quarterly data are: *AQ_qtr* (out-of-sample measure of AQ using sales as the scalar), *AQ_qtr_A* (out-of-sample measure of AQ using total assets as the scalar), *AQ_qtr_Ind* (out-of-sample measure of AQ using total assets as the scalar, and all quarterly data items used in the estimation are industry-mean-adjusted), *AQ_no4q* (similar as *AQ_qtr* except that all fourth-quarter observations are removed), and Abs(*AbAcc*) (absolute level of abnormal accruals). All returns are delisting-adjusted. All variables are winsorized at the 1st and 99th percentiles over the full sample.

Table 2: **The Time-Series Mean of Cross-Sectional Correlations of Variables**

	AQ_FLOS	*AQ_annual*	*AQ_qtr*	*AQ_qtr_A*	*AQ_qtr_Ind*	*AQ_no4q*	Abs(*AbAcc*)	Ret	Ret6	Ret12	Ret24	Ret60

This table presents the time-series mean of the cross-sectional correlations of the variables. The *AQ* measures using annual data are: *AQ_FLOS* (*AQ* measure following FLOS), and *AQ_annual* (a modified, out-of-sample measure of *AQ*). The *AQ* measures using quarterly data are: *AQ_qtr* (out-of-sample measure of *AQ* using sales as the scalar), *AQ_qtr_A* (out-of-sample measure of *AQ* using total assets as the scalar), *AQ_qtr_Ind* (out-of-sample measure of *AQ* using total assets as the scalar, and all quarterly data items used in the estimation are industry-mean-adjusted), *AQ_no4q* (similar to *AQ_qtr* except that all fourth-quarter observations are removed), and Abs(*AbAcc*) (absolute level of abnormal accruals). All correlations are significant at the 5% level.

	[4.46]***	[-0.55]	[-0.1]	[4.9]***	[1.16]	[-6.21]***

This table presents coefficient estimates from the Fama and MacBeth (1973) cross-sectional regressions of returns (multiplied by 100) on *AQ_FLOS* (Panel A) and *AQ_annual* (Panel B). The control variables are: *beta* (beta from CAPM estimated with returns of the past 60 months), ln(*ME*) (logarithm of lagged monthly equity), ln(*BEME*) (logarithm of the book-to-market ratio), and *PMOM* (price momentum, past twelve-month return). The estimates are the averages of the time-series coefficients of the monthly regression slopes for January 1970 to December 2012. Numbers in square brackets are *t*-statistics. All of the *t*-statistics are adjusted for the Newey and West (1987) autocorrelation with the number of lags corresponding to the degree of overlapping in returns; i.e., the adjusted serial lags are 5 for 6-month returns upto 59 for 5-year returns. ***, **, and * indicate significance at the 1%, 5% and 10% levels, respectively.

Table 4: **Robustness of the Pricing of the Annual AQ Measures**

Panels A and B present the coefficient estimates of *AQ_FLOS* and *AQ_annual* from the Fama and MacBeth (1973) cross-sectional regressions of returns (multiplied by 100) over different subperiods. The control variables in Panels A and B are Fama-French four-factor variables of beta, size (ln(ME)), book-to-market (ln($BEME$)), and price momentum ($PMOM$); the results on the control variables are omitted for brevity. In Panel C, the additional control variables are SUE (standardized unexpected earnings in Chan et al. (1996)), EY (earnings yield, earnings to beginning-of-the-month price), and $ILLIQ$ (the illiquidity measure in Amihud (2002)). The estimates are the averages of the time-series coefficients of the monthly regression slopes. Numbers in square brackets are t-statistics. All of the t-statistics are adjusted for the Newey and West (1987) autocorrelation with the number of lags corresponding to the degree of overlapping in returns; i.e., the adjusted serial lags are 5 for 6-month returns upto 59 for 5-year returns. ***, **, and * indicate significance at the 1%, 5% and 10% levels, respectively.

This table reports alphas of the 10 portfolios formed with increasing *AQ_annual* breakpoints. The breakpoints are determined by the ranked values of *AQ_annual* of all stocks in the sample and are updated month by month. alpha is Jensen's alpha relative to Fama-French four-factors of market, SMB, HML and momentum, calculated from a system of equations consisting of the 10 portfolios. "D1−D10" is the spread between decile 1 and decile 10, and "D1:5−D6:10" is the spread between the mean of deciles 1–5 and the mean of deciles 6–10. Numbers in square brackets are robust *t*-statistics. All of the *t*-statistics are adjusted for the Newey and West (1987) autocorrelation with the number of lags corresponding to the degree of overlapping in returns; i.e., the adjusted serial lags are 5 for 6-month returns upto 59 for 5-year returns. ***, **, and * indicate significance at the 1%, 5% and 10% levels, respectively.

This table presents coefficient estimates from the Fama and MacBeth (1973) cross-sectional regressions of returns (multiplied by 100) on *AQ_qtr*. The control variables are: *beta* (beta from CAPM estimated with returns of the past 60 months), ln(*ME*) (logarithm of lagged monthly equity), ln(*BEME*) (logarithm of the book-to-market ratio), *PMOM* (price momentum, past twelve-month return), *SUE* (standardized unexpected earnings), *EY* (earnings yield, earnings to beginning-of-the-month price), and *ILLIQ* (the illiquidity measure in Amihud (2002)). The estimates are the averages of the time-series coefficients of the monthly regression slopes for January 1980 to December 2012. Numbers in square brackets are *t*-statistics. All of the *t*-statistics are adjusted for the Newey and West (1987) autocorrelation with the number of lags corresponding to the degree of overlapping in returns; i.e., the adjusted serial lags are 5 for 6-month returns upto 59 for 5-year returns. ***, **, and * indicate significance at the 1%, 5% and 10% levels, respectively.

Table 7: Robustness of the Pricing of Accruals Quality to Alternative Quarterly AQ Measures: Coefficient Estimate of AQ in Cross-Sectional Return Regressions

Return	*AQ_qtr_A*	*AQ_qtr_Ind*	*AQ_no4q*	Abs(*AbAcc*)

	[-3.00]***	[-2.72]***	[-5.22]***	[-6.33]***
2-year	-175.96	-178.64	-14.62	-16.42
	[-6.19]***	[-5.73]***	[-6.94]***	[-8.45]***
5-year	-559.05	-605.95	-36.29	-36.34
	[-5.79]***	[-4.54]***	[-8.38]***	[-8.69]***

This table reports the coefficient estimates of alternative quarterly *AQ* measures from the Fama and MacBeth (1973) cross-sectional regressions of returns (multiplied by 100) over 1980–2012. The control variables are Fama-French four-factor variables of beta, size (ln(*ME*)), book-to-market (ln(*BEME*)), and price momentum (*PMOM*); the results on the control variables are omitted for brevity. The alternative AQ measures using quarterly data are: *AQ_qtr_A* (out-of-sample measure of *AQ* using total assets as the scalar), *AQ_qtr_Ind* (out-of-sample measure of AQ using total assets as the scalar, and all quarterly data items used in the estimation are industry-mean-adjusted), *AQ_no4q* (similar as *AQ_qtr* except that all fourth-quarter observations are removed), and Abs(*AbAcc*) (absolute level of abnormal accruals). Numbers in square brackets are robust *t*-statistics. ***, **, and * indicate significance at the 1%, 5% and 10% levels, respectively.

This table reports alphas of the 10 portfolios formed with increasing *AQ_qtr* breakpoints. The breakpoints are determined by the ranked values of *AQ_qtr* of all stocks in the sample and are updated month by month. alpha is Jensen's alpha relative to Fama-French four-factors of market, SMB, HML and momentum, calculated from a system of equations consisting of the 10 portfolios. "D1−D10" is the spread between decile 1 and decile 10, and "D1:5−D6:10" is the spread between the mean of deciles 1–5 and the mean of deciles 6–10. Numbers in square brackets are robust *t*-statistics. All of the *t*-statistics are adjusted for the Newey and West (1987) autocorrelation with the number of lags corresponding to the degree of overlapping in returns; i.e., the adjusted serial lags are 5 for 6-month returns upto 59 for 5-year returns. ***, **, and * indicate significance at the 1%, 5% and 10% levels, respectively.

Table 9: **Economic Significance of the Pricing of Accruals Quality**

5-year	-1.96	-39.15	-3.74	-74.87
	[-5.03]***		[-6.27]***	

This table presents coefficient estimates of *AQ_annual* and *AQ_qtr* deciles in cross-sectional return regressions. Each month we transform *AQ_annual* and *AQ_qtr* into decile ranks, and run return regressions of *AQ_annual* decile or *AQ_qtr* decile with the control variables of Fama-French four-factor variables of beta, size ($\ln(ME)$), book-to-market ($\ln(BEME)$), and price momentum (*PMOM*). The results on the control variables are omitted for brevity. The column "Annualized impact of 1 decile change (bps)" is the annualized impact of one decile change, expressed in basis points of return. Numbers in square brackets are robust t-statistics. ***, **, and * indicate significance at the 1%, 5% and 10% levels, respectively.

This table reports the coefficient estimates of *AQ* and information uncertainty measures from the Fama and MacBeth (1973) cross-sectional regressions of returns (multiplied by 100). In each model, we regress returns on an *AQ* proxy (either *AQ_annual* or *AQ_qtr*), one or two information uncertainty proxies, and the control variables. Information uncertainty proxies and *AQ* proxies are all expressed in monthly decile rank for ease of comparison. In model (1), we include the information uncertainty proxy of idiosyncratic volatility (*IRV*, calculated as per Ang et al. (2006)). In model (2), we include the information uncertainty proxy of cash flow volatility (*CFV*, standard deviation of cash flow to assets over the past five years for *AQ_annual*, and standard deviation of cash flow to sales over the past 16 quarters for *AQ_qtr*). In model (3), we include both *IRV* and *CFV*. The control variables are Fama-French four-factor variables of beta, size ($\ln(ME)$), book-to-market ($\ln(BEME)$), and price momentum (*PMOM*); the results on the control variables are omitted for brevity. Numbers in square brackets are robust t-statistics. ***, **, and * indicate significance at the 1%, 5% and 10% levels, respectively.

□ □ □ □ □ □ The 52-Week High and the Anchoring Bias of Chinese Investors and Analysts

Investors and analysts in the Chinese stock market anchor on a stock's 52-week high price when assessing information. Investors under-react to positive (negative) earnings surprises when a stock's price is near (far from) the 52-week high, generating positive (negative) price drift after earnings announcements. Analysts under-react to positive (negative) news and inadequately revise forecasts upward (downward) when a stock is near (far from) its 52-week high, generating positive (negative) price drift after the revised forecast is announced. No price drift follows announcements of earnings or of analysts' revised forecasts among stocks with unanchored prices. These findings suggest that post earnings announcement drift and post analyst forecast revision drift in the Chinese stock market are attributable to anchoring bias.

Keywords: Anchoring; 52-week high; Post earnings announcement drift; Post analyst forecast revision drift; Chinese stock market

JEL Descriptors: G12, G14, M41

Introduction

Post earnings announcement drift (PEAD) is the tendency for stock prices to move in the direction of unexpected earnings even after they are announced publicly. Post analyst forecast revision drift (PAFRD) is the tendency for prices to move in the direction of analysts' revised forecasts even after they are announced publicly. PEAD and PAFRD have been documented in various stock markets during different periods (Ball and Brown 1968; Bernard and Thomas 1989; Chan, Jegadeesh and Lakonishok 1996; Truong 2011). It is difficult to explain these phenomena in a manner consistent with rational pricing, so prior studies incorporate psychology into formal models to explain these and other anomalies. This study examines how one type of robust and measurable psychological bias—anchoring—generates PEAD and PAFRD in the Chinese stock market. Previous studies also suggest psychological bias is more severe in more uncertain environments (Daniel, Hirshleifer, and Subrahmanyam 1998; Hirshleifer 2001; Zhang 2006a, 2006b); Great uncertainty characterizes China's young and developing stock market, rendering it an excellent setting for this study.

Anchoring is a type of cognitive bias. It refers to people's tendency to rely on salient but irrelevant information (the anchor) when making decisions under uncertainty. Kahneman (2011, p. 119) describes anchoring as "…one of the most reliable and robust results of experimental psychology". In equities markets, 52-week high stock prices are salient but irrelevant information. Financial websites and newspapers almost universally report 52-week highs alongside current prices. Their prominence and ubiquity (i.e., salience) might convince investors to use them when formulating beliefs about a security's fundamental value, and previous studies suggest this is indeed the case. For example, George and Hwang (2004) consider an investment strategy, which involves buying the quintile of stocks with prices near 52-week highs and shorting stocks with prices distant from them, that ranks stocks by the nearness of their current prices to the 52-week high. Profits from this strategy in the U.S.

market are significant and even dominate profits generated by the return momentum strategies of Jegadeesh and Titman (1993). Liu, Liu, and Ma (2010) extend George and Hwang's strategy to international markets and find that its profitability is prevalent. In another study of the U.S. market, Li and Yu (2011) reveal a strong systematic element to this relation in a time series: Dow Index returns are predictable based on its proximity to its 52-week high. These studies present their findings as consistent with investors' anchoring on 52-week high. Investors are reluctant to push prices higher for stocks near the 52-week highs and to push them downward if far from the 52-week high.

George, Hwang, and Li (2014) examine the role of anchoring on the 52-week high in generating PEAD in the U.S. Their proposition is straightforward as follows: investors have difficulty estimating the dollar value of an earnings surprise when assessing whether securities are fairly priced; to avoid this difficulty, they might simply ask whether earnings information is already incorporated into the current price and assess whether the price has room to run. The 52-week high is a ready metric of the highest price others have recently paid for the stock. Therefore, if a current price is near that high, investors might infer that a positive earnings surprise is embodied in the current price and decide not to bid it higher. These investors' collective decisions would restrain the price reaction to positive earnings surprises for stocks priced near their 52-week highs. If current price is distant from the 52-week high and the surprise is negative, investors might infer that price already reflects the negative earnings surprise. Investors' collective behaviors restrain price reaction to the negative earnings surprises of stocks priced far from their 52-week highs. Consistent with their argument, George, Hwang, and Li (2014) find that PEAD in the U.S. market is attributable entirely to anchoring on the 52-week high. They, further, find that price reactions to extreme earnings surprises are more muted when the anchoring effect is stronger.

Following George, Hwang, and Li (2014), we examine the role of anchoring on the 52-week high in generating PEAD in the Chinese stock market. We find that in the absence of the anchoring effect, the difference between price drift during the 120 days after announcements of the top 20% most positive earnings surprises and price drift following announcements of the bottom 20% most negative earnings surprises is −0.61% (*t-statistic* = −0.29). In contrast, the difference is 12.76% (*t-statistic* = 9.40) when 52-week high anchoring is strongest. Mirroring results for the U.S., PEAD in the Chinese market is entirely attributable to anchoring. Furthermore, we find that the 120 days' PEAD unconditional on anchoring is 6.14%, which is approximately half of PEAD when the anchoring effect is the strongest. This result suggests that the profit from exploiting PEAD doubles by conditioning on stocks anchored to their 52-week highs.

Moreover, we find that among stocks with positive earnings surprises price reactions are less positive when the pre-announcement stock price is nearer its 52-week high (i.e., the anchoring effect is stronger). A corresponding pattern exists for negative earnings surprises. This finding directly demonstrates that investors' under-reaction to earnings news is influenced by anchoring, confirming our previous results regarding PEAD. Finally, we find that historical stock return is irrelevant to PEAD because they are not saliently presented as 52-week highs, a finding consistent with U.S. results in George, Hwang, and Li (2014).

Kahneman (2011, p.124) observes that the anchoring bias afflicts professionals alongside novices even though financial analysts are considered experts. Cen, Hilary, and Wei (2013) show that analysts anchor on industry norms (an industry's historically stable range of earnings per share (EPS)) when forecasting earnings. Since the 52-week high is more readily observable than industry EPS norms, analysts might also anchor on it when forecasting, in turn engendering PAFRD. Specifically, if a stock price is near its 52-week high, analysts might discount positive information, hesitant to believe its price should overshoot its52-week high. On the other hand, if the stock price is distant from its 52-week high, analysts might discount negative information because they are hesitant to believe its price can fall even lower.

Issuing revised forecasts is among the most important ways in which analysts update new information. They revise forecasts upward (downward) upon receiving new positive (negative) information. Anchoring on the 52-week high when assessing new information, as we hypothesize, their upward (downward) revisions will be more inadequate when stock price is nearer (further from) the 52-week high. If investors rely on analysts' revisions to make investment decisions, analysts' anchoring-induced under-reaction will be reflected in stock price, resulting in PAFRD. Hence, if our hypothesis is correct, PAFRD following upwardly (downwardly) revised forecasts should be more (negative) positive when price is nearer (farther from) the 52-week high.

This outcome is indeed what we find. We first confirm that PAFRD exists in the Chinese stock market. More importantly, we find that PAFRD in the Chinese market, similar to PEAD, is attributable entirely to anchoring. In the absence of the 52-week high anchoring effect, the difference between price drift during the 120 days after announcements of extremely positive revised forecasts and price drift following announcements of extremely negative revisions is −2.09% (*t-statistic* = −0.70). On the other hand, the difference is 11.16% (*t-statistic* = 5.48) when the anchoring effect is strongest. In comparison, the 120 days' PAFRD unconditioned on anchoring is 5.63%. Hence, the profit from exploiting PAFRD also almost doubles by conditioning on stocks anchored to their 52-week highs. Finally, we find that historical stock returns are irrelevant to PAFRD.

We also examine analysts' forecast errors and subsequent forecast revisions to test whether anchoring prompts analysts to under-react to new information when revising forecasts. If analysts anchor on the 52-week high when assessing new information, forecast errors and subsequent forecast revisions should exhibit distinctive patterns. When analysts receive positive news and revise forecasts upward, the closer the price is to its 52-week high, the less optimistic will be their current forecasts. The outcome is a greater number of negative forecast errors (defined as analyst forecasts minus actual EPS) and more positive subsequent forecast revisions. On the other hand, when analysts receive negative news and revise forecasts downward, the farther the price is from the 52-week high, the less pessimistic their current forecasts will be. The results are a greater number of positive forecast errors and more negative subsequent forecast revisions. We indeed find these patterns, suggesting that analysts anchor on the 52-week high in their decisions, supporting our finding concerning PAFRD.

We find no evidence that investors anchor on the 52-week high when reacting to announcements of analysts' revised forecasts. This might be because retail investors own more than 90% of the tradable shares on the Chinese stock market (Wang, Qian, and Chee, 2005), and retail investors might heed financial experts without second guessing.

China has become one of the fastest growing economies in the world and China's capital market has become central to its economy: Its capitalization exceeded 50% of China's GDP in 2000 (MacNeil 2002). This significance to one of the world's fastest-growing economies makes it important to decipher what promotes or deters efficient transmission of information in this market. This paper demonstrates that psychology is one important factor.

Further, China's stock market is relatively young and features greater uncertainty than mature markets. Since investors and analysts are more susceptible to psychological bias amid uncertainty (Daniel, Hirshleifer, and Subrahmanyam 1998; Hirshleifer 2001), China provides an ideal setting to test psychological bias in equity markets. This paper presents empirical evidence for the broad theme in behavioral finance that psychological biases systematically affect decision-making in capital markets.

2. Anchoring and PEAD

This section examines the role of anchoring on the 52-week high in generating PEAD in the Chinese market. Section 2.1 describes the data and methodology. Section 2.2 tests how anchoring influences PEAD. Section 2.3 examines how anchoring affects investors' reactions to earnings announcements.

2.1 Data and methodology

All data used in this section come from CSMAR. Its records of quarterly earnings begin in 2003, our sample spans 2003 to 2012. Fiscal quarters of all sampled stocks end in March, June, September, and December. For each fiscal quarter, we sorted stocks independently on the basis of their standardized unexpected earnings (*SUE*) and 52-week high anchoring measures (*PRC*) based on their earnings announcements for that quarter. *SUE* is calculated as $(e_q - e_{q-4})/\sigma_q$, where e_q is current-quarter EPS, e_{q-4} is EPS for the same fiscal quarter the previous year, and σ_q is the standard deviation of $(e_q - e_{q-4})$ over the prior eight fiscal quarters (we require at least four prior quarters of data).

We sorted stocks into quintiles based on *SUE* (SUE1–SUE5). SUE1 and SUE2 include stocks with extremely and moderately negative earnings surprises, respectively. These two groups are denoted SUE_{BB} and SUE_B. SUE5 and SUE4 include stocks with extremely and moderately positive earnings surprises, respectively. They are denoted SUE_{GG} and SUE_G. SUE3 includes stocks with the lowest magnitude of SUE. It is the no-earnings-surprises group.

PRC, our 52-week high anchoring measure, is calculated as the stock price (adjusted for splits and dividends) 10 days before the date of current quarterly earnings are announced, divided by the highest stock price during the past 52 weeks. The 20% of stocks with the lowest (highest) *PRC* occupy the group denoted LPRC (HPRC); the rest are in the group denoted MPRC. Combinations of the four earnings-surprise groups (SUE_{GG}, SUE_G, SUE_B,

SUE_{BB}) and the three PRC groups (LPRC, MPRC, HPRC) produce 12 groups. As explained later, stocks in the no-earnings-surprises group (SUE3) are used as benchmarks to calculate PEAD for stocks in groups with earnings surprises.

We are interested in whether anchoring on the 52-week high affects PEAD, given the sign and magnitude of announced earnings surprises. Therefore, we examine how *PEAD* changes with *PRC* within each of four earnings-surprises groups. If investors anchor when assessing earnings surprises, their under-reaction to positive (negative) surprises will be greater when stock price is nearer (farther from) its 52-week high, prompting greater positive (negative) price drift. Therefore, we expect *PEAD* to increase with *PRC* in each of the four earnings-surprises groups.

PEAD is measured as an abnormal return occurring two to 120 days after an earnings announcement. Care is warranted in defining abnormal return to capture the impact of anchoring on *PEAD*. George and Hwang (2004) show that stocks with higher *PRC* have higher future returns unconditioned on earnings surprises, indicating that even if investors do *not* anchor on 52-week highs when reacting to earnings news higher (lower) *PRC* stocks might still have more positive (negative) price drift. This pure anchoring effect, which is an effect of anchoring bias on price drift of *all* stocks irrespective of earnings surprises, must be controlled. We do so using stocks in the no-earnings-surprises group (SUE3) as benchmarks. The procedures are as follows.

Each fiscal quarter, for each stock *i* in the 12 groups, we choose one matching stock *im* from SUE3 using the following criteria: *PRC* of stock *im* is the closest to that of stock *i* among all stocks in its PRC group (LPRC, MPRC, and HPRC). Then *PEAD* of *i* is calculated using the formula:

$$PEAD_{i,} = Exret\,(2,\,120)_{it} - Exret\,(2{,}120)_{im},\qquad (1)$$

where *Exret* (*2, 120*)$_{i}$ is the size-adjusted and book-to-market-adjusted buy-and-hold return of stock *i* occurring two to 120 days after its earnings announcement. This return is calculated by subtracting the mean buy-and-hold return of an equal-weighted portfolio of stocks in the same 5×5 size and book-to-market group over the same holding period. The 5×5 independent sorting is performed at the beginning of the year.

Consider two stocks, *i* and *im*, which have the same high magnitude of *PRC*. The existence of the pure anchoring effect suggests identical positive price drift for both stocks. Subtracting the price drift of stock *im*, the pure anchoring effect is removed from price drift of stock *i*. Hence, $PEAD_i$ calculated using formula (1), emerges as the abnormal return adjusted by size, book-to-market, and anchoring. The relation between *PEAD* and *PRC* will reflect how *PRC* affects investors' under-reaction to earnings news.

Table 1 reports the summary statistics of stocks with earnings surprises (treatment stocks), together with the corresponding characteristics of their benchmark stocks from the no-surprises group. The statistics for benchmark stocks are presented in *italic* in Table 1. As the table shows, for treatment and benchmark stocks, average SUE values within each earnings-surprises group are little-affected by stocks' PRC ranks. The finding also is true of PRC values: They are insensitive to SUE rankings. This means that neither ranking is merely identifying extremes by the other ranking criterion. Independent variation in both criteria is available in the sample to explain returns if indeed such relations exist. Further, *PRCs* of the treatment stocks are almost the same as those of their benchmark stocks, which reinforces the validity of using these benchmark stocks to remove the pure anchoring effect.

2.2 Results on anchoring bias and PEAD

The results are reported in Panel A of Table 2. We first confirm the existence of PEAD in our sample. The first row labelled as 'ALL' reports the average *PEAD* in each of the four SUE groups. Average *PEAD* is 4.26% among stocks with extremely positive earnings surprises (SUE_{GG}) and it's -1.88% among stocks with extremely negative earnings surprises (SUE_{BB}). The difference is 6.14% and statistically significant (*t-statistic* = 8.96). Test statistic of the difference is based on standard errors clustered by stock and earnings announcement date.

We then report the average *PEAD* of stocks in each of the 12 groups stratified by SUE and PRC. As shown, within SUE_{GG}, average *PEAD* is positive in all three PRC groups. More importantly, it increases from 2.99% in LPRC to 7.97% in HPRC. The difference is 4.98% (*t-statistic* = 2.85). Similar patterns appear within SUE_{G}. These results suggest that investors are more likely to under-react to positive earnings surprises if stock price is nearer its 52-week high, generating more positive *PEAD*. Within SUE_{BB}, average *PEAD* is - 4.79% in LPRC and 3.60% in HPRC. Hence, the returns following extremely negative earnings surprise are more negative for stocks whose prices are farther from 52-week high; and are less negative (they are actually positive) for stocks whose prices are near 52-week high. Similar patterns appear within SUE_{B}. These results suggest that investors are more likely to under-react to negative earnings surprises if stock price is farther from its 52-week high, generating more negative *PEAD*.

Earnings surprises of stocks in the lower-right and upper-left corners are most vulnerable to anchoring bias. The difference in *PEAD* between these opposed corners represents price drift after earnings announcements when anchoring bias is strongest. The difference of 12.76% (= 7.97% + 4.79%) is statistically significant (*t-statistic* = 9.40). On the other hand, earnings surprises of stocks in the upper-right and lower-left corners are least vulnerable to anchoring bias, so the difference in *PEAD* represents price drift after earnings announcements when anchoring bias is absent. The difference of −0.61% (= 2.99% − 3.60%) is statistically insignificant (*t-statistic* = −0.29). This suggests there is almost no price drift after earnings surprises of unanchored stocks. In other words, the under-reaction to information contained in earnings surprises typified by PEAD is attributable entirely to anchored stocks. This conclusion reinforces that of George, Hwang, and Li (2014) in their investigation of PEAD in the U.S. market. Further, compared to the unconditional *PEAD* at 6.14%, this result suggests that the profitability of exploiting PEAD doubles by conditioning on the 20% most anchored stocks. .

In Panel A of Table 2, *PEAD* increases with *PRC* within each of the four earnings-surprises groups. Now we test whether this positive relationship is confirmed by regression, which allows for controlling other variables. The regression is specified as:

$$PEAD_i = b_0 + b_1\, SUE_i + b_2\, PRC_i + b_j\, controls_j + \varepsilon_i \tag{2}$$

PEAD, *SUE*, and *PRC* are defined in Section 2.1. We control for firm size (*LOGMV*) and book-to-market ratio (*LOGBM*) that are calculated at the beginning of the year wherein earnings are announced; both are transformed into logarithmic forms. We include time-fixed effects based on fiscal quarter.

We run regression (2) on stocks with positive earnings surprises (stocks in SUE_{GG} and SUE_G) and with negative earnings surprises (stocks in SUE_{BB} and SUE_B). Test statistics are based on standard errors clustered by firm and earnings announcement date. Results appear in Panel B of Table 2. Among sampled stocks with positive earnings surprises, the coefficient on *PRC* is positive and significant (*t-statistic* = 3.06). Among sampled stocks with negative earnings surprises, the coefficient of *PRC* is also positive and significant (*t-statistic* = 5.20). These results suggest that *PEAD* increases with *PRC* for a given *SUE*, a finding consistent with the stratified results in Panel A.

Panel C of Table 2 includes previous stock returns (*RETMOM*) in the regression to test whether they affect PEAD. *RETMOM* is calculated as the six months' buy-and-hold return ending 10 days before the announcement date. Among stocks with both positive and negative earnings surprises, coefficients on *RETMOM* are not statistically significant (*t-statistic* =0.70

for positive surprises, and *t-statistic* = −0.86 for negative surprises). This result suggests *PEAD* is unaffected by historical stock returns. The finding is consistent with results for the U.S. market that indicate investors do not anchor on historical return when assessing earnings surprises (George, Hwang, and Li 2014).

2.3 Returns around current earnings announcement

Besides PEAD, George, Hwang, and Li (2014) examine stock returns during the three days surrounding current earnings announcements. They argue that if the cause of PEAD is investors' anchoring their beliefs on the 52-week high when extreme earnings are announced, then daily returns surrounding current earnings announcements should exhibit specific patterns consistent with anchoring. For positive earnings surprises, price reactions should become more muted the closer stock price is to its 52-week high. For negative earnings surprises, price reaction should be more muted the further the price is from its 52-week high. Following George, Hwang, and Li (2014), we test whether earnings announcement returns exhibit these patterns in China. Earnings announcement returns are calculated as the size-adjusted and book-to-market-adjusted buy-and-hold stock return during the three days around earnings announcements. Results are reported in Table 3.

Panel A of Table 3 reports average earnings announcement returns in each of the 12 groups stratified by *SUE* and *PRC*. Within SUE_{GG} and SUE_G, differences in the average earnings announcement returns between HPRC and LPRC are −0.56% and −0.36% respectively (*t-statistic* = −2.50 for SUE_{GG} and −1.85 for SUE_G). Within SUE_{BB} and SUE_B, the corresponding differences are −0.19% and −0.54% (*t-statistic* = −0.87 for SUE_{BB} = −2.46 for SUE_B). These results suggest that price reaction generally is less affirmative (less negative) for positive (negative) earnings surprises when price is nearer (farther from) its 52-week high. This finding reinforces the patterns specified above.

Next, we use regression to examine the relation between *PRC* and earnings announcement returns. We again employ regression (2), except that the dependent variable is earnings announcement returns. Results appear in Panel B of Table 3. Among stocks with positive and negative earnings surprises, coefficients of *PRC* are negative and significant (*t-statistic* = −2.31 for positive surprises and −2.88 for negative). This finding is consistent with the stratified results in Panel A. These results provide direct evidence suggesting that investors' under-reaction to positive (negative) earnings surprise is greater when price is nearer (farther from) its 52-week high. They confirm findings in Section 2 regarding PEAD.

3. Anchoring and PAFRD

This section examines the role of anchoring in generating PAFRD. Section 3.1 describes the data and methodology, Section 3.2 how anchoring affects PAFRD, and Section 3.3 investigates how anchoring influences analysts' forecast errors and revisions.

3.1 Data and methodology

Data concerning analysts' forecasts are from I/B/E/S. Stock prices and returns are retrieved from CSMAR. I/B/E/S has records of analysts' forecasts for sizable number of firms from year 2003. Our sample period starts in 2003 and ends in 2012.

Observations of the sample in this section are specific to forecast revisions and are not firm-specific as in Section 2. A forecast revision (*FR*) is calculated as an analyst's current annual EPS estimate minus the most recent consensus forecast for that firm for the same fiscal year, scaled by the absolute value of the latter. We disregard price as the scalar because price is highly related to our variable of interest, the 52-week high anchoring measure (*PRC*). The consensus forecast is calculated on the date when anchoring (i.e., *PRC*) is measured and is referred to as the anchoring date. The consensus forecast is the average of the most recent forecast by each individual analyst before the anchoring date. *FR* reflects an analyst's assessment of new information received after the anchoring date.

As the anchoring date we use the start of the week before the week during which *FR* is issued. This choice assures at least one week's gap between the anchoring date and the *FR*'s issuance. This gap is not required in our hypothesis. In our theory, the anchoring date is immediately prior to the issue date. However, we are also interested in how *PRC* affects the price reaction to *FR* later, and that requires *PRC* to be exogenous to how price reacts to revised forecasts. Too narrow a gap might result in *PRC* being affected by the price reaction to *FR*.

All observations are sorted independently by *FR* and *PRC* based on the whole sample. Revisions with positive *FR* suggest that analysts received positive news after the anchoring date. Positive revisions are subdivided into groups FR_{GG} and FR_G, based on the magnitude of *FR*. FR_{GG} includes revised forecasts with extremely positive news. FR_G includes revised forecasts with moderately positive news. Revisions with negative *FR* suggest that analysts received negative news after the anchoring date and are subdivided into groups FR_{BB} and FR_B, based on the magnitude of *FR*. FR_{BB} includes forecast revisions based on extremely negative news. FR_B includes *FR*'s with moderately negative news. *PRC* is sorted into three groups. Twenty percent of the observations with the lowest (highest) *PRC* are included in LPRC (HPRC), and the remaining observations are included in the MPRC. Combinations of the four *FR* groups (FR_{GG}, FR_G, FR_B, FR_{BB}) and the three PRC groups (LPRC, MPRC, HPRC) produce 12 groups.

We are interested in how anchoring bias affects price drift after analysts announce revised forecasts (i.e., PAFRD), given the sign and magnitude of the revision. Therefore, we examine within each of the four revision groups how *PAFRD* changes with *PRC*. If analysts suffer from anchoring bias, their assessments will be inadequate when stock price is already near or far from its 52-week high. Particularly, if it is near (far from) its high on the anchoring date and an analyst receives positive (negative) news thereafter, she will under-react to either news out of reluctance to believe the stock's price will move higher (lower). This behavior leads to greater positive (negative) price drift post-revision. Therefore, if analysts' assessments are afflicted by anchoring bias, as we hypothesize, *PAFRD* will increase with *PRC* within each forecast revision group.

PAFRD is measured as abnormal returns occurring two to 120 days following the revision date. Similar to our investigation of *PEAD* in Section 2, we exercise caution in defining abnormal return to capture the impact of analysts' anchoring bias on *PAFRD*. That is, we control the pure anchoring effect by using stocks for which analysts do not issue forecasts as benchmarks to adjust the returns of stocks with revised forecasts. For each forecast revision of stock *i*, we choose one matching stock *im* from those for which no analysts issued forecasts during one year around the revision date of stock *i*. The benchmark stock is chosen using the following criteria: *PRC* of stock *im* is the closest to that of stock *i* among all stocks on the anchoring date. Then *PAFRD* of stock *i* is calculated as

$$PAFRD_i = Exret\ (2,\ 120)_i - Exret\ (2{,}120)_{im}, \tag{3}$$

where $Exret\ (2,\ 120)_i$ is the size-adjusted and book-to-market-adjusted buy-and-hold return of stock *i* from two to 120 days after the revision date. Similar to *PEAD*, *PAFRD* can be regarded as the abnormal return adjusted by size, book-to-market, and anchoring. The pure anchoring effect is removed from *PAFRD*.

Table 4 reports summary statistics of the sample of forecast revisions. Average *FR* values within each forecast revision group are little affected by stocks' PRC ranks. The same is true of PRC values; they are insensitive to forecast revision rankings. Further, *PRCs* of the treatment stocks are almost similar as their benchmark stocks, which ensure that these benchmark stocks can be relied on to remove the pure anchoring effect from *PAFRD*.

3.2 Results on anchoring bias and PAFRD

The results are reported in Panel A of Table 5. We first confirm the existence of PAFRD in our sample. The first row labelled as 'ALL' reports average *PAFRD* in each of the four FR groups. The difference in average *PAFRD* between forecast revisions with extremely positive news (FR_{GG}) and forecast revisions with extremely negative news (FR_{BB}) is 5.63% (*t-statistic* = 6.45).

We then report average *PAFRD* in each of the 12 groups stratified by *FR* and *PRC*. Within both positive forecast revision groups (FR_{GG} and FR_{G}), average *PAFRD* increases from low to high PRC groups. The difference in average *PAFRD* between HPRC and LPRC is 7.52% in FR_{GG} (*t-statistic* = 2.60) and 8.63% in FR_{G} (*t-statistic* = 3.71). In both negative forecast revision groups (FR_{BB} and FR_{B}), average *PAFRD* decreases from high to low PRC groups. The difference in average *PAFRD* between HPRC and LPRC is 5.73% in FR_{BB} (*t-statistic* = 2.45) and 10.17% in FR_{B} (*t-statistic* = 5.16). These results correspond with anchoring on the 52-week high causing under-reaction to information.

The difference in average *PAFRD* between lower-right and upper-left corners represents the price drift after forecast revision when the anchoring effect is strongest. The difference of 11.16% (= 7.63% + 3.53%) is statistically significant (*t-statistics* = 5.48). On the other hand, the difference in average *PAFRD* between upper-right and lower-left corners of −2.09% (= 0.11% − 2.20%) is statistically insignificant (*t-statistic* = −0.70). Because forecast revisions in these opposed corners are least susceptible to anchoring bias, this result suggests there is no *PAFRD* in the absence of anchoring. Further, compared to the unconditional *PAFRD* at 5.63%, this result suggests that the profitability of exploiting PAFRD almost doubles by conditioning on the 20% most anchored stocks.

Panel A of Table 5 reveals that *PAFRD* increases with *PRC* within each of the four forecast revision groups. We test whether positive relation between these two variables exists using a regression to control other variables. The regression is

$$PAFRD_i = b_0 + b_1\, FR_i + b_2\, PRC_i + b_j\, controls_j + e_i. \tag{4}$$

Similar to regression (2), we include firm size (*LOGMV*) and book-to-market ratio (*LOGBM*) as controls. In addition, we include time-fixed effects based on fiscal years for which forecasts are issued. Test statistics are based on standard errors clustered by firm and forecast revision date. We run regression (4) on upwardly revised forecasts (in FR_{GG} and FR_G) and downward revisions (in FR_{BB} and FR_B) separately. Panel B of Table 5 reports the results. In the sample of upward revisions, the coefficient on *PRC* is positive and significant (*t-statistic* = 3.50). In the sample of downward revisions, the coefficient on *PRC* is also positive and significant (*t-statistic* = 3.77). These results suggest that for a given forecast revision *PAFRD* increases with *PRC*, a finding consistent with the stratified results in Panel A.

Panel C of Table 5 includes historical stock return (*RETMOM*) in the regression to see whether it affects *PAFRD*. Coefficients on *RETMOM* are not statistically significant for both upward and downward revisions (*t-statistic* = −1.57 for upward and −1.21 for downward revisions). This result suggests that, unlike the 52-week high, past stock return is not an anchor in the generation of *PAFRD*, a finding similar to our analysis of *PEAD*.

3.3 Forecast error and subsequent forecast revision

If analysts' anchoring bias generates *PAFRD*, as we argue, their forecast errors and subsequent forecast revisions should exhibit patterns consistent with anchoring on the 52-week high. First, consider the case in which an analyst receives positive news and elevates her forecast. The closer the stock price is to its 52-week high, the more likely that the analyst will discount positive news, and the more pessimistic will be her upward revision. The result is greater negative forecast error (analyst forecast minus actual EPS) and greater positive subsequent forecast revision. When an analyst receives negative news and reduces her forecast, the further the stock price is from its 52-week high, the more likely the analyst will discount negative news, and less pessimistic her downward revised forecast will be. The result is greater positive forecast error and greater negative subsequent forecast revision. Forecast error is the difference between an analyst's current forecast and corresponding actual EPS announced by the firm later, scaled by the absolute value of the latter. Subsequent forecast revision is the difference between the analyst's next forecast and her current forecast, scaled by the absolute value of the latter.

As Panel A of Table 6 shows, average forecast errors are positive in all 12 cells, suggesting analysts' forecasts are generally optimistic, a finding consistent with previous studies. However, within both groups of upwardly revised forecasts (FR_{GG} and FR_G), average error decreases from LPRC to HPRC. The difference in forecast error between HPRC and LPRC within FR_{GG} is −0.90 (*t-statistic* = −7.65), and difference within FR_G is −0.51 (*t-statistic* = −6.93). These results suggest analysts' upwardly revised forecasts are less optimistic when stock price is nearer its 52-week high. On the other hand, within both groups of downwardly revised forecasts (FR_{BB} and FR_B), average forecast error increases from HPRC to LPRC. The difference in error between LPRC and HPRC within FR_{BB} is 0.54 (*t-statistic* = 7.14), and difference within FR_B is 0.44 (*t-statistic* = 7.15). These results suggest analysts' downwardly revised forecasts are more optimistic when stock price is farther from its 52-week high.

Opposite patterns appear in analysts' subsequent forecast revisions. Within both groups of upwardly revised forecasts, subsequent revisions are more positive if stock prices are near their 52-week highs, suggesting analysts' subsequent upwardly revisions become more inadequate as stock prices are nearer to 52-week highs. Within both groups of downward revisions, subsequent revisions become more negative as stock prices recede from 52-week highs, suggesting analysts' current downwardly revised forecasts are more insufficient as prices are further distant from 52-week highs. These results for forecast errors and revisions are consistent with analysts anchoring on 52-week highs when forecasting earnings.

Regression results reported in Panel B of Table 6 confirm findings in the stratified tables. Particularly, among both upwardly and downwardly revised forecasts, *PRC* is related negatively to forecast error and positively to subsequent forecast revisions. All relations are statistically significant.

Our assertion that *PAFRD* is generated by analysts' anchoring on 52-week highs when revising forecasts is supported empirically in Table 6. However, it is also likely that investors anchor on 52-week highs when reacting to announcements of analysts' forecast revisions, much like they react to firms' earnings announcements. Particularly, investors might under-react to analysts' upward forecast revisions when prices approach 52-week highs and under-react to downward forecast revisions when prices are far from 52-week highs. If either is the case, *PAFRD* also might be attributable to investors' anchoring bias.

To test whether this is the case, we examine the impact of anchoring bias on reactions of stock prices to analysts' revised forecasts. Price reaction is measured as the abnormal return during the three days around the forecast revision date, similar to how Section 3.3 estimated price reaction to earnings announcements. Results for price reactions appear in Table 6 under the heading "Announcement Return." We find no evidence that anchoring bias prompts investors to under-react to analysts' revised forecasts. The three forecast revisions FR_{BB}, FR_{B}, and FR_{G}, display no significant differences in price reaction between LPRC and HPRC. Within FR_{GG}, price reaction is actually stronger when price is nearer its 52-week high.

The regression result shows a similar pattern. These results suggest that, unlike their reaction to earnings announcements, investors do not anchor on 52-week highs when reacting to announcements of analysts' revised forecasts. One potential reason is that trading in the Chinese stock market is dominated by retail investors, who generally follow the advice of financial experts without second guessing.

4. Conclusion

This paper examined the role of anchoring on 52-week highs in generating PEAD and PAFRD in the Chinese stock market. We found evidence of PEAD only among stocks with anchored prices and no evidence of PEAD among stocks with unanchored prices. Further, we found that investors' reaction to positive (negative) earnings news is less positive (negative) when the price of the stock is nearer (farther from) its 52-week high. These findings suggest that PEAD is attributable to investors' anchoring on 52-week highs in assessing earnings announcements; they under-react to positive (negative) earnings surprises when the pre-earnings-announcement price is near to (far from) its 52-week high. This behavior generates price drift after earnings announcements.

Findings regarding PAFRD resemble those for PEAD. We find evidence of PAFRD only among stocks with anchored prices. When earnings forecasts are revised upward, the closer the stock is to its 52-week high, the more pessimistic the revised forecast. Opposite patterns characterize downward revisions. In addition, we found no evidence of anchoring bias in investors' reactions to analysts' revised forecasts. These results suggest PAFRD is attributable to analysts' anchoring on 52-week highs when assessing information; they under-react to positive (negative) news and do not sufficiently revise forecasts upward (downward) when stock prices are near (far from) 52-week highs. This behavior yields price drift after their revised forecasts.

The Chinese stock market is dominated by retail investors, who may be susceptible to cognitive bias. Also, China's market is relatively young, and new markets generally present greater uncertainty. Psychological biases are more likely in uncertain environments (Daniel, Hirshleifer, and Subrahmanyam 1998; Hirshleifer 2001; Zhang 2006a, 2006b). This study examines one type of psychological bias— anchoring on 52-week highs. Future study can investigate effects of other psychological biases.

Table 1 Summary Statistics of the PEAD Sample

For each fiscal quarter, stocks are sorted independently on the basis of their standardized unexpected earnings (*SUE*) and 52-week high anchoring measures (*PRC*) based on their earnings announcements for that quarter. *SUE* is calculated as $(e_q - e_{q-4}) / \sigma_q$, where e_q is current-quarter EPS, e_{q-4} is EPS for the same fiscal quarter the previous year, and σ_q is the standard deviation of $(e_q - e_{q-4})$ over the prior eight fiscal quarters (we require at least four prior quarters of data). Stocks are sorted into quintiles based on *SUE* (SUE1–SUE5). SUE1 and SUE2 include stocks with extremely and moderately negative earnings surprises, respectively. These two groups are denoted SUE_{BB} and SUE_B. SUE5 and SUE4 include stocks with extremely and moderately positive earnings surprises, respectively. They are denoted SUE_{GG} and SUE_G. SUE3 includes stocks with the lowest magnitude of SUE. It is the no-earnings-surprises group. *PRC*, our 52-week high anchoring measure, is calculated as the stock price (adjusted for splits and dividends) 10 days before the date of current quarterly earnings are announced, divided by the highest stock price during the past 52 weeks. The 20% of stocks with the lowest (highest) *PRC* occupy the group denoted LPRC (HPRC); the rest are in the group denoted MPRC. Combinations of the four earnings-surprise groups (SUE_{GG}, SUE_G, SUE_B, SUE_{BB}) and the three PRC groups (LPRC, MPRC, HPRC) produce 12 groups. For each stock *i* in the 12 groups, we choose one matching stock *im* from SUE3 using the following criteria: *PRC* of stock *im* is the closest to that of stock *i* among all stocks in its PRC group (LPRC, MPRC, and HPRC). This table presents the average *SUE*, average *PRC* and total number of observations in each group. The characteristics of benchmark stocks (*im*) are in *italics*. *SUE* is winsorized at the 1st and 99th percentiles. The sample period is from year 2003 to 2012.

Table 1 Continued

	SUE				*PRC*				No. of observations

Table 2 Anchoring Bias and PEAD

Panel A reports the average *PEAD* of stocks in each of the 12 groups stratified by SUE and PRC. The first row labelled as 'ALL' reports the average *PEAD* of all stocks within each SUE group. *PEAD* of *i* is calculated using the formula: $PEAD_i = Exret\ (2,\ 120)_i - Exret\ (2,120)_{im}$. $Exret\ (2,\ 120)_i$ is the size-adjusted and book-to-market-adjusted buy-and-hold return of stock *i* occurring two to 120 days after its earnings announcement. This return is calculated by subtracting the mean buy-and-hold return of an equal-weighted portfolio of stocks in the same 5×5 size and book-to-market group over the same holding period. The 5×5 independent sorting is performed at the beginning of the year. $Exret\ (2,120)_{im}$ is the size-adjusted and book-to-market-adjusted buy-and-hold return of stock *im* occurring two to 120 days after its earnings announcement. Stock *im* is the benchmark of stock *i.* The selection criteria of *im* are specified in Table 1. Panel B and C report the results of the following regression: $PEAD_i = b_0 + b_1\ SUE_i + b_2\ PRC_i + b_j\ controls_j + \varepsilon_i$. The control variables (*controls*) in Panel B include firm size (*LOGMV*) and book-to-market ratio (*LOGBM*) that are calculated at the beginning of the year wherein earnings are announced; both are transformed into logarithmic forms. We also include time-fixed effects based on fiscal quarter. Panel C includes previous stock returns (*RETMOM*) as an additional control variable. *RETMOM* is calculated as the six months' buy-and-hold return ending 10 days before the announcement date. The regression is run separately on stocks with positive earnings surprises (stocks in SUE_{GG} and SUE_G) and with negative earnings surprises (stocks in SUE_{BB} and SUE_B). T-statistics (in parentheses) are based on standard errors clustered by stock and earnings announcement date. All variables in the table are winsorized at 1st and 99th percentiles.

Table 3 Returns around Current Earnings Announcement

Panel A reports the average earnings announcement return in each of the 12 groups stratified by SUE and PRC. Earnings announcement return is calculated as the size-adjusted and book-to-market-adjusted buy-and-hold stock return during the three days around earnings announcements. The first row labelled as 'ALL' reports the average earnings announcement return of all stocks within each SUE group. Panel B reports the result of a regression which is similar to that in Panel B of Table 2, except that the dependent variable is replaced by earnings announcement return. T-statistics (in parentheses) are based on standard errors clustered by firm and earnings announcement date. All variables in the table are winsorized at 1st and 99th percentiles.

Table 4 Summary Statistics of the PAFRD sample

All observations are sorted independently by *FR* and *PRC* based on the whole sample. A forecast revision (*FR*) is calculated as an analyst's current annual EPS estimate minus the most recent consensus forecast for that firm for the same fiscal year, scaled by the absolute value of the latter. The consensus forecast is calculated on the date when anchoring (i.e., *PRC*) is measured and is referred to as the anchoring date. We use the start of the week before the week during which *FR* is issued as the anchoring date. The consensus forecast is the average of the most recent forecast by each individual analyst before the anchoring date. Positive revisions ($FR > 0$) are subdivided into groups FR_{GG} and FR_G, based on the magnitude of *FR*. FR_{GG} includes revised forecasts with extremely positive news. FR_G includes revised forecasts with moderately positive news. Negative revisions ($FR < 0$) are subdivided into groups FR_{BB} and FR_B, based on the magnitude of *FR*. FR_{BB} includes forecast revisions based on extremely negative news. FR_B includes *FR*'s with moderately negative news. *PRC* is sorted into three groups. Twenty percent of the observations with the lowest (highest) *PRC* are included in LPRC (HPRC), and the remaining observations are included in the MPRC. Combinations of the four *FR* groups (FR_{GG}, FR_G, FR_B, FR_{BB}) and the three PRC groups (LPRC, MPRC, HPRC) produce 12 groups. For each forecast revision of stock *i*, we choose one matching stock *im* from those for which no analysts issued forecasts during one year around the revision date of stock *i*. The benchmark stock is chosen using the following criteria: *PRC* of stock *im* is the closest to that of stock *i* among all stocks on the anchoring date.). This table presents the average *FR*, average *PRC* and total number of observations in each group. The statistics of benchmark stocks (*im*) are in *italics*. *FR* is winsorized at the 1st and 99th percentiles. The sample period is from year 2003 to 2012.

Table 5 Anchoring Bias and PAFRD

Panel A reports the average *PAFRD* of stocks in each of the 12 groups stratified by FR and PRC. The first row labelled as 'ALL' reports the average *PAFRD* of all stocks within each FR group. *PAFRD* of *i* is calculated using the formula: $PAFRD_i = Exret\ (2,\ 120)_i - Exret\ (2,120)_{im}$. $Exret\ (2,\ 120)_i$ is the size-adjusted and book-to-market-adjusted buy-and-hold return of stock *i* occurring two to 120 days after the revision date. This return is calculated by subtracting the mean buy-and-hold return of an equal-weighted portfolio of stocks in the same 5×5 size and book-to-market group over the same holding period. The 5×5 independent sorting is performed at the beginning of the year. $Exret\ (2,120)_{im}$ is the size-adjusted and book-to-market-adjusted buy-and-hold return of stock *im* occurring during the same holding period. Stock *im* is the benchmark of stock *i*. The selection criteria of *im* are specified in Table 4. Panel B and C report the results of the following regression: $PAFRD_i = b_0 + b_1\ FR_i + b_2\ PRC_i + b_j\ controls_j + \varepsilon_i$. The control variables (*controls*) in Panel B include firm size (*LOGMV*) and book-to-market ratio (*LOGBM*) that are calculated at the beginning of the year wherein earnings are announced; both are transformed into logarithmic forms. We also include time-fixed effects based on fiscal year for which these forecasts are issued. Panel C includes previous stock returns (*RETMOM*) as an additional control variable. *RETMOM* is calculated as the six months' buy-and-hold return ending at the anchoring date. The regression is run separately on stocks with positive forecast revisions (stocks in FR_{GG} and FR_G) and with negative forecast revisions (stocks in FR_{BB} and FR_B). T-statistics (in parentheses) are based on standard errors clustered by stock and forecast revision date. All variables in the table are winsorized at 1st and 99th percentiles.

Table 6 Forecast Error, Subsequent Forecast Revision and Price Reaction to Current Forecast Revision

Panel A reports the average forecast error, average subsequent forecast revision and average price reaction to current forecast revision in each of the 12 groups stratified by FR and PRC. The first row labelled as 'ALL' reports the average of each variable based on all stocks within each FR group. Forecast error is the difference between an analyst's current forecast and corresponding actual EPS announced by the firm later, scaled by the absolute value of the latter. Subsequent forecast revision is the difference between the analyst's next forecast and her current forecast, scaled by the absolute value of the latter. Price reaction to a forecast revision is calculated as the size-adjusted and book-to-market-adjusted buy-and-hold stock return during the three days around the forecast revision date. Panel B reports the results of the regressions in which the dependent variables are forecast error, subsequent forecast revision and price reaction to a current forecast revision, separately. The definitions of the explanatory variables are the same as those in Table 5. The regression is run separately on stocks with positive forecast revisions (stocks in FR_{GG} and FR_G) and with negative forecast revisions (stocks in FR_{BB} and FR_B). T-statistics (in parentheses) are based on standard errors clustered by stock and forecast revision date. All variables in the table are winsorized at 1st and 99th percentiles.

wang0371@e.ntu.edu.sg

We classify institutions into socially responsible institutions (SRI) and non-socially-responsible institutions (NSRI) based on the value weighted Corporate Social Responsibility (CSR) scores of their portfolio holdings. Controlling for CSR scores, stocks that experience an increase in NSRI ownership realize positive excess returns the following quarter. The positive relation between excess returns and NSRI ownership is stronger for stocks with higher CSR scores. We also find that CSR scores tend to increase more for stocks with lower NSRI holdings. These results, which are consistent with the existence of excess CSR expenditures that reduce firm values, suggest that the mix of institutional investors influences CSR choices.

Keywords: Corporate Social Responsibility, institutional investor, institutional ownership, shareholders activism.

JEL Classifications: M14, G23

There is a large and growing literature that examines how institutional investors evaluate and influence corporations.[1] The premise of most of this literature is that institutions encourage firms to make value maximizing choices. However, a number of institutions also attempt to influence the social responsibility of the firms in which they invest. Indeed, according to the US Social Investment Forum, $6.57 trillion in assets, or over 17.8% of total investment assets, were managed using Socially Responsible Investing guidelines at the beginning of 2014.

While very few institutional investors promote themselves as not being socially responsible,[2] there are a number of funds that put relatively little weight on the social responsibility of the firms in which they invest and are primarily focused on maximizing returns. If the portfolio choices of the socially responsible investors tend to bid up the stock prices of socially responsible firms, then those investors who are less interested in social responsibility, per se, may underweight these stocks.

The focus of this paper is on these "non-socially-responsible institutions" (NSRI), which we identify by weighting the corporate social responsibility scores of their portfolio holdings, as measured by the scores reported in the Kinder, Lyndenberg, and Domini (KLD) STATS database. As we show, the tendency of institutions to hold the stocks of firms with relatively low social responsibility scores is a persistent investor characteristic that tends to be correlated with institutional investor types. For example, hedge funds are much more likely than mutual funds to be a NSRI.

[1] See Gompers and Metrick (2001) and Sias, Starks, and Titman (2006) for evidence on the relation between institutional ownership and future stock returns and Karpoff (2001) for a review of the literature on institutional activism.

[2] We are aware of one mutual fund named the Vice Fund, which does focus on gambling, defense, tobacco and alcohol stocks.

As a first step, we examine the relation between the firms' KLD scores, NSRI holdings, and future stock returns. Specifically, against a null of zero excess returns, we test whether low KLD stocks have higher returns (i.e., they are underpriced because socially responsible investors avoid them) and whether stocks with high NSRI holdings have higher returns (i.e., they are held by investors who are presumably more focused on generating excess returns). After controlling for firm characteristics that are associated with excess returns (e.g., book-to-market ratios) we fail to find a reliable relation between KLD scores and future returns. We do find, however, that the stocks selected by NSRIs tend to realize higher returns on average and that these excess returns are especially strong for the stocks with high KLD scores.

One explanation for the latter finding is that the NSRIs are particularly good at identifying firms that implement social policies that "do well and do good." By this we mean that the NSRIs are good at identifying firms that are able to have high levels of CSR without destroying firm value. An alternative (but not mutually exclusive) explanation is that NSRIs tend to be good at identifying firms with value-reducing CSR policies and, through their ability to monitor and influence future choices, induce these firms to reduce the extent of these policies.

To distinguish between these alternatives we estimate a second set of regressions that examine the relation between CSR activities and ownership structure. In particular, we examine the relation between the types of institutions that own a firm's stock and future changes in its CSR activities. The "do well and do good" hypothesis provides no predictions about the relation between ownership structure and future changes in CSR activities, however, the monitoring hypothesis indicates that higher NSRI holdings will be associated with declines (or more moderate increases) in future CSR activities. Our evidence tends to support the latter hypothesis.

As we show, KLD scores tended to increase over our sample period, especially among the larger and better performing firms. This time series trend probably reflects the increased interest in socially responsible investing over this time period. We also find that the increase is higher among the larger and more profitable firms, which is consistent with the arguments of Jensen (1986) and others who suggest that managers of larger and more successful firms can more easily engage in excessive (from the perspective of value-maximization) CSR activities. However, consistent with the monitoring hypothesis, the tendency to increase KLD scores is mitigated when NSRI holdings are larger. This last finding is especially true for firms with higher earnings and stock returns, i.e., firms with managers that are expected to have more descretion.

As we mentioned at the outset, this research contributes to a large literature that examines how institutional investors influence corporate behavior. An early contributor, Bushee (1998), finds a relation between the amounts held by different types of institutional investors and R&D expenditures. Subsequent work by Hartzell and Starks (2003) consider the effect of concentrated institutional ownership and find stronger pay for performance sensitivity at firms with more concentrated institutional ownership and Chen, Harford and Li (2007) show that the concentrated holdings of independent long-term institutions are related to the performance of firms following major acquisitions.

Consistent with this earlier research we focus on a specific decision. However, the earlier studies all consider decisions that are assumed to be value-enhancing, and assume that institutions all want to encourage value-enhancing choices. In contrast, we provide evidence that different institutions have different tastes for corporate social responsibility, and consider how the decisions of firms are influenced by the tastes of the particular institutions that hold their stocks.[3]

Our analysis is also tangentially related to the literature that examines how CSR influences share prices. In theory, if a significant fraction of investors have a taste for Corporate Social Responsibility (CSR), they will push up the stock prices of high CSR firms, lowering their costs of capital, and thereby provide an incentive for all firms to improve social responsibility. Hence, firms can take socially responsible actions that reduce cash flows and still improve firm value if the cash flow decline is offset by a decline in the discount rate.

Unfortunately, detecting the empirical relation between CSR activities and firm values is challenging for a number of reasons. First, an increase in the presence of socially responsible investors will initially result in price increases for high CSR stocks, which will in turn cause their subsequent risk adjusted returns to be lower. Hence, the relation between socially responsible investing and future returns can be either positive or negative depending on whether returns are measured in the interval

[3] There is also a related literature that explicitly looks at the purchases of activist hedge funds. For example, Brav, Jiang, Partnoy, and Thomas (2008) (2008) and Klein and Zur (2009) show that stock prices respond positively to hedge funds' filing of 13D, which signifies that an activist hedge fund has accumulated at least 5% of the firm's stock. Some of these activist hedge funds are also in our NSRI sample, but do not drive our results.

in which socially responsible investors are accumulating the stock or in the period subsequent to the accumulation. Second, the endogeneity of CSR policy choices causes an additional inference problem if firms feel that they can afford the luxury of adopting strong CSR policies when their businesses are otherwise performing very well. Perhaps, because of these measurement issues, the results of existing studies of the relation between CSR activities and stock returns are somewhat mixed.[4]

In contrast, while our study does not attempt to provide direct evidence on how social responsibility affects stock returns, we present results that provide indirect evidence that there exist firms that engage in value-reducing socially responsible activities. Specifically, our evidence suggests that firms with high CSR expenditures tend to realize positive abnormal returns when these activities are likely to be curtailed in the future.

The rest of paper is organized as follows. Section 2 describes the data and methods to calculate the key variables and provides some summary statistics. Section 3 presents the main empirical results. Section 4 concludes the paper.

2. Data

2.1. Data and Sample

Our sample includes quarterly institutional holdings for all common stocks

[4] Deng, Kang and Low (2013) show that higher CSR firms that are involved in acquisitions perform better than their lower CSR counterparts, while Dhaliwal, Li, Tsang and Yang (2011) document a drop in cost of capital after they voluntarily disclose CSR activities. Brammer, Brooks and Pavelin (2006) find lower returns for UK stocks with higher social performance scores. In addition, Hong and Kacperczyk (2009) find that sin stocks, (those involved in producing alcohol, tobacco, and gaming) tend to have higher returns.

traded on NYSE, AMEX, and NASDAQ from the first quarter of 1980 to the fourth quarter of 2011. This data, obtained from Thomson Financial, come from the Securities and Exchange Commission (SEC)'s Form 13-F, which must be filed by all U.S. institutions with over $100 million in assets. Institutional ownership for each stock is defined as the number of shares held by institutional investors divided by the total number of shares outstanding.[5] The stock price, stock return, shares outstanding and turnover are from the Center for Research in Security Prices (CRSP) monthly database. The book value of equity, total assets, and cash dividends are from COMPUSTAT.

Corporate social responsibility data is from the Kinder, Lyndenberg, and Domini (KLD) STATS database. KLD annually reports approximately 80 indicators of corporate social responsibility that cover seven major areas that include strengths and concerns about Community, Corporate Governance, Diversity, Employee Relations, Environment, Human Rights and Product.[6] Most of the concerns that are reported by KLD relate to potential legal problems that are associated with environmental damages, product safety, marketing and contracting disputes and potential anti-trust violations. Since we do not think it is likely that institutions will target firms for having too few concerns of this type, our focus is on the strengths that are reported by KLD. Henceforth, we will use CSR, KLD and KLD strength interchangeably.

KLD provides this data starting in 1991 with a sample of about 650 firms that are in either the S&P 500 or Domini 400 Social Index. In 2001 KLD expanded its

[5] The observations with total institutional ownership greater than 100% are deleted.

[6] Details of the KLD strength indicators are presented in the appendix B.

coverage to about 1100 firms, which includes all firms in the Russell 1000. In 2003 KLD added full coverage of the Russell 3000, increasing coverage to about 3100 firms. Because our analysis requires a broad cross-section and available information about future changes in KLD scores our sample starts in 2003 and ends in 2011.

Appendix C reports the number of KLD strength indicators, and the minimum, median and maximum strength scores for the seven categories respectively. KLD strength rating includes 47 indicators. Although the median KLD strength score is only 1, some firms have very high strength scores. The maximum KLD strength score is 22 and the minimum score is 0 in our sample. We plot the value of average KLD in our sample over the years in Figure 1. As the figure indicates, average KLD scores have increased over time, which is consistent with the growing popularity of social responsible investments we mentioned earlier. Interestingly, despite a generally upward trend, KLD scores declined during the financial crisis in 2008 and 2009, which is consistent with the hypothesis that corporate social responsibility is viewed as a luxury good, i.e., firms tend to increase KLD scores when they are more profitable.

2.2. Non-Socially-Responsible Institutional (NRSI) Ownership Measures

We measure the taste for the social responsibility (SR) of institutional investors by aggregating the KLD scores of the firms whose stocks they hold to determine the SR rating for each institution. Since there is a strong positive relation between firms'

KLD scores and size,[7] an institution's SR rating is strongly determined by the average size of the firms in the institution's portfolio. In an effort to purge this size effect, we use size-adjusted KLD (*ADKLD*). Each quarter, we sort the stocks into 10 deciles based on size and calculate the average KLD rating of stocks for each size decile. A firm's size-adjusted KLD is its raw KLD rating minus the average KLD ratings of stocks in its decile.

Specifically, institutional social responsibility ratings (SR) are calculated as follows:

$$\mathrm{SR}_{i,t} = \sum_{j \in i} \omega_{j,t} ADKLD_j \qquad (1)$$

Where $\mathrm{SR}_{i,t}$ is the social responsibility rating for institution i at the end of quarter t, $\omega_{j,t}$ is the weight of stock j in institution i's portfolio at the end of quarter t and $ADKLD_j$ is the size-adjusted social responsibility strength rating for stock j at the previous year end. Stocks with missing ratings are removed when calculating the institutional SR ratings. Each quarter, we sort institutional SR ratings into three groups, with institutions in the bottom group, which have the lowest ratings, defined as NSRIs, and the rest of the institutions defined as SRIs. Finally, for each stock in each quarter, we measure the NSRI percentage ownership as the number of shares held by NSRI divided by the total number of shares outstanding.

[7] The correlation between KLD and logsize is about 0.50 reported in Panel B of Table 1.

2.3. Control Variables

As in Gompers and Metrick (2001), Baik, Kang and Kim (2010) and Yan and Zhang (2009), our return regressions include controls for a number of characteristics that are associated with stock returns. These include size, B/M, Age, Cash Dividend, Price, Turnover, Past Returns ($Ret_{t-3,t}$, $Ret_{t-12,t-3}$), Volatility, and an indicator of whether or not the stock is in the S&P 500. All variables except institutional ownership, returns, and the S&P500 dummy are expressed in natural logarithms.[8] In our CSR regressions, we control for factors that potentially affect firm CSR activities such as size and past ROA.

2.4. Summary Statistic

Panel A of Table 1 reports the time-series mean, median, standard deviation, minimum and maximum of the variables that we include in our regressions. The key variables in the regressions are the level and the change of institutional holdings. The average institutional ownership (*IO*) is 67.0% in our sample, and on average, NSRIs hold 15.30% of the share outstanding. On average, the change in total institutional ownership is 0.12% and the change in NSRI holdings is 0.06%.

Panel B reports the time-series average of the cross-sectional correlations. By construction, NSRIs tend to hold firms with lower CSR activities, so of course we find a negative correlation between NSRI ownership and firm KLD strength ratings. The positive correlations between KLD and size and age indicate that high KLD firms

[8] Details of variable constructions are in Appendix A.

are larger and older, which in turn implies that NSRIs tend to hold smaller and younger firms.

2.5 The Persistence of NSRI

In Table 2, we examine the persistence of our NSRI classification. Panel A shows the transition matrix between NSRI and SRI. Among all NSRIs in a particular quarter, approximately 90% are still classified as NSRI after one quarter, 78.9% after one year and 70.5% after 2 years. Similarly, the percentage of SRIs that continue to be SRI is about 93.6 after one quarter, 84.1% after one year and 76.4% after 2 years. In Panel B, we compare the KLD of stocks purchased by NSRIs and SRIs. In every quarter, we record the equally weighted average of the KLD scores of stocks purchased by NSRIs and SRIs, and report the time series averages. We further distinguish between the purchase of stocks they didn't hold in the preceding quarter (Newly Purchased) and those they already own (additional purchases of existing holdings). Panel B reveals that in both cases NSRIs tend to buy stocks with significantly lower KLD ratings on average. These results indicate that the NSRI classification and the taste of NSRI for low CSR stocks can be characterized as a persistent investment style.

2.6 Institutional Classifications

Consistent with earlier work by Hong and Kacperczyk (2009), who find that sin stocks tend to be held less by pension funds and more by mutual funds and different tastes for CSR. Specifically, at the end of each quarter we calculate (averaging across quarters and firms) the percent of the institutional ownership (*IO*) held by each of the five individual categories (*IO_T1* to *IO_T5*), as classified by Thomson Reuters.[9] We report these percentages in the first row of Table 3. Similarly, we calculate the percent of the total NSRI ownership (*NSRIO*) held by the different categories, which we report in the second row. Finally, within each type of institution, we calculate the percentage of institutional ownership that comes from NSRIs by taking the ratio of *NSRIO* to the ownership of each category of institution (*IO_T1* to *IO_T5*). These percentages are reported in the third row.

A few interesting patterns emerge from these calculations. First, from Panel A we see that more than half (52.94%) of the institutional ownership in our sample comes from what Brian Bushee classifies as Type 4 institutions. Second, NSRI ownership is dominated (84.74%) by Type 4 institutions. Type 4 institutions also constitute the largest percentage (36.40%) of *NSRI* ownership.

3. Empirical Results

3.1. Change in NSRI Ownership (ΔNSRIO) and Future Stock Returns

We start by examining the relation between corporate social responsibility,

[9] In its S34 database, Thomson Reuters classifies institutional investors into five regulated types. Type 1 includes bank trust; Type 2 includes insurance company; Type 3 includes investment company; Type 4 includes independent investment advisor; Type 5 includes corporate pension fund, public pension fund, university and foundation endowments and miscellaneous. As noted on the Thomson Reuters website, the type code variable is not reliable after 1998 and Brian Bushee has done a reclassification. We find that about 80% of all institutions are classified as Type 5 institutions based on S34 since most institutions are misallocated into Type 5 after 1998 in Thomson Financial. However, based on Bushee's new classification, Type 5 institutions are only 13.22% of the total institutions, and percentages of all other types increase, especially that of Type 4 institutions. We thank Professor Bushee for sharing his database.

institutional ownership, and stock returns. Specifically, we run the following regressions of returns on lagged institutional ownership and other firm characteristics:

$$r_{i,t+1} = \alpha_t + \beta_t NSRIO_{i,t-1} + \theta_t \Delta NSRIO_{i,t} + \gamma_t X_{i,t} + \varepsilon_t \qquad (2)$$

$$r_{i,t+1} = \alpha_t + \beta_t NSRIO_{i,t-1} + \theta_t \Delta NSRIO_{i,t} + \delta_t IO_{i,t-1} + \varphi_t \Delta IO_{i,t} + \gamma_t X_{i,t} + \varepsilon_t \qquad (3)$$

where $r_{i,t+1}$ is the one quarter ahead return of stock *i*, $IO_{i,t-1}$ and $NSRIO_{i,t-1}$ are total institutional ownership and NSRI ownership of stock *i* at the end of quarter *t-1*, $\Delta IO_{i,t}$ and $\Delta NSRIO_{i,t}$ are the quarterly changes in total and NSRI ownership respectively from quarter *t-1* to quarter *t*. Finally, $X_{i,t}$ is the vector of characteristics measured at the end of *quarter t*. These characteristics include the standard controls used in the literature, e.g., log of the book-to-market ratio and past 12 month returns, as well as the firms' KLD score measured at the end of the previous calendar year (since the KLD score is updated annually at the end of each year). These regressions, which are reported in Table 4, are estimated using the Fama-MacBeth (1973) methodology with Newey-West standard errors.

The first thing to note in Table 4 is that the coefficients of the KLD scores are not reliably different than zero. As we mentioned in the introduction, the coefficient of KLD is difficult to interpret. On one hand, high KLD scores can be associated with higher returns because of the increased interest in socially responsible investment, which could have pushed up the price of high KLD stocks in our sample period. On the other hand, the increased price (i.e., lower required rate of return) associated with social responsibility leads to lower future returns. The lack of a significant finding could imply that neither effect is important, or alternatively, that the two effects offset each other.

In contrast to the lack of significance of the KLD coefficients, our estimates of the coefficients of the NSRI variables reveals a strong and positive relation between the change in NSRI ownership ($\Delta NSRIO$) and next quarter's return. The average coefficient of $\Delta NSRIO$ is 0.0899 in model (1) and is statistically significant at the 1% level. When both change in total institutional ownership (ΔIO) and change in NSRI ownership ($\Delta NSRIO$) are included in the regression, shown in model (2), the average coefficient of $\Delta NSRIO$ increases while the coefficient of ΔIO is negative and significant. When we control for industry fixed effects, the results are very similar, as shown in column (3) and column (4). These results indicate that returns tend to be higher following an increase in NSRI holdings.

We also use a portfolio approach to evaluate the returns associated with NSRI holdings. At the end of each quarter, we allocate stocks into 5 equally-weighted portfolios based on the change in NSRI ownership ($\Delta NSRIO$) and the change in SRI ownership ($\Delta SRIO$). We report the holding period returns of each portfolio as well as the return on an investment strategy that buy stocks with the largest increase in NSRI (SRI) ownership (Group 5) and short stocks with largest decrease in NSRI (SRI) ownership (Group 1). In addition to raw returns, we report DGTW adjusted returns that control for the size, B/M and momentum of the individual stocks.

As shown in Table 5, the return of the portfolio that buys stocks with the largest increase in NSRI ownership ($\Delta NSRIO$) and shorts stocks with the largest decrease has a raw return of 1.54% per quarter (t=2.68), and a DGTW-adjusted return of 1.13% per quarter (t=2.80). In contrast, stocks with the largest increase in SRI ownership ($\Delta SRIO$) underperform those with the largest decrease by -2.63% per quarter (t=-2.20) with the DGTW adjusted difference of -2.30% (t=-2.36). The difference between these raw returns is 4.17% (t=2.79) and DGTW adjusted returns are 3.43% (t=3.04).

3.2. Are the Results Driven by the Type of Institution?

There are a number of potential explanations for the better performance of stocks held by NSRIs. The first is that these institutions have a singular focus on selecting stocks that outperform and are thus less distracted by other agendas that influence the choices of some of the other institutions. The second possibility is the monitoring hypothesis, which postulates that the NSRIs are good monitors who have the ability to mitigate the increase or reduce the future KLD scores of firms with excessive CSR activities.

To evaluate these possibilities, we first look more closely at the types of institutions that tend to be NSRIs. Both of the above explanations suggest that NSRIs are likely to be hedge funds and other active investors. Indeed, as we showed previously in Table 3, about 80% of NSRIs are Type 4 investors (i.e., independent advisors and hedge funds). While such a finding is consistent with our arguments, it creates a potential inference problem, since these institutions may outperform other institutions for reasons that have nothing to do with socially responsible investing.

To investigate this issue more closely, we first confirm that Type 4 institutions outperform other institutions in our sample period. To do this we estimate our base line regressions, model (1) and model (2) in Table 4, replacing $\Delta NSRIO$ and $NSRIO$ with ΔIO_T4 and IO_T4, the change and the level of the holdings of Type 4 institutions respectively. These regression estimates, reported as model (1) and model (2) in Table 6, indicate that changes in Type 4 institutional holdings do positively predict returns.

Next, we repeat our base line regressions, except we now separate the change of NSRI holdings, $\Delta NSRIO$, into those from Type 4 institutions ($\Delta NSRIO\_T4$) and those from non-Type 4 institutions $\Delta NSRIO\_NONT4$. The level of NSRI holdings from Type 4 and non-Type 4 institutions are similarly constructed and denoted as $NSRIO\_T4$ and $NSRIO\_NONT4$ respectively. These regression estimates are reported as model (3) and model (4) in Table 6. If the return predicting power of NSRI holdings comes from the fact that most NSRIs are Type 4 institutions, the coefficient of $\Delta NSRIO\_T4$ will be significantly larger than that of $\Delta NSRIO\_NONT4$. However, we find that these two coefficients are very similar in both model (3) and model (4), indicating that the return predicting power of $\Delta NSRIO$ is not generated solely from the Type 4 institutions.

3.3. How is NSRI Performance Related to KLD Scores?

If we believe the monitor hypothesis explains the positive association between NSRI holdings and returns, then the returns associated with NSRI holdings may be different for stocks with high and low KLD scores. Specifically, if the holdings reflect the influence of these institutions, the evidence of outperformance will be stronger in the high KLD subsample where there is likely to be a greater tendency for excess CSR expenditures. On the other hand, the alternative explanation that NSRIs have a singular focus on selecting stocks that outperform makes no such prediction.

We sort stocks independently by their prior period KLD strength ratings (above and below the median) and then estimate the regressions reported in Table 4 for each of the subsamples. As we show in Table 7, consistent with the monitoring hypothesis, the coefficients of $\Delta NSRIO$ are positive and marginal significant in the sample of low KLD firms but are highly significant in the sample with high KLD firms.

3.4. Are Changes in KLD Scores Predictable?

3.4.1. Do NSRIs' Holdings Predict Changes in KLD Scores?

In this section we explicitly examine whether the level of NSRI holdings predict changes in KLD scores. The monitoring hypothesis suggests that the presence of NSRIs can offset the tendency of firms to increase CSR activities over our sample period.

To test this hypothesis we regress changes in KLD scores on past NSRI holdings and other control variables. Because we assume that influencing a firm's tendency to act socially responsibly may take time, we examine the relation between NSRI ownership at the end of the second quarter in year t on changes in KLD scores over the following calendar year. For robustness, we replicate this analysis using NSRI ownership at the end of year t. We estimate these relationships for our full sample as well as for the sample of firms with above median KLD scores.

We start by sorting stocks into three portfolios based on *NSRI* ownership at the end of the second quarter of year t and record the average change in KLD scores from the end of year t to the end of year t+1 for the full sample as well as the high and low subsamples. These changes, reported in the columns marked "Full", "Low" and "High" in the upper panel of Table 8, reveal that KLD scores tend to increase over time, but increase less for firms with high KLD scores and less for firms with high NSRI ownership. We repeat the same procedure except that stocks are sorted by total institutional ownership (sum of NSRI ownership and SRI ownership) and report the results in the middle panel of Table 8. Unlike the pattern we see for NSRI ownership, KLD increases more for firms with high total institutional ownership than for firms with low total institutional ownership, suggesting the impact of NSRI ownership on KLD change is opposite to that of SRI ownership. The bottom panel of Table 8 reveals that NSRI ownership and SRI ownership have very different effects on KLD changes, especially for high KLD firms.

Table 9 examines these same relations with regressions that control for other factors that may influence CSR activities. We control for the asset size and the ROA in these regressions because larger and more profitable firms increased their engagement in CSR activities over our sample period. We also include the level of KLD in *year t* as a control variable to capture the possibility of mean reversion in a firm's KLD scores. In all regressions, we control for industry-year fixed effects and the t-statistics are calculated with standard errors clustered by firm.

Consistent with the monitoring hypothesis, we observe negative coefficients of *NSRIO* in model (1) in both the Full sample and the High KLD subsample, and as expected, the coefficients are more negative in the high KLD subsample. In model (2), we find that the coefficient of total *IO* (i.e. the sum of *NSRIO* and *SRIO*) is also significantly negative in both panels. But this effect mainly comes from *NSRIO;* in model (3), which includes both *NSRIO* and total *IO*, the coefficient of *IO* is significant only in the high KLD subsample and it has a positive sign.

3.4.2. The Relationship between Stock Returns and Future KLD Changes

Up to this point we documented two basic results that are consistent with the monitoring hypothesis. We showed in Table 4 that stocks experiencing an increase in NSRI ownership realize positive excess returns the following quarter, and then we showed in Table 9 that high *NSRIO* firms tend to reduce KLD scores (or increase them less) the following year. In this subsection we examine the relation between stock returns and future KLD scores.

To understand why stock returns may be related to future changes in KLD scores lets first consider the possibility that stock returns directly influence CSR choices. In particular, since firms with high stock returns are likely to have more favorable future prospects, they are better able to afford the luxury of increasing CSR expenditures. The evidence in Table 9, indicating that firms with higher ROA tend to have higher KLD scores, is consistent with the hypothesis that firms tend to spend more on CSR activities when they are doing relatively well.

The above argument suggests that high stock returns can lead to positive changes in KLD scores, which would create a positive correlation between these variables. Stock returns, however, may also be influenced by the anticipated changes in a firm's CSR activities, and this effect can create a negative correlation between these variables. In particular, if some firms have a tendency to over invest in CSR activities (relative to value maximization), higher anticipated future KLD scores can cause stock prices to decline and the lower anticipated future KLD scores can cause stock prices to rise. Hence, the correlation between stock returns and future changes in KLD scores can potentially be either positive or negative, depending on the importance of the two offsetting channels.

The tests that follow assume that the relative importance of these two channels depends on the ownership structure of the firm's stock. In particular, we test the hypothesis that when NSRIs are sufficiently influential, the causal channel running from stock returns to changes in CSR activity is substantially mitigated. Specifically, because of NSRI monitoring, the tendency of executives to increase CSR activity when stock returns are favorable is mitigated in firms with high NSRI ownership. In contrast, the relevance of the second channel does not depend on the ownership structure; if there is a tendency to overinvest in CSR activity, an increase (decrease) in anticipated KLD scores leads to lower (higher) values regardless of the firm's ownership structure. As a result, given the assumed tendency to overinvest in CSR activity, we expect to see a negative relation between stock returns and future KLD scores for the high NSRI ownership firms.

To test these predictions we add past stock returns and the interaction of past stock returns with NSRIO to the regressions reported in Table 9. Specifically, we measure NSRIO at the end of the second quarter of year t, and stock returns, *Qret(2)*, during the last two quarters of year t. We then interact these last two quarter stock returns with dummy variables for both high and low NSRIO (defined based on median yearly) and regress these variables, along with the variables described in Table 9, on future changes in KLD scores, i.e., the change from the end of year t to the end of year t+1.

Model (1) in Table 10 reports the regressions that include only past stock returns and ROA as predictors of changes in KLD scores. Consistent with the above arguments, we find that ROA is still positively associated with future changes in KLD scores, which is consistent with the Jensen (1986) free cash flow interpretation, i.e., firms invest more in CSR activities when they are generating more cash. On the other hand, stock return *Qret(2)* is insignificant, suggesting the effects from the two channels discussed above offset each other in the overall sample. However, after we separate the effects into those among high NSRIO firms and those among low NSRIO firms in model (2), a very different pattern emerges. Conditioned on high NSRIO, the positive effect of ROA on changes in KLD scores is mitigated as evidenced by the significantly positive Low NSRIO/ROA interaction and an insignificant High NSRIO/ROA interaction. The coefficients of the NSRIO and return interactions are similar, except for the very significant negative coefficient on the High NSRIO/return interaction variable, indicating that for High NSRIO firms, higher stock returns are associated with future reductions in KLD scores. This last result is consistent with the idea that expected CSR reductions are viewed favorably by market participants.

The Table 10 regressions are estimated separately for a sample that included only the firms with high KLD scores. A comparison of these regressions with the regressions on the entire sample reveals that the coefficient of ROA is twice as high in the estimates on the high KLD sample. This evidence is consistent with the idea that high KLD firms tend to overinvest in CSR activities, and that their tendency to do so is greater when ROA is higher. However, this subsample generates even stronger evidence that expected reductions in CSR activities are viewed favorably by market participants for high NSRIO firms.

4. Conclusion

We expect that all else equal, corporate executives prefer to be viewed as socially responsible, and are thus willing to sacrifice at least some value to achieve a higher social responsibility score. The tradeoff between being seen as socially responsible and acting to maximize shareholder value is also likely to be true for portfolio managers. Of course, different managers have different tastes for social responsibility and are likely to view these tradeoffs differently, leading to cross-sectional differences in the corporate responsibility scores of both firms and institutional investors. Consistent with this view, the evidence suggests that investors with relatively less focus on social responsibility, and implicitly, more focus on returns, achieve slightly higher returns on average.

Our evidence, which exploits observed differences in the tastes of institutional investors, also provides evidence that institutions can influence corporate behavior. In particular, we find that firms that are held more by the "not socially responsible institutions" tend to increase their socially responsible activities less than other firms. In addition, we provide indirect evidence, consistent with the above tradeoff, that higher levels of socially responsible activities tend to be negatively associated with firm value. Specifically, we find that on average, stock returns are positive following increases in the holdings of the NSRIs, and for those firms with higher NSRI holdings, higher stock returns are negatively associated with future changes in socially responsible activities.

Appendix A: Variable Definitions

This appendix presents the detailed definitions of the variables used in the analyses and regressions. NSRI represents Non-Social Responsible Institution and SRI represents Social Responsible Institution.

Variables	Definitions
Institutional Ownership Variables	
IO_t	Total institutional ownership at the end of quarter t, which is defined as shares held by all institutions divided by total shares outstanding.
ΔIO	Change in total institutional ownership from quarter t-1 to t.
$NSRIO_t$	Total NSRI ownership at the end of quarter t, which is defined as shares held by all NSRIs divided by total shares outstanding.
$\Delta NSRIO$	Change in total NSRI ownership from quarter t-1 to t.
$SRIO_t$	Total SRI ownership at the end of quarter t, which is defined as shares held by all SRIs divided by total shares outstanding.
$\Delta SRIO$	Change in total SRI ownership from quarter t-1 to t.
$NSRIO\_NONT4_t$	Total non-type 4 NSRI ownership at the end of quarter t, which is defined as shares held by all non-Type 4 NSRIs divided by total shares outstanding.
$\Delta NSRIO\_NONT4$	Change in total non-type 4 NSRI ownership from quarter t-1 to t.
$NSRIO\_T4_t$	Total type 4 NSRI ownership at the end of quarter t, which is defined as shares held by all Type 4 NSRIs divided by total shares outstanding.
$\Delta NSRIO\_T4$	Change in total type 4 NSRI ownership from quarter t-1 to t.
IO_T4	Total type 4 institutional ownership at the end of quarter t, which is defined as shares held by all Type 4 institutions divided by total shares outstanding.
ΔIO_T4	Change in total type 4 institutional ownership from quarter t-1 to t.
Stock Return and Turnover Variables	
$Qret_{t+1}$	Firm's buy and hold stock returns from quarter t to t+1.
$Qret(2)$	Firm's buy and hold stock returns from quarter t to t+2.
$RET_{t-3,t}$	Firm's 3-month gross stock return from month t-3 to t.
$RET_{t-12,t-3}$	Firm's 9-month gross stock return from month t-12 to t-3.
Logturnover	The log of average monthly stock turnover over previous quarter.
Logprice	The log of quarter end stock price.
Logvol	The log of stock return volatility, which is calculated as the variance of monthly returns over previous two years.
Firm Characteristics Variables	
KLD	Firm's KLD strengths score.
Logage	The log of the number of months since the first return of the stock appears in CRSP.
SP500	A dummy variable indicating S&P 500 membership.
Financial Variables	
Logbm	The log of firm's book-to-market value, which is defined as the book value of the firm for the fiscal year ended before the most recent Jun 30, divided by firm size as of Dec 31 during that fiscal year.
Logsize	The log of firm size, which is defined as the quarter end market capitalization.
LogCDV	The log of scaled cash dividend, which is defined as the cash dividends for the fiscal year ended before the most recent Jun 30, scaled by firm size as of Dec 31 in that fiscal year.
LogAssets	The log of firm's total assets.
ROA	Return on asset, which is defined as $EBITDA_t$ divided by Total $Assets_{t-1}$.

Appendix B: Indicators of KLD Qualitative Issue Areas

This Appendix provides detailed definitions of KLD strength indicators in all seven major KLD Qualitative Issue Areas with 2008 scores for Coca-Cola Company and PepsiCo, Inc. for illustration purpose.[10] KLD indicates a score of positive one for a strength of a company in a particular issue. If the company did not have a strength in that issue, a score of zero will be indicated. A company's KLD strength score is the summation of all positive ones in the qualitative issues.

Indicators	Definitions	Coca-Cola	Pepsi
Community Indicators		**2**	**2**
Charitable Giving	The firm has consistently given over 1.5% of trailing three-year net EBT to charity, or has otherwise been notably generous in its giving.	0	0
Innovative Giving	The firm has a notably innovative giving program that supports nonprofit organizations.	0	0
Non-US Charitable Giving	The firm must make at least 20% of its giving, or have taken notably innovative initiatives in its giving program outside the US.	1	1
Support for Housing	The firm is a prominent participant in public/private partnerships that support housing initiatives for the economically disadvantaged.	0	0
Support for Education	The firm has been notably innovative in its support for primary or secondary school education, or job-training programs for youth.	1	1
Volunteer Programs	The firm has an exceptionally strong volunteer program.	0	0
Other Strength	The firm has either an exceptionally strong in-kind giving program or engages in other notably positive community activities.	0	0
Corporate Governance Indicators		**2**	**2**
Limited Compensation	Recently, total annual compensation is less than $500,000 for a CEO or $30,000 for outside directors.	0	0
Ownership	The firm owns between 20% and 50% of another firm KLD has cited as having an area of social strength, or is more than 20% owned by a firm that KLD as having social strengths.	0	0
Transparency	The firm is effective in reporting on social and environmental performance measures.	1	1
Political Accountability	The firm has shown markedly responsible leadership on public policy issues and/or has an exceptional record of transparency and accountability concerning its political involvement in state or federal-level U.S. politics, or in non-U.S. politics.	1	1
Other Strength	The firm has a unique and positive corporate culture, or has undertaken a noteworthy initiative not covered by KLD's other corporate governance ratings.	0	0
Diversity Indicators		**4**	**4**
CEO	The firm's CEO is a woman or a member of a minority group.	0	1
Promotion	The firm has made notable progress in the promotion of women and minorities.	1	0
Board of Directors	Women, minorities, and/or the disabled hold 4 seats or more on the board, or 1/3 or more if the board size less than 12.	0	1
Work/Life Benefits	The firm has outstanding employee benefits programs addressing work/life concerns like childcare, elder care or flextime.	1	0
Women & Minority Contracting	The firm does at least 5% of its subcontracting, or has a strong record on contracting with women/minority-owned businesses.	1	1
Employment of the Disabled	The firm has taken hiring programs for the disabled, or has a superior reputation as an employer of the disabled	0	0

[10] More information on KLD indicators of qualitative issue areas can be found in the manual provided in WRDS database. https://wrds-web.wharton.upenn.edu/wrds/support/Data/_001Manuals%20and%20Overviews/_070KLD/index.cfm

Appendix B (*Continued*)

Indicators	Definitions	Coca-Cola	Pepsi
Diversity Indicators ***(continue)***			
Gay & Lesbian	The firm has implemented notably progressive policies toward its gay and lesbian employees.	1	1
Other Strength	The firm has made a notable commitment to diversity not covered by other KLD ratings.	0	0
Employee Relations Indicators		**0**	**2**
Union Relations	The firm has taken exceptional steps to treat its unionized workforce fairly.	0	0
Cash Profit Sharing	The firm has a cash profit-sharing program and has recently made distributions to a majority of its workforce.	0	0
Employee Involvement	The firm strongly encourages worker involvement and/or ownership through stock options available to a majority of its employees.	0	1
Retirement Benefits	The firm has a notably strong retirement benefits program.	0	0
Health and Safety	The firm has strong health and safety programs.	0	1
Other Strength	The firm has strong employee relations initiatives not covered by other KLD ratings.	0	0
Environment Indicators		**3**	**3**
Beneficial Products & Services	The firm derives substantial revenues from innovative remediation products, environmental services, or products that promote the efficient use of energy, or it has developed innovative products with environmental benefits.	0	0
Pollution Prevention	The firm has notably strong pollution prevention programs including both emissions reductions and toxic-use reduction programs.	0	0
Recycling	The firm is a substantial user of recycled materials as raw materials in its manufacturing processes, or a major factor in the recycling industry.	1	0
Clean Energy	The firm has taken significant measures to reduce its impact on climate change and air pollution through use of renewable energy and clean fuels.	0	1
Management Systems	The firm has demonstrated a superior commitment to management systems through ISO 14001 certification and other voluntary programs.	1	1
Other Strength	The firm has demonstrated a superior commitment to management systems, voluntary programs, or other environmentally proactive activities.	1	1
Human Rights Indicators		**1**	**0**
Indigenous Peoples Relations	The firm has established relations with indigenous peoples near its proposed or current operations.	0	0
Labor Rights	The firm has great transparency on overseas sourcing disclosure and monitoring, or has particularly good union relations outside the U.S., or has undertaken labor rights-related initiatives.	0	0
Other Strength	The firm has undertaken exceptional human rights initiatives, or has shown industry leadership on human rights issues not covered by other KLD ratings.	1	0
Product Indicators		**0**	**0**
Quality	The firm has a long-term, well-developed, company-wide quality program, or it has a quality program recognized as exceptional in U.S. industry.	0	0
R&D/Innovation	The firm is a leader in its industry for R&D particularly by bringing notably innovative products to market.	0	0
Economically Disadvantaged	The firm has as part of its basic mission the provision of products or services for the economically disadvantaged.	0	0
Other Strength	The firm's products have notable social benefits that are highly unusual or unique for its industry.	0	0
Total		**12**	**13**

Appendix C: Summary of KLD Scores

This appendix presents the distribution of KLD strength indicators and scores of all the firms covered in KLD STATS from 2003 to 2011 across seven major qualitative issues.

KLD Strength Scores Summary				
	No. of Indicators	KLD strength Scores		
		Min	Median	Max
Community Issues	8	0	0	5
Corporate Governance Issues	6	0	0	3
Diversity Issues	9	0	0	7
Employee Relations Issues	8	0	0	5
Environment Issues	7	0	0	4
Human Rights Issues	4	0	0	1
Product Issues	5	0	0	3
All Strength Issues	47	0	1	22

Figure 1: Trend of KLD

This figure shows the trend of average KLD strength scores of firms in our sample from 2003 to 2011.

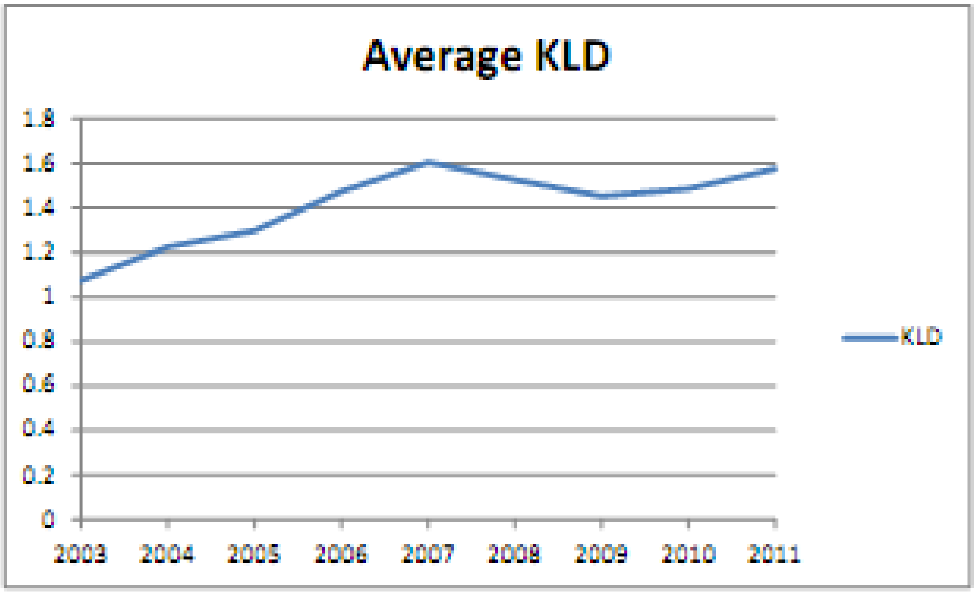

Table 1: Summary Statistics

This table shows the time-series average of cross-sectional values and correlations of institutional ownerships, change in institutional ownerships, firms' KLD strength scores and other stock and firm characteristics from 2003:Q1 to 2011:Q4. Panel A presents the time-series mean, median, standard deviation, minimum and maximum of the variables and Panel B presents the correlations between each variable. We obtained quarterly institutional ownership values from Thomason Financial database and calculated KLD strength scores based on the issues indicators provided by KLD STATS database. Each quarter, we sort institutions into three groups according to value weighted Corporate Social Responsibility (CSR) scores of their portfolio holdings, with the institutions in the bottom group, which have the lowest scores, defined as Non-Social Responsible Institutions (NSRIs) and the rest of the institutions defined as Social Responsible Institutions (SRIs). The definitions of all the variables are described in Appendix A. Superscripts ***, **, * denote statistical significance at the 1%, 5% and 10% levels, respectively.

Panel A: Time-Series Average of Cross-Sectional Values

	Mean	Median	Standard Deviation	Minimum	Maximum
IO(%)	66.99	71.97	22.44	0.88	99.95
ΔIO(%)	0.12	0.20	6.01	-76.82	61.77
NSRIO(%)	15.30	13.43	11.33	0.03	88.06
ΔNSRIO(%)	0.06	0.02	4.62	-39.87	40.77
KLD	1.39	1.00	2.15	0.00	18.49
MV($mil.)	5823.43	1112.73	19913.89	14.10	379515.28
B/M	0.60	0.50	0.52	0.00	8.09
Price($)	35.02	22.84	304.53	0.49	14443.79
Volatility	0.02	0.01	0.05	0.00	2.11
Turnover	1.54	1.18	1.47	0.03	22.41

Table 3: Institutional Types of NSRI

This table reports the distributions of institutional types. Institutions are classified into 5 types (Type X=1, 2, 3, 4 and 5) based on Brian Bushee's institutional classifications. Each quarter, we calculate three percentage measures and report the time-series average of the percentages in the table. They are (1) Percentage of total institutional ownership that are from Type X institutions, calculated as the ownership of Type X institutions divided by the total institutional ownership, (2) Percentage of NSRI ownership that are from Type X institutions, calculated as the ownership of Type X NSRI divided by the NSRI ownership and (3) Percentage of Type X institutional ownership that are from NSRI, calculated as the ownership of Type X NSRI divided by the Type X institutional ownership.

Type X	1	2	3	4	5
Percentage of total institutional ownership that are from Type X institutions	18.06	5.08	15.37	52.94	7.90
Percentage of NSRI ownership that are from Type X institutions	0.24	1.16	4.35	84.74	9.49
Percentage of Type X institutional ownership that are from NSRI	0.31	5.21	6.44	36.40	27.33

Table 4: NSRI Ownership and Future Returns

This table examines the effects of change in NSRI ownerships in quarter t ($\Delta NSRIO$) on next quarter stock returns ($Qret_{t+1}$) using Fama-MacBeth regressions from 2003:Q1 to 2011:Q4. $NSRIO_{t-1}$ is the non-social responsible institutional ownership in a particular stock at the end of quarter t-1. IO_{t-1} is the total institutional ownership in a particular stock at the end of quarter t-1 and ΔIO is the change in total institutional ownership in quarter t. *KLD* is the KLD strength scores of a particular stock at the end of previous calendar year. Other variables including *Logbm*, *Logsize*, *Logvol*, *Logturnover*, *Logprice*, $Ret_{t-1,t-3}$, $Ret_{t-12,t-3}$, *Logage*, *SP500*, *LogCDV* and Fama-French 48 industries are also controlled and their definitions can be found in Appendix A. The Newey-West adjusted t-statistics are presented in the parenthesis and superscripts ***, **, * denote statistical significance at the 1%, 5% and 10% levels, respectively.

	(1)	(2)	(3)	(4)
$\Delta NSRIO$	0.0899^{***}	0.1054^{***}	0.0769^{***}	0.1000^{***}
	(3.03)	(2.90)	(3.05)	(3.07)
$NSRIO_{t-1}$	0.0439^{*}	0.0298	0.0305^{**}	0.0314^{*}
	(2.00)	(1.56)	(2.16)	(2.01)
ΔIO		-0.0728^{**}		-0.0691^{**}
		(-2.09)		(-2.39)
IO_{t-1}		0.0115		-0.0025
		(1.33)		(-0.24)
KLD	0.0003	0.0002	0.0007	0.0006
	(0.38)	(0.30)	(1.08)	(1.02)
Intercept	-0.0015	-0.0034	0.0088	0.0078
	(-0.03)	(-0.07)	(0.13)	(0.12)
Control variables	Yes	Yes	Yes	Yes
Industry dummy	No	No	Yes	Yes
Observations	75,507	75,507	75,507	75,507
Adj-R^2	0.075	0.077	0.133	0.135

Table 5: Portfolio Returns for NSRI and SRI

The table reports the average holding period (quarter) returns of portfolios constructed based on the change in the NSRI ownership (ΔNSRIO) and SRI ownership (ΔSRIO) from 2003:Q1 to 2011:Q4. At the end of each quarter, we sort all stocks into 5 equally weighted portfolios based on $\Delta NSRIO$ and $\Delta SRIO$ respectively. Stocks in Portfolio 1 have the smallest change in ownership and stocks in Portfolio 5 have the largest change in ownership. Then we calculate and report the time-series average of both raw returns and DGTW benchmark adjusted returns for all the 5 portfolios. 'High-Low' is the average hedge portfolio return by purchasing portfolio 5 and shorting portfolio 1. 'HL($\Delta NSRIO$)-HL($\Delta SRIO$)' is the average difference between hedge portfolio return of $\Delta NSRIO$ and hedge portfolio return of $\Delta SRIO$. The Newey-West adjusted t-statistics are presented in the parenthesis and superscripts ***, **, * denote statistical significance at the 1%, 5% and 10% levels, respectively.

	Raw Return		DGTW Adjusted Return	
	$\Delta NSRIO$	$\Delta SRIO$	$\Delta NSRIO$	$\Delta SRIO$
1 (Low)	0.0283	0.0490	0.0024	0.0193
2	0.0269	0.0374	0.0021	0.0109
3	0.0283	0.0280	0.0052	0.0039
4	0.0368	0.0267	0.0099	0.0025
5 (High)	0.0437	0.0227	0.0137	-0.0037
High-Low	0.0154**	-0.0263**	0.0113***	-0.0230**
	(2.68)	(-2.20)	(2.80)	(-2.36)
HL($\Delta NSRIO$)-HL($\Delta SRIO$)	0.0417***		0.0343***	
	(2.79)		(3.04)	

Table 6: The Relation between Type 4 and Non-Type 4 NSRI Ownership and Next Quarter's Return

This table examines the effects of changes in Type 4 NSRI ownership ($\Delta NSRIO\_T4$) and Non-Type 4 NSRI ownership ($\Delta NSRIO\_NONT4$) in quarter t on quarter t+1 stock returns ($Qret_{t+1}$) using Fama-MacBeth regressions from 2003:Q1 to 2011:Q4. Institutions are classified into five types based on Brian Bushee's institutional classifications. $NSRIO\_T4_{t-1}$($NSRIO\_NONT4_{t-1}$) is the Type 4 (non-Type 4) non-social responsible institutional ownership in a particular stock at the end of quarter t-1. IO_{t-1} is the total institutional ownership in a particular stock at the end of quarter t-1 and ΔIO is the change in total institutional ownership in quarter t. IO_T4_{t-1} is the total type 4 institutional ownership in a particular stock at the end of quarter t-1 and ΔIO_T4 is the change in total Type 4 institutional ownership in quarter t. KLD is the KLD strength scores of a particular stock at the end of previous calendar year. Other variables including *Logbm*, *Logsize*, *Logvol*, *Logturnover*, *Logprice*, $Ret_{t-1,t-3}$, $Ret_{t-12,t-3}$, *Logage*, *SP500*, *LogCDV* and Fama-French 48 industries are also controlled and their definitions can be found in Appendix A. The Newey-West adjusted t-statistics are presented in the parenthesis and superscripts ***, **, * denote statistical significance at the 1%, 5% and 10% levels, respectively.

	(1)	(2)	(3)	(4)

Table 7: The Relation between NSRI Ownership and Next Quarter's Return: KLD Strengths Subsamples Analyses

This table presents Fama-MacBeth regressions of changes in NSRI ownerships in quarter t (*ΔNSRIO*) on next quarter's stock returns ($Qret_{t+1}$) on subsamples for stocks with above and below median KLD strength scores measured at the previous calendar year end. $NSRIO_{t-1}$ is the NSRI ownership in a particular stock at the end of quarter t-1. IO_{t-1} is the total institutional ownership in a particular stock at the end of quarter t-1 and *ΔIO* is the change in total institutional ownership in quarter t. *KLD* is the KLD strength score of a particular stock at the end of previous calendar year. Other variables including *Logbm*, *Logsize*, *Logvol*, *Logturnover*, *Logprice*, $Ret_{t-1,t-3}$, $Ret_{t-12,t-4}$, *Logage*, *SP500*, *LogCDV* and Fama-French 48 industries are also controlled and their definitions can be found in Appendix A. The Newey-West adjusted t-statistics are presented in the parenthesis and superscripts ***, **, * denote statistical significance at the 1%, 5% and 10% levels, respectively.

	Low KLD subsample		High KLD subsample

Table 8: Change of Firm's CSR and NSRI Ownership

The table reports the change of KLD in t+1 for portfolios sorted on the $NSRIO_t$ (IO_t) and KLD. $NSRIO_t$ is the ownership of NSRI at the end of the second quarter and IO_t is the ownership of all the institutions at the end of the second quarter in the current calendar year t. KLD is the KLD strength score of a particular stock at the end of year t. Each year, we sort all stocks into 3 equally weighted portfolios based on the $NSRIO_t$ and IO_t, respectively. Stocks in Portfolio 1 have the smallest ownership and stocks in Portfolio 3 have the largest ownership. A firm is classified as low KLD if its KLD is lower than the cross-sectional median at the end of year t. Otherwise, it is classified as high KLD. The Full portfolio includes all stocks. We calculate and report the time-series average of the change in KLD from the end of year t to the end of year t+1 for all portfolios. 'High-Low' is the average change of KLD for the hedge portfolio that purchases portfolio 3 and shorts portfolio 1. '$NSRIO_t$ - IO_t' is the average difference between the change in KLD for the respective portfolios formed based on $NSRIO_t$ and IO_t. The Newey-West adjusted t-statistics are presented in the parenthesis and superscripts ***, **, * denote statistical significance at the 1%, 5% and 10% levels, respectively.

Table 9: The Effects of NSRI Ownership on Firm's CSR

This table reports pooled regressions of changes in KLD scores on lagged NSRI ownership and other control variables. $NSRIO_t$ is the ownership of NSRI at the end of the second quarter and IO_t is the ownership of all the institutions at the end of the second quarter in current calendar year t. *KLD* is the KLD strength score of a particular stock at the end of year t. The dependent variable is the change in a firm's KLD strength score from the end of year t to the end of year t+1. High KLD subsample includes all stocks whose KLD strength scores at the end of year t are above the cross-sectional median. Fama-French 48 industries and year dummies are included as controls and all the other control variables are defined in Appendix A. Standard errors are clustered by firms. The t-statistics are presented in the parenthesis and superscripts ***, **, * denote statistical significance at the 1%, 5% and 10% levels, respectively.

Futures prices reflect the price that both the buyer and the seller agree will be the price of a commodity upon delivery. Therefore, these prices provide direct information about investor's expectations about the future price of the commodity of interest. This purpose of this research is two-fold. First, the research investigates the predictive accuracy and biasedness of futures prices predictions from reverse regression using in-sample criteria as well as from the performance of the models based upon ex post forecasts generated by alternative time series models. Second, following earlier investigations, an effort is made to understand the extent to which the spot energy (oil) price contains information content in the current period useful for predicting the forward-looking variable. The working hypothesis is that both own-commodity spot prices and spot energy (oil) prices are significant predictors of future commodity prices at alternative leads (lags).

I. Introduction

Futures prices reflect the price that both the buyer and the seller agree will be the price of a commodity upon delivery. Therefore, these prices provide direct information about investor's expectations about the future price of the commodity of interest. This purpose of this research is two-fold. First, this research attempts to give insight into the relationship between futures and spot prices for commodities by evaluating the empirical forecasting performance of spot prices. The working hypothesis is that both own-commodity spot prices and spot energy (oil) prices are significant predictors of future commodity prices at alternative leads (lags).

This article reports on the predictive accuracy and biasedness of futures prices predictions from in- sample goodness-of-fit and from the performance of *ex post* forecasts generated by alternative time series models. Second, following earlier investigations an effort is made to investigate the contribution that the spot energy (oil) price makes to improving in-sample fit and *ex post* forecast performance.

In support of the these research interests, forecasting futures prices is understood to be a key input to a profitable futures trading strategy (Gradnitski and Osborn, 1993) and past research going back at least as far as Frank and Stengos (1989), Blank (1991), and DeCoster et al. (1992) has made clear that futures prices follow non-linear processes. The importance of energy markets in explaining volatility in agricultural commodities prices has been a topic of considerable interest. The oil price transmission to agricultural commodity prices states that a rise in oil prices results in higher agricultural commodity prices by increasing costs of production through its impacts on fertilizer, chemicals, transportation costs, and other inputs. Scholarly work focused on the relationship between the energy sector and agricultural commodities has been published by, Yu, Bessler and Fuller (2006), Baffes (2007), Zhang and Reed(2008), Muhammed, A. and Kebede, E. (2009), Balcombe(2010), Gilbert (2010a, 2010b), Saghaian (2010), Nazlioglu, S. (2011), Trujillo-Barrera, Mallory, and Garcia (2012), and Cartwright and Riabko (2015a, 2015b). Baffes (2007) reports that among non-energy commodities, oil prices have the highest pass-through to food commodities and fertilizers. Saghaian (2010) using time-series and directed graph theory approaches, finds a correlation between oil and commodity prices, but the evidence of a (Granger) causal link is mixed. Cartwright and Riabko (2015a, 2015b) find mixed results depending on temporal aggregation and model specification. Campiche, Bryant, Richardson and Outlaw (2007) examined the covariability between crude oil prices and corn, sorghum, sugar, soybeans, soybean oil and palm oil prices over the period 2003-2007. Issues concerning time series modelling of commodity prices, and oil prices in particular, can also be found in the papers by Bopp and Lady (1991), Chen, Kuo, and Chen (2010), Chen and Lin (2014). The literature indicates that indicates the relationship between oil prices and those of agricultural commodities if far from clear-cut justifying ongoing study.

In Section II, in order to clarify interest in this research, literature relevant to linkages between prices of arable crops and oil prices is summarized. Section III discusses the data used in the study and Section IV describes the methodology which is based on reverse regressions (Campbell and Shiller (1987), Engel and West (2005), and Chen, Rogoff and Rossi (2008)) this paper formulates time series models for prediction of commodity futures prices using the spot prices of the commodity in question as well as taking into consideration information content in the oil spot price at period t of use for predicting the future futures price. Following Engle (1982), Bollerslev (1986), Bollerslev, T., Engle, R.F. and Nelson (1994) and Engle (2002) the first models of interest in this research are the generalized autoregressive conditional heteroscedastic (GARCH) models. Second, exponential generalized autoregressive conditional heteroscedastic (EGARCH) models (Nelson (1991)) are considered.

Section V of the paper discusses the results in detail focusing, first, on the daily results and, second on models based on weekly specifications. Estimation results for the full sample are considered as well as the outcomes from *ex post* forecasting. Section VI provides a summary of the paper and conclusions.

II. Linkages between prices of arable crops and oil prices

In "Deconstructing Wheat Price Spikes: A Model of Supply and Demand, Financial Speculation, and Commodity Price Comovement" (Janzen, Carter, Smith, and Adjemian, 2014) it is recognized that wheat futures prices spiked in early 2008 before rapidly crashing, though this hardly makes wheat market unique. Other commodities such as crude oil, natural gas, corn, and cotton exhibited price spikes and crashes at around the same time. But the magnitude of the wheat price spike combined with the coincidence of these other extreme price movements' raises important questions. Specifically, it is of interest to know whether wheat, or other agricultural commodities prices, responds to the same of economic factors.

Taking wheat as a case of interest and one of five agricultural commodities studied in this research, the three mayor classes of wheat grown in the United States are traded on three separate futures markets (hard red winter, Kansas City, hard red spring, Minneapolis, and soft red winter, Chicago). Expiring futures prices, particularly in Chicago and Kansas City, are known to routinely far exceed the prevailing cash price in their respective delivery markets, a phenomenon known as non-convergence. Wheat specific factors that contribute to price volatility may have either supply or demand origins, but consistent with price variation for most agricultural commodities, supply shocks appear to dominate short run variation in wheat prices. Following Janzen, Adjemian and Smith (2012), once the crop is planted, supply is virtually perfectly inelastic, and shocks that shift the supply curve cause most price changes. Since 1960, the global wheat supply has grown steadily, nearly tripling during the period. The US share of global wheat production has declined over time, but the United States remains a major producer. Soft red wheat (SRW) analyzed in this research paper together with hard red spring (HRS) wheat made up 23 and 20 percent of US 2011 production, respectively. Since 2004, wheat prices have risen and reminded at historically elevated levels. The presence of three wheat futures contracts conflicts with the demand from wheat futures traders for market liquidity, especially among speculators (Silber, 1981). Futures trading volume in wheat has grown rapidly in the 2000s, especially in the CBOT market. In 2011, the traded wheat amounts in KCBT and MGEX increased as well. It is unclear whether this reflects the consolidation of trading on a single exchange, as trading volume has prices may be an alternative mechanism by which financial speculation and the presence of commodity index traders affect agricultural commodity prices. The same study finds correlation between many commodity prices and the price of crude oil, the most widely traded commodity futures contract, which rose over the period in which CIT trading became prevalent. This effect was stronger for commodities included in major indexes than for non-index commodities. According to Tang and Xiong (2012) after testing the linkage between returns for many non-energy commodities and crude oil they concluded that this co-movement among prices was driven by the inclusion of commodities into major indexes such as GSCI and the DJ-UBSCI.

According to Janzen, Carter, Smith and M.K. Adjemian (2014), to separate precautionary demand from co movement related to CIT's, one must recognize that financialization, or an increase in the influence of financial markets and institutions , affected many commodities at the same time including both wheat and crude oil prices. Their study measures the extent to which wheat prices move together with external commodities such as crude oil when movements are not explained by fluctuations in supply drivers such as weather, demand drivers related to economic activity or expectations about future price movement. If the implications of the financialization hypothesis are correct, it should follow that non-agricultural commodity prices have to some extent driven wheat prices changes. According to Tang and Xiong (2012), the strength of the relationship between wheat and crude oil prices should have increased since 2004. Their analysis is repeated using the value of the GSCI, introduced earlier as an alternate measure of external market price movement. It represents a basket of commodity prices with heavy weight placed on energy commodities. However, according to J.P. Janzen, C.A. Carter, A.D. Smith and M.K. Adjemian (2014) there is little evidence of co-movement-driven price effect associated with commodity index traders. These researchers suggest that wheat futures markets perform efficiently in the sense that wheat futures prices have reflected fundamental factors.

Baumeister and L. Kilian (2013) investigated evidence for a link from oil prices to food prices and they examine the transmission of oil price shocks to food prices both prior to and after the change in US biofuel policies in 2006. According to Baumeister and L. Kilian (2013), historically the food price increases associated with corn, wheat, soybeans and rice can be seen in response to prices paid by US farmers for agricultural inputs such as fuel, fertilizer and animal feed. The prices received by US farmers closely mirror the spot prices quoted on commodity exchanges and reported by the International Monetary Fund. The paper shows a stronger statistical relationship between oil prices and the grain crop prices received by US farmers pointing toward consideration of the degree of co- movement of agricultural products and oil prices and the extent to which this co-movement has strengthened in recent years.

After May 2006, the co-movement between the real price of oil and real agricultural product prices became more pronounced, but still weak overall. One possible explanation is that the increased co-movement reflects increased demand for oil in emerging economies. Another potential explanation is that higher oil prices are associated with increased prices for agricultural inputs that drive up crop prices. Other views suggest that US Agricultural policies created a tighter link from oil prices to agricultural product prices, or perhaps, the price movements are due to financialization of global commodity markets after 2003. Findings show that only the growth rate of wheat prices exhibit a similar increase in volatility as that for oil over the time period January 1974 to May 2013. In contrast, corn prices increase by only 10 percent, soybean prices actually fell by 5 percent and the price of rice declined by 30 percent. Moreover, comparing wheat and corn, evidence shows that the smaller volatility increases apply to the growth in the real price of corn, which one might expect to be most exposed to higher oil price volatility. Findings also show that the positive spike in the growth rate of real retail food prices coincides with the negative spike in the growth rate of the real price of oil; however, there is no large spike in either direction in the growth rate of the real price of corn. Thus, this finding shows that only fuel prices, but not fertilizer or animal feed prices, responded to this exogenous oil price shock. It follows that proponents of such a causal link must make the case that the hypothesized link between prices emerged only in recent years.

A natural candidate for a structural market shift is changes in US biofuel policies. Baumeister and Kilian (2013) suggest that the obvious source of higher food prices is increases in the prices of raw agricultural products driven by higher oil prices. More generally, the macroeconomic determinants of the real price of oil would also be expected to raise the real price of wheat and soybeans, although not to the same extent, as higher incomes in emerging economies alter food consumption patterns. From the viewpoint of US farmers and US consumers, the impact of excess variability in the price of diesel is similar to an oil price shock, except that it does not involve a simultaneous change in the global demand for food and agricultural crops by construction. This observation suggests that one could interpret the unexpected variation in the US diesel price spread as a domestic diesel price shock, which may reflect either exogenous variation in US refining or US specific variation in the demand for US diesel fuel. A finding that that food prices significantly respond to diesel price spread shocks, could lead to the conclusion that higher oil prices cause higher crop prices and food prices. In the absence of such evidence, earlier claims supporting such a link would seem to reflect shifts in the global demand with no independent role for oil prices. According to Kilian and Hicks (2013), Kilian and Murphy (2013), and Kilian and Lee (2013) the real oil price shocks since 2003 have primarily reflected global shocks to the flow demand for oil associated with unexpected industrial growth in emerging Asia. Thus, an alternative interpretation is that increases in the real price of oil and increases in real crop prices in recent years have shared a common component that is associated with fluctuations in the global real activity and incomes. Baumeister and Kilian (2013) point out that the increases in the real price of wheat in 2007 are not mirrored by similar increases in the real price of corn or soybeans, suggesting an idiosyncratic supply or demand shock in the wheat market in 2007 and 2008, which includes domestic supply shocks as well as fluctuations in foreign demand for US crops and in foreign supplies of crops competing with US crops. Finally, Baumeister and Kilian (2013) provide evidence that there has been no systematically increased food price volatility. Only for wheat is there any evidence of a noticeable increase in price volatility and the reasons appear to be idiosyncratic rather than systematic.

According to Baffes (2013), some models suggest that the direct energy component of agriculture alone is four to five times higher than for manufacturing sectors. As an energy-intensive sector, agriculture plays a big role on the demand-side of the energy equation. The sector is directly affected by high and volatile world oil prices that, in turn, affect the cost of agricultural production (Nazlioglu and Soytas, 2011). Over the last few decades, high energy prices increase the costs of producing agricultural products that yield food, feed, energy and fiber. Economic theory suggests that increasing crude oil prices directly affect agricultural prices through higher input and transportation costs (Gardebroek and Hernandez, 2013).

Recent empirical research suggests there is an indirect link of varying magnitude between the prices (Alghalith, 2010; Esmaeili and Shokoohi, 2011; Ciaian and Kancs, 2011). In contrast, Gohin and Chantret (2010) find a negative impact of petroleum prices on agricultural prices when employing a general equilibrium model with fully specified macroeconomic linkages. According to Nigatu, Hjort, Hansen, and Somwaru (2014), price expectations for those commodities where futures markets do not exist may be based on futures prices of closely related commodities and (or) on trends in domestic or regional prices. Similarly, producers in importing countries are more likely to develop price expectations based on trends in local or national market prices. The results of Nigatu, Hjort, Hansen, and Somwaru (2014) suggest two scenarios where the high petroleum price scenario begins with a 37 percent price increase in 2015, which climbs to about 61 percent above the reference price in 2018, and then declines gradually to 49 percent above the 2022 reference price. The low oil price projection is more uniform, with crude oil prices falling 25 percent in 2015, and then gradually declining to 36 percent below the base price in 2022. Price shocks of these magnitudes have significant impacts on corn, soybean, wheat and rice production costs. The projected high and low energy prices produce less than a 1 percent change in the production of major commodities in the United States by the year 2022.

Except for rice, US producers are expected to decrease the production of other crops in anticipation of high energy prices and vice versa. It is projected that there is relatively little or no change in the production of corn and soybeans, the two most important feed stocks for ethanol and biodiesel production, respectively. US wheat producers are somewhat more responsive to the changes in energy prices, reducing production by 0.6 percent with high oil prices.

According to the OECD report on food rising prices (2008), price for wheat, coarse grains, and rice and oilseed crops nearly doubled between the 2005 and 2007 marketing years. The causes are complex and due to a combination of mutually reinforcing factors including droughts in key grain producing regions, low stocks for cereals and oilseeds, increased feedstock use in the production of biofuels, rapidly rising oil prices and a continuing devaluation of the US dollar, the currency in which indicator prices for these commodities are typically quoted. The oil price, and energy prices in general, is a critically important contributing factor to the increase in production costs for agricultural commodities and food, and ultimately, in the market prices for these goods. Price projections discussed in the OECD report reflect the widely held belief that the oil price increases are permanent, lifting future prices to higher average levels. Demand for cereals for use as feed stocks in biofuel production is projected, under current policies, to almost double between 2007 and 2017, but the largest part of future growth in total use is explained by rising food and feed demand, particularly in countries outside the OECD area that are experiencing strong economic growth.

According to M. Patton, I. S. Kim, L. Zhang, J. Davis, J. Binfield and P. Westhoff (2012), there is a positive relationship between the crude oil price and the price of crops, but the rapeseed price is more correlated to oil price changes than wheat and barley. The oil market has always exerted an influence on the agricultural sector as an important determinant of input costs. A rise in the price of oil feeds through to the agricultural sector through higher costs of crop and livestock production, which leads to reductions in supply and hence, higher commodity prices. Ciaian and Kancs (2010) also demonstrate using co-integration analysis with world agricultural commodity prices and the world oil price that the influence of the energy market on the agricultural market has increased over time. The authors found limited evidence of co-integration pre-2004, but strong evidence of co-integration post-2004. Using impulse response functions the authors showed that the price transmission elasticity is higher for agricultural commodity goods that are also used for bioenergy purposes (sugar, soybeans, corn and wheat). As for the EU market, about 90 per cent of domestic bioethanol production is projected to come from wheat-based bioethanol. In response to increase of wheat-based bioethanol production, wheat demand for bioethanol production is projected to increase between 2010 and 2020. The expansion of the biofuels industry in the US mirrors that seen in the EU. In the US, however, it is ethanol that accounts for the majority of biofuels consumed and this is almost all produced from maize. At this time, as much maize goes into ethanol as goes into feed in the US, and this has increased the link between developments in oil markets and agricultural markets. M. Patton, I. S. Kim, L. Zhang, J. Davis, J. Binfield and P. Westhoff (2012) show in their research regarding the relationship between oil prices and maize prices for the US, increasing oil prices initially have no impact on maize prices, but higher oil prices make ethanol from maize competitive. Within this study, a partial equilibrium modelling system is used to examine the extent to which price volatility in the energy sector is transmitted to the biofuel and agricultural sectors. The stochastic results indicate that there is a positive correlation between crude oil prices, biofuels prices and feedstock prices.

The study by Nazlioglu extends the literature on the oil–agricultural commodity prices nexus, concentrating on nonlinear causal relationships between the world oil and three key agricultural commodity prices (corn, soybeans, and wheat). On the one hand, it is found that the agricultural commodity prices and oil prices do not cause each other, supporting the neutrality hypothesis (for instance, Yu et al., 2006; Zhang and Reed, 2008; Kaltalioglu and Soytas, 2009; Gilbert, 2010; Mutuc et al., 2010, Nazlioglu and Soytas, in press). On the other hand, a small number of studies find unidirectional causality from oil prices to agricultural commodity prices (for example, Hameed and Arshad, 2008; Cooke and Robles, 2009). It is argued that the volatile agricultural price dynamics during the recent years compared with the past are attributed to the instability of the energy prices (Saghaian, 2010). In order to cope with the negative effects of soaring and volatile agricultural prices on the agricultural markets, governments take different measures such as price controls and trade barriers. However, the common view is that the interventions to domestic agricultural markets further spur the rise in and volatility of the global prices of agricultural commodities. Therefore, while the agricultural commodity prices may gradually adjust to the oil prices in the past, an increase in the oil prices may be rapidly transmitted to the agricultural commodity prices during the recent years, implying an asymmetric price linkage between energy and agricultural markets. The study shows that the story for wheat–oil prices is slightly different than those of corn and soybeans. According to the trace statistics, the null of no co-integration between the wheat and the oil prices is rejected for all periods with the exception of the sub-period 1998–2004. Indeed, this result is expected since wheat requires an energy-intensive production process. With respect to the nonlinear causal linkages between the oil and the wheat prices, the results for raw data indicate two-way causal linkages. However, the nonlinear causality test on the residuals does not support the existence of nonlinear causality. One can infer that even though there may be an asymmetric price transmission between the oil and the wheat prices, this relationship does not seem to be persistent. The findings obtained from the linear and the nonlinear causality analyses provide different policy implications. The linear causality analysis does not show any feedback from the oil to the agricultural prices, which implies that the movements in the oil prices do not play a role on the fluctuations of agricultural commodity prices. On the other hand, the nonlinear causality analysis indicates that the changes in the oil prices have predictive power in determining the future dynamics of the agricultural commodity prices. The findings from the nonlinear causality analysis imply that the recent surge in the agricultural commodity prices can be attributed the changes in the oil prices. The findings also provide some policy implications. For example, government policymakers should design agricultural policies within the context of tendencies in energy markets and policies.

According to the European Commission (EC) study "High commodity prices and volatility ...what lies behind the roller coaster ride?" (2011), the relative increase in volatility for many products was greater in the European Union (E.U.) following successive policy changes towards enhanced market orientation of E.U. agriculture. However, in absolute terms, volatility remains higher on the world than on the E.U. markets for all products (except chicken where levels are comparable and relatively low). Contrary to popular belief, the analysis confirms that there is a global long-term trend of a slowdown in world consumption growth for agricultural products, in line with lower population growth. This is reflected in the decline for wheat, rice and total feed grains. Even taking account of rising demand for biofuels, this does not reverse the overall trend of declining growth in consumption of feed grains. Maize world consumption growth slightly accelerated in recent decades, long before the development of maize-based ethanol. The EC also conducted more detailed analyses by region confirming these findings. Both the EU and the US experienced a slowdown in demand growth over time, apart from vegetable oils where demand has accelerated recently. The same broad trend can be seen for emerging countries, which are considered to be underpinning growing world food demand. There's an impact of strong demand for oil on the cost of agricultural inputs, particularly fertilizers. During 2004-2010, average world agricultural prices grew by 50 percent compared to the average of 1986-2003. By comparison energy prices jumped by 220 percent and fertilizer prices by 150 presses over the period. An OECD report (2008) identifies a number of factors including fluctuations in demand for agricultural non-food commodities and the increasing correlation between oil and agricultural markets. Higher and more volatile oil prices filter through to agricultural prices (due to input costs and the biofuels outlet for agricultural commodities). This may also stem from a sharper linkage with financial investment in commodity markets. Since the causes of price volatility are multiple and varied, this does not lend itself to simple solutions. Despite some common factors that appear to be at play across and beyond commodity markets, there are specific factors related to agricultural production (linkage to food security and the environment, dependency on life cycles, weather and seasons, sanitary conditions) which further complicate the potential impact of policy.

According to Woods , et al. (2010), agricultural demand for fossil energy, while growing, represents a relatively insignificant and shrinking share of the overall fossil energy supply market. On the other hand, as yields and the inputs needed to support those yields increase, agriculture is becoming more dependent on fossil fuels, either directly for tillage and crop management or through the application of energy-intensive inputs, e.g., nitrogen fertilizer and pesticides. According to Woods , et al. (2010), cereals tend to follow the same pattern in terms of energy inputs and wheat is used here as a proxy for cereals in general. The dominant energy carrier in non-organic wheat production is thus natural gas, but it is crude oil in organic wheat production and in China it would be coal. The embodied energy in machinery is an overhead of about 40 percent of the energy used in diesel, reflecting the high wear environment of cultivating and harvesting, as well as continually high power demand on engines, compared with road transport. Woods et al. (2010) note that increasing fossil fuel prices could pose a major risk to agriculture as production costs increase, and also cause increased volatility in prices between the different major agricultural commodities.

III. Data

Daily data have been collected for all series of interest and weekly aggregates computed on a consistent basis across time series. On the daily basis, the data cover 14 November 2006 through 31 December 2013; 1861 daily observations. Spot and 30-day futures prices data were collected for US soy, wheat and maize contracts. Wheat futures data have been collected for France and corn 30-day futures and spot prices were collected for Brazil. Spot and futures price data for Brent oil have been collected on a consistent basis with the data for agricultural commodities. The daily spot rates and daily futures rates were taken from the International Grain Council (International Grain Council, 2013) data base which corresponds to International Exchange (ICE) data. The ICE Brent Crude Futures contract is a deliverable contract based on EFP delivery with an option to cash settlement. Aggregate weekly have been computed directly from the daily data series in order to guarantee correspondence between the series over time. The daily futures series are plotted in Figures 1-5. The daily spot price for Brent Crude is shown in Figure 6. The weekly series are plotted in Figures 7-12.

It is well-known that the situation of missing observations in financial time series is common. While it is not the primary focus of this study, the methodology used to replace or impute missing observations is important. Overall, the series were virtually complete having less than 5 percent of the observations missing. Missing observations were imputed using simple linear interpolation for missing observations was applied.

IV. Methodology

This paper tests two classes of time series models for prediction of commodity futures prices using the spot prices of the commodity in question as well as taking into consideration information content in the oil spot price at period t of use for predicting the future futures price. Interest is in the reverse regression (Campbell and Shiller (1987), Engel and West (2005), and Chen, Rogoff and Rossi (2008)). Fundamentally, the reverse regression points to the notion that today's market state (and past realizations in the dynamic case considered below) affects the forward-looking variable. More, technically, the idea is that the price today reflects expectations of future changes in market conditions, so it should be a useful predictor.

The empirical analysis is based on daily and weekly prices. The models are estimated over alternative levels of aggregation as Drost and Nijman (1993) have shown that classical GARCH assumptions are not robust to the specification of the sampling interval. The selection of these aggregation levels is based on work of Cartwright and Riabko (2015a, 2015b) indicating the reasonableness of the daily and weekly intervals relative to the monthly increment of temporal aggregation. The daily periodicity is highly volatile and poses modelling challenges owing to that volatility. However, daily prices are highly relevant for practioners. Based upon significance of parameter estimates, overall, Cartwright and Riabko (2015a, 2015b) favor the the daily and weekly periodicities. Monthly aggregations are not modelled in this research owing to the fact that aggregation eliminates considerable information content presumed useful for forecasting.

Following the earlier work, the basic model is given by

1) $f^{k}(t+n) = \Psi + \beta s(t) + \varepsilon(t+n)$

where

$f^{k}(t+n)$ = the average of the k-day forward contract price recorded at period t+n

$s(t)$ = the spot price on contracts of the commodity at period t

$\varepsilon(t)$ = error disturbance assumed distributed normal and independently with zero mean variance σ^2

n= number of periods into the future from the time period t

k= maturity of the futures contract in days.

It is well-known that intertemporal effects in financial models are prevalent. Intertemporal effects have been recognized at least since the work of Merton (1976) and Black (1976). The model of interest is of the form

2) $f^{k}(t+n) = \Psi' + \phi' f^{k}(t) + \beta' s(t) + \varepsilon'(t+n)$

where $f^k(t+n)$ indicates the futures contract with maturity k recorded at time period t. It is expected that the coefficient $0 \geq \phi < 1$ and the error term is assumed to have zero expectation and constant variance (Judge, Griffiths, Hill, Lütkepohl and Lee (1985)).[1]

Building on research by Cartwright and Riabko (2015a, 2015b) an effort is made to better under the transmission or spillover effects from energy (oil) prices onto futures contract prices. The model is augmented by including the spot oil price such that

3) $f^k(t+n) = \Psi'' + \phi'' f^k(t) + \beta'' s(t) + \delta'' o(t) + \varepsilon''(t+n)$

where

$o(t)$ = the spot price for oil (Brent) at period t.

All other variables are defined as indicated following equations 1) and 2).

Following Engle (1982), Bollerslev (1986), Bollerslev, T., Engle, R.F. and Nelson (1994) and Engle (2002) consider the time series, $y_t = E_{t-1}(y_t) + \varepsilon_t$, where $E_{t-1}(y_t)$ is the conditional expectation of y_t at time t-1 and ε_t is the error at time period t. The GARCH model of Bollerslev (1986) is given as

4) $\varepsilon_t = h_t^{1/2} \eta_t,\ \ \eta_t \sim N(0,1)$

5) $h_t = \omega + \sum_{j=1}^{p} \alpha_j \varepsilon^2_{t-j} + \sum_{j=1}^{q} \beta_j h_{t-j} = \omega + \alpha(L)\varepsilon^2_t + \beta(L)\sigma^2_t$

where

[1] Cartwright and Riabko (2015a) consider a simple one-period lagged dependent variable model (LDV) applying feasible generalized least squares for estimation. However, on average, the model has limited explanatory power.

$\omega > 0$, $\alpha_i \geq 0$ and $\beta_j \geq 0$ are sufficient to ensure that the conditional variance $h_t > 0$. L is the backshift operator. In Equation 5 α_i represents the ARCH effect, β_j captures the GARCH effects and $(\alpha_i + \beta_j)$ measures the persistence of the shocks to the variable of interest I to long-run persistence. Provided that the roots of $(1 - \alpha(L) - \beta(L))$ and $(1- \beta(L))$ lie outside the unit circle, then ε_t^2 exhibits stability and covariance stationarity.

Last, the proposed EGARCH of Nelson (1991) is used for this evaluation. EGARCH accommodates asymmetry between positive and negative shocks as well as leverage and interprets ARMA models for the logarithm of the condition variances such that

6) $ln\ h_t = \omega + \sum_{i=1}^{p} \alpha_i\ |\eta_{t-i}| + \sum_{i=1}^{p} \gamma_i\ \eta_{t-i} + \sum_{j=1}^{q} \beta_j\ ln\,h_{t-j}$.

In Equation 6) $|\ \eta_{t-i}\ |$ and η_{t-i} capture the size and sign effects, respectively, of the standardized shocks, i.e., $\eta_{t-i} = (\ \varepsilon_{t-i}/\ \sigma_{t-i})$. More specifically, 6) implies that the leverage effect allowing the variance to respond differently following negative or positive shocks of equal magnitude is exponential and that the forecasts of the conditional variance are necessarily non-negative. The presence of leverage effects can be tested by $\gamma_i < 0$. The impact is asymmetric if $\gamma_i \neq 0$. So, the model estimates both the sign and magnitude effects. McAleer (2005) and McAleer et al. (2007) provide a discussion of differences between GARCH and EGARCH models. Other methods and specifications such as GJR-GARCH (Glosten et al., 1992) are interesting, however, EGARCH has been applied to capture size and assign effects as the methods uses standardized residuals to capture conditional shocks and there are no restrictions on the parameters for the conditional variance.

Applying general procedures for time series methods, the autocorrelation (ACF) and partial autocorrelation functions (PACF) for the data series are estimated and the Phillips-Perron test for a unit root was applied. Consequently, all models are estimated with first differences of the time series of interest. Applying ARCH and EARCH specifications, model performance is evaluated considering two criteria and four metrics. First, models are estimated over the full sample and one-step prediction errors are calculated over the full sample. The metrics generated to assess model performance are bias given by mean error (ME) and accuracy measured by mean square error (MSE), AIC and BIC. Models of increasing leads (lags) of one incremental time period are estimated, the maximum lead (lag) being determined by the specification in which estimated coefficients on the futures contract price, the spot commodity price and the spot oil commodity price taken separately at time period t, respectively, are no longer significant at any reasonable confidence level or until the model specification is not estimable owing to violation of the invertibility conditions or the non-concavity of the likelihood function. Admittedly, this is *ad hoc*, but application of this method is intended to provide insight into 1) whether or not spot prices of interest contain information useful for predicting futures contract prices and 2) the time horizon relevant for forecasting.

Second, we conduct an *ex post* forecasting exercise. Models are estimated using the data up to a given split point, instead of the full sample, and forecasts are generated for the remaining hold-out periods. The issue of sample splitting in order to generate *ex post* forecasts is problematic. In this research it is acknowledged is that selection of a particular split point leaves researchers open to challenge that the split point was selected to favor a particular models (Hansen, P.R. and Timmermann, A., 2012). Further, there is a second concern that per series selection rules might well outperform approaches applying one method to all series under consideration (Fildes, R. and Petropoulos, F., 2013) . In this research, time horizons for daily data of 5 and 10 periods have been selected, while horizons of 4 and 8 steps have been selected for the weekly periodicity. The justification is simply that these horizons represent, respectively, 1 and 2 weeks and 1 and 2 months of activity.

Models are selected following the same process as used for the full sample although on the basis of results using the truncated sample. Diagnostics are calculated and reported for the 5 and 10 period hold-out samples. ME, mean absolute error (MAE) and mean square forecast error (MSFE) over the horizons indicated are considered out-of-sample. Baselines for evaluating forecast performance are given by diagnostics for random walk models generated using the STATA ucm command (STATA, *Time Series, Release 12 (1985-2011)*). Finally, forecasts are static, i.e., not dynamic or recursive.

V. Results

5.1 Daily Data

5.1.1 Full Sample Estimation

The first-differenced daily series including Brent oil are shown in Figures 7-12. The GARCH and EGARCH models are estimated autoregressive heteroscedastic model for daily observations using the arch procedure in STATA, *Time Series, Release 12 (1985-2011)*. In this procedure the conditional variances are modeled as univariate generalized autoregressive conditionally heteroscedastic models and the covariances are modeled as nonlinear functions of the conditional variances (Engle, 2002). While only the final selected specifications are reported, for the GARCH (p,q) models alternative values for p and q were tested. The popularity of the GARCH (1, 1) model is indicated by a significant body of literature, e.g. Nelson (1990). The GARCH (1, 1) model has often been found sufficient to capture the main features of the volatility process.

Models of increasing leads (lags) of one incremental time period are estimated as indicated in the previous section. Results are summarized in Tables 1, 2, and 3. Table 1 reports the detailed results for the models estimated. The most salient results are that, first, for the 49 models tested with respect to statistical significance at the 10 percent significance level or better, the parameter estimates on the dependent variable at time period t, the own-commodity spot price at t, and the spot oil price at period t are significant 45, 56, and 60 percent of time, respectively. The horizons over which the estimates are significant vary considerably with respect to commodity, pointing to the heterogeneity of the markets under analysis.

The estimated coefficient on the dependent variable at time period t is significant 22 times and the horizon varies between 11 periods (Brazilian corn) and being insignificant for cases such as US maize. Perhaps more interesting, the estimated coefficient on the differenced spot own-commodity spot rate is significant at the 90 percent confidence level or better out to 3 periods for US Wheat futures prices (GARCH and EGARCH), 3 periods for the US maize futures prices (EGARCH), and 3 periods for the US soy futures prices (GARCH and EGARCH). For French wheat futures the estimated coefficient on the differenced spot own-commodity price is statistically significant for the 3 period lag for the EGARCH model. For Brazilian corn futures, the spot own-commodity spot price is consistently significant 11 periods and 8 periods out for the GARCH and EGARCH models, respectively.

As concerns the spot Brent oil price, for the US wheat futures, the estimated coefficient is significant at the 90 percent confidence level or better out 1 period (GARCH) and out 5 periods for the EGARCH models. For the case of US Maize futures, the spot oil price variable is significant at the 1 period lag for GARCH and out to 3 periods for EGARCH. With respect to the US soy futures the spot oil price is shown to be significant at the 1 period lag (GARCH) and the 2 period lag (EGARCH). Further, for the French wheat futures, the spot oil price parameter is estimate is statistically significant at the 1 period land for GARCH and out to three periods for EGARCH. Finally, with respect to the Brazilian corn futures prices, the estimates on the own-commodity price are significant out as far as 11 periods (GARCH) and 9 periods (EGARCH). The estimated coefficients on the spot oil price are significant out to 11 periods for the GARCH specification and out to 8 periods for EGARCH.

As concerns the arch and garch parameter estimates, as indicated in Table 3, the signs of the coefficients are positive as expected the variance of the current period error is an increasing function of the magnitude of the lagged errors, hence, large errors tend to be followed by large errors irrespective of sign. The parameter estimates for earch, egarcha and egarch correspond to the sign effects, size effects and persistence effects as in equation 6). Overall, the results indicate that indicate that positive shocks tend to be more destabilizing than negative shocks (sign effects) . The size effects are positive indicating that lagged large market movements result in large movements in following period. For all models and specifications the errors show large persistence effects (eparch) indicating that the series have quite long memories.

The ME and MSE criteria vary considerably with respect to commodity, model specification, and time horizon indicating the heterogeneity of the processes associated with the markets, and therefore, importance of considering multiple models. For example, for the US Wheat GARCH models the ME closest to zero is Wheat-US+3, while the minimum MSE is reached for Wheat-US+1. For the US Wheat EGARCH models, I indicate a preference for Wheat-US+4, while minimum MSE is attained for Wheat-US+1.

Finally, the last columns of Table 1 show the AIC and BIC statistics. The model selection literature contains considerable debate about using AIC or BIC. The mathematical literature, e.g., Burnham and Anderson (2004) tends to favor BIC. Acknowledging that AIC and BIC model selection can both be derived as either frequentist or Bayesian procedures, for purposes of this research AIC is considered to address the question of which model is best or "least wrong", while BIC considers the question of which model is most likely to be "true". Irrespective of the interpretation, for the model test neither criterion found to be useful in the sense that with the exception of the Brazilian corn series, the AIC and BIC are minimized for models of maximum lead (lag) and for these cases , not all (if any) of the estimates of ϕ, β and δ are statistically significant. In the case of the Brazilian corn series, the AIC and BIC suggest models Corn-BR+4 (GARCH) and Corn-BR+2 (EGARCH).

	-			1		

*Significant at the 10 percent significance level or better

At this point, with respect to the key interests of this research, it is reasonable to conclude that based upon the results for the 49 tested models, that the reverse regressions are often useful in that today's market state captured by the spot own-commodity price effects the forward-looking variable . In fact, for the models tested, the estimated coefficient on the own-commodity spot price is significant in 23 of the 49 cases considered. Of considerable interest is the evidence that in 28 of the 49 models considered the spot oil price is significant at the 10 percent confidence level or better.

5.1.2 *Ex post* forecasts

For the purposed of providing a benchmark for comparing forecast performance, random walk models are estimated for the 5 and 10 period *ex post* forecasting horizons. Based on the process of model selection described in section 1.1 models are reported for the forecasting exercise, i.e., the maximum lead (lag) specification is based upon the significance of the estimated coefficients (ϕ, β, δ). As above, estimation of increased order models is terminated when parameter estimates on ϕ, β, δ are not significant at any reasonable confidence, the model specification is not estimable owing to violation of the invertibility conditions, or the model specification is not estimable owing to the non-concavity of the likelihood function.

* Indicates significance at the 90 percent confidence level
** Indicates significance at the 95 percent confidence level or better
standard errors shown in parentheses
NA Indicates not estimable

Generally, the model results do not differ significantly from the obtained using the full sample fit. On the basis of the hold-out sample, ME, MAE and MSFE are computed for both the 5 and 10 period daily horizons and the overall averages by commodity are calculated. The results are summarized in Table 4.

With respect to *ex post* forecasting results summarized in Table 5, on a commodity-by-commodity basis, there is considerable variation in the extent to which the full models yield significant reductions in forecast error relative to the random walk formulations. In terms of MAE and MSFE, the French Wheat models perform best. The average reduction in relative MAE for the 5-step horizon is 30.4 percent and MSFE is reduced 68.7 percent. For the 10-step horizon MAE is improved by 35.9 percent and MSFE by 63.7 percent. The worst performing models are those for Brazilian corn futures. For the 5 period horizon MAE is reduced by 5 percent and MSFE is reduced by 8 percent. For the 10-step horizon, MAE is improved by 2 percent and MSFE by 52.2 Percent. This is an interesting result as the Brazilian corn series indicate the longest presence of statistically significant lead (lag) relationships between the futures price t+n steps forward and the own-commodity futures price, the own-commodity spot price and the spot oil price all at period t. Intermediate outcomes are reported for the other series. For example, the US Wheat series 5-steps out, on average the full models improve forecast accuracy in terms of MAE by 23.7 percent and by 20 percent in terms of MSFE. For the US Wheat series 10 steps out, in terms of MAE and MSFE, the full models yield and improvement of 15.5 and 15.1 percent, respectively.

5.2 Weekly Data

5.2.1 Full Sample Estimation

Models using aggregated weekly data are estimated following the same procedures applied to the daily data series. The first differences of the weekly data series are plotted in Figures 13 – 18. A generalization concerning this research thus far concerns the relative performance of the models with respect to time aggregation. The data are relatively smooth although the presence of heteroskedasticity remains clear. The weekly estimation results indicate a significant deterioration in the information content of the series at least with respect to the significance of the parameter estimates. It is also the case that that problems were encountered due to the failure of the optimization algorithms to converge owing to the non-convexity of the likelihood function. It is well-known that owing to the non-convexity and non-linearity of the models in this research that estimates can be difficult to compute. It is possible to compute estimates using nonlinear programming techniques, although this approach has not been taken in this current study (Altay-Salih, Pinar and Leyffer, 2003)

Figure 13. US Wheat Futures Price, 30 Day, First-Difference, Weekly (n=371)

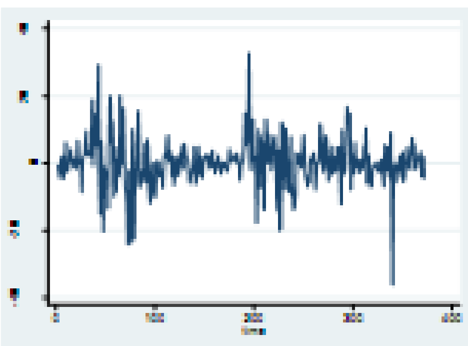

Figure 14. US Maize Futures Price, 30 Day, First-Difference, Weekly (n=371)

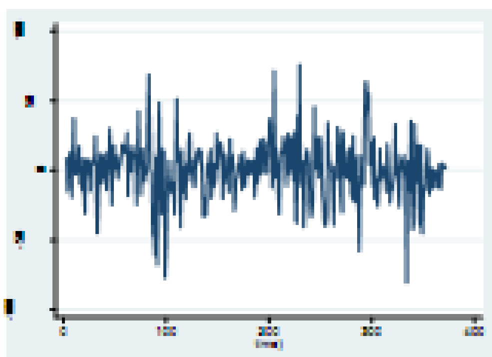

Figure 15. US Soy Futures Price, 30 Day, First-Difference, Weekly (n=371)

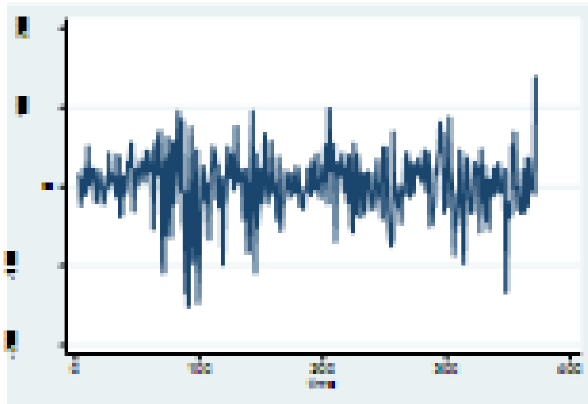

Figure 16. France Wheat Futures Price, 30 Day, First-Difference, Weekly (n=371)

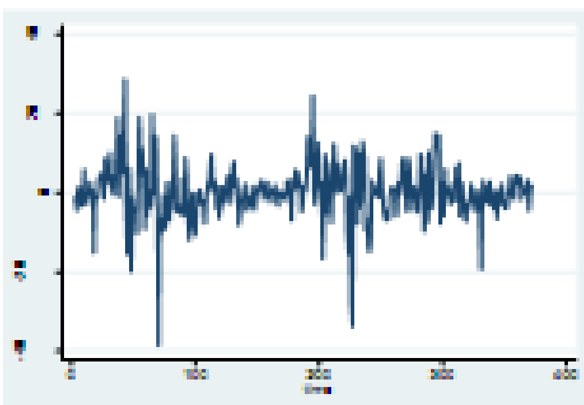

Figure 17. Brazil Corn Futures Price, 30 Day, First-Difference, Weekly (n=371)

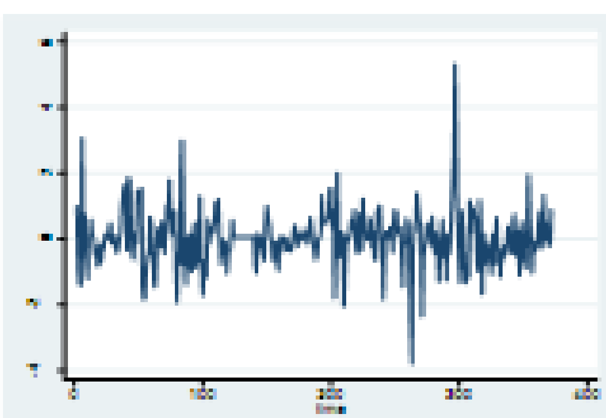

Figure 18. Brent Oil Spot Price, First-Difference, Weekly (n=371)

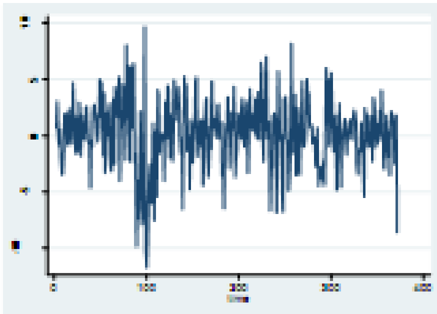

From Table 6, given the full sample results, the only case for which all of the estimates for the own-commodity futures price, the own commodity spot price and the oil spot price are statistically significant is US Wheat. However, significant coefficient estimates for the GARCH and EGARCH models are reported for other series at varied leads (lags). Overall, the daily models outperform weekly models with respect to bias (ME); however, the results for MSE are clearly mixed. For example, the MSE performance of the daily models is superior for US Wheat, but not for US Maize and US Soy.

Table 6. GARCH and EGARCH, In-Sample Results, Weekly (n=371)

	EGARCH	3	1	1	1
Total		19	8	4	5

*Significant at the 10 percent significance level or better.

As expected, where significant the signs on the ARCH and GARCH processes are positive. These results are summarized in Table 7 and Table 8. As is the case for the daily models, the weekly results indicate that indicate that positive shocks tend to be more destabilizing than negative shocks (sign effects) and that lagged large market movements result in large movements in following period. Large persistence effects (egarch) indicate that the series have quite long memories.

Table 8. Signs and Significance of Parameter Estimates, GARCH and EGARCH, In-Sample Results, First-Difference, Weekly (n=371)*

5.2.2. *Ex post* forecasts

With respect to the *ex post* forecasting models using weekly data, time forecast time horizon of 4 and 8 are selected corresponding to 1 and 2 month horizons, respectively. The results confirm that considerably fewer models at varied leads (lags) result in significant coefficient estimates for ϕ, β, δ. After shortening the estimation period for the hold-out series, the models for US Maize are dropped from consideration. The overall results for periods used or fitting the models are reported in Table 9 and the results are compared to random walk specification in Table 10. As with the daily models, generally, the weekly models outperform random walk specifications.

Corn-BR+1 GARCH	8	.222** (.056)	-.005 (.048)	.005 (.010)	.206** (.053)	.700** (.042)				.272	.466	.289

* Indicates significance at the 90 percent confidence level
** Indicates significance at the 95 percent confidence level or better
Standard errors shown in parentheses
NA indicates not estimable

Overall, the *ex post* forecasts show that the performance of the GARCH and EGARCH specifications relative to the random walk models is mixed. It is particularly interesting that with respect to MSFE the random walk models for US Wheat and US Soy perform better than the more complex specifications.

Table 10. Comparative Performance, *Ex Post* Forecasts, GARCH and EGARCH vs Random Walk, Weekly

VI. Summary and Conclusions

As indicated in the Introduction and the literature review in Section II, there is an extensive interest and literature in understanding the effects of energy-oil prices on prices of agricultural commodities and the transmission mechanisms for which an empirical relationship has been identified. It is thought that this paper represents a significant contribution to research done to-date.

Applying reverse regressions, this paper investigates the extent to which spot prices contain information content useful for predicting future futures prices. The working hypothesis is that both own-commodity spot prices and spot energy (oil) prices are significant predictors of future commodity prices at alternative leads (lags). The paper tests the hypothesized relationships using daily and weekly aggregates of daily data for five agricultural commodities. Both GARCH and EGARCH specifications are considered for testing.

Based on the results thus far, it is reasonable to conclude that the reverse regressions are often useful in that today's market state captured by the spot own-commodity price effects the forward-looking variable. For the daily models tested, the estimated coefficient on the own-commodity spot price is significant in 23 of the 49 cases considered. Of considerable interest is the evidence that in 28 of the 49 models considered the spot oil price is significant at the 10 percent confidence level or better. As concerns the weekly data, model performance is relatively poor with significant lead (lag) responsiveness being very short at best. In some cases the models are not estimable owing to "flat" likelihood functions.

Ex post forecasts are generated for 5 and 10-step daily horizons and 4 and 8-step weekly horizons. Again, the weekly models perform markedly worse than the daily models, which is somewhat surprising given the earlier results of Cartwright and Riabko (2015c) showing that weekly models perform at least as well as models estimated at the daily level of aggregation. Overall, however, the *ex post* forecasts at both the daily and weekly levels out-perform random walk models, although this observation is not unequivocally the case.

In short, the results thus far indicate that in some cases spot own-commodity prices and spot oil prices are useful for predicting prices of futures contracts although the lead-lag relationships vary considerably as between commodities considered as well as with respect to temporal aggregation.

Understanding the extent of the relationships and reasons for the differences forms the basis for continuing research.

This paper examines the relationship between income diversification and bank efficiency in across 83 countries over the period 2003–2012. We also evaluate how ownership structure varies the impact of bank diversification on cost efficiency. Using stochastic frontier approach to estimate bank's cost efficiency, we find the evidence that increased diversification tend to improve bank efficiency, and government-controlled banks with fewer volatile income sources are likely to have lower efficiency of income diversification. Our results also reveal that more diversified foreign-controlled banks tend to be less efficient in developed countries, while increased foreign ownership of banks appears to improve the diversification benefits in developing countries after the financial crisis. Our findings highlight the implications of bank income diversification and ownership for efficiency and are relevant to bank regulators who are considering additional regulations on bank efficiency.

Keywords: Income diversification, ownership structure, efficiency, banking

1. Introduction

What drives bank efficiency? Understanding the determinants of bank efficiency is important because bank efficiency establishes banks' health and is important drivers of economic growth (Allen and Gale, 2000; Levine, 2005). A growing literature takes up this task, documenting positive and negative empirical links between bank efficiency and various bank and market characteristics. With financial deregulation and market integration, the scope of banks' activities has been completely reshaped, from traditional intermediation products to an array of new businesses (Clark and Siems, 2002). These trends have led to substantial consolidation in the banking industry and, consequently, to significant changes in ownership structure. However, this literature contains few empirical studies examining the link among bank efficiency, income diversification and ownership structure. We contribute to this nascent literature by examining the effects of the two interrelated dimensions of bank income diversification and ownership structure on efficiency.

However, while that literature has provided considerable understanding of the effects of bank frontier efficiency, its primary focus is mostly based on traditional balance sheet figures (e.g., Lensink et al., 2008). Siems and Clark (1997) and Rogers (1998) argued that models that ignored non-traditional outputs penalized against banks that are heavily involved in such activities, because resources used to produce these non-traditional services were included in the input vector without accommodating the relevant variables in the output vector. Therefore, there is no general consensus in the literature as regards the definition of the relevant output vector. Furthermore, relatively few studies provide a comparison of models developed both with and without proxies for non-traditional activities, thereby offering a bleak picture of their relative significance in bank efficiency estimates. Most of the studies report that ignoring measures of non-traditional activities in the estimation of bank efficiency can be misleading, although at least two studies in the literature find little or no impact of off-balance sheet (OBS) activities (Jagtiani et al., 1995; Pasiouras, 2008) while the results of Clark and Siems (2002) are mixed, dependent on examination of cost or profit efficiency.

Additionally, bank strategies differ because of differences in customer preferences, information quality and production methods, which could be driven by differences in bank ownership structure. In few studies of the benefits of state ownership have the efficiency arguments for state ownership been supported (e.g., police and prison ownership, see Hart et al., 1997). In contrast, most studies have found that state-owned firms do not better serve the public interest (i.e., Grossman and Krueger, 1993) and, in fact, that state-owned firms are typically extremely inefficient (i.e., Boycko et al., 1995; Dewenter and Malatesta, 2001). On the other hand, there is a tendency for foreign-owned institutions or foreign banks to be more oriented toward transactions lending and provide financial services to large corporate clients rather than to lend to smaller firms, more likely catered by domestic banks. Empirical studies show that foreign banks tend to have wholesale orientation and may favorably lend to large corporate affiliates of their customers in their home nation (Grosse and Goldberg, 1991; DeYoung and Nolle, 1996). In addition, foreign banks are more exposed to developed country banking markets, which tend to be more competitive and use more sophisticated information and communication technologies (Claessens et al., 2001). These advantages could favor foreign banks in managing operating and financial leverage when diversifying toward non-interest activities. Despite the extensive literature on bank efficiency (see Berger and Humphrey, 1997; Berger, 2007), a comprehensive study on whether bank income diversification and ownership enhance or impede efficiency does not yet exist.

The purpose of this paper is to contribute to the assessment of the types of bank income diversification and ownership that work best to achieve well-functioning banking systems. To our knowledge, no research has addressed whether bank efficiency may be different for privately owned banks and publicly held banks under specific ownership profiles. Thus, our aim herein is to assess banks' efficiency levels by combining the two interrelated dimensions of bank diversification and ownership structure. Particularly, our cross-country analysis is able to compare the impact of bank income diversification and ownership across different levels of economic development (e.g. advanced and developing) and across different geographic regions. Furthermore, we are able to incorporate other country-based characteristics such as the relative presence of foreign and government-owned banks in the market, the degree of information sharing, and the degree of bank regulation. Policymakers can surely make more informed decisions about the income diversification of banks when they know the likely effect of those decisions on bank performance.

This study contributes to the existing literature in several ways. First, the existing literature mostly based on the relationship between bank income diversification and performance (DeYoung and Roland, 2001; Stiroh, 2004; Stiroh and Rumble, 2006). In contrast, we estimate bank efficiency using a stochastic frontier technique and it is superior compared to traditional measures of performance because efficient frontier approach could account simultaneously for a variety of output/input specifications (Berger and Humphrey, 1997). Second, while there is a related study of Lozano-Vivas and Pasiouras (2010) that examines the effect of non-traditional activities in bank efficiency. Unlike Lozano-Vivas and Pasiouras (2010), we use both income diversification and non-interest income as two main independent variables to investigate the impact of a shift toward non-interest activities on bank's cost efficiency. This allows us to clarify the framework that decomposes the effect of strategic shifts into a "direct exposure effect" of an increased share of non-interest income and an "indirect diversification effect" of a resultant variation in income concentration. In addition, this paper also shifts the focus to banks and to the question of whether the ownership structure of banks influences their efficiency levels.

Finally, our paper is to provide international evidence about relevance of bank income diversification and ownership in the estimation of bank efficiency levels. As some related studies investigate mainly the US (e.g., Siems and Clark, 1997; Rogers, 1998; Stiroh, 2000) and a few developed countries such as Spain (Tortosa-Ausina, 2003), Switzerland (Rime and Stiroh, 2003), Taiwan (Lieu et al., 2005), and Greece (Pasiouras, 2008), our knowledge with regard to a broader range of countries, in particular the transition and less developed countries of the world, remains limited.

We investigate the effects of ownership structure on the relation between income diversification and bank efficiency using data for more than 7533 bank-year observations in 83 countries over the period 2003–2012. We obtain the following main findings. First, we find that increases in income diversification are positively associated with bank efficiency, but these benefits of diversification are offset by increasing exposure to volatile non-interest activities. Second, state-controlled banks tend to have lower diversification benefits than their private-controlled counterparts, even though they have low costs of diversification. Third, we find that the more the proportion of foreign shareholders owned, the less the benefits of bank diversification in developed countries, but these gains are likely to be higher for foreign-controlled banks located in developing countries after the financial crisis. Finally, banks with foreign-controlled ownership located in developed countries are able to mitigate better the costs of diversity compared to domestic private banks, while the opposite is true for their participation in developing countries.

The rest of the paper is organized as follows. Section 2 reviews the existing literature on bank efficiency, ownership structure and income diversification. Section 3 presents our measures of bank efficiency, ownership structure and income diversification, and analyzes how ownership structure affects the income diversification-bank efficiency nexus. Section 4 describes the data sources and estimated efficiency scores. Section 5 analyzes empirical results and discusses their implication. Finally, section 6 concludes the paper with a concise discussion on the policy implications.

2. Literature review and hypothesis development

2.1 Effects of income diversification on bank efficiency

The spreading activities across different products and economic environments may help banks reduce their expected costs of financial distress/bankruptcy (Boot and Schmeits, 2000). As screeners or monitors of borrowers, banks with a better diversified intermediary can minimize their cost of monitoring information and thus lower total costs, even in a risk neutral economy. In models of delegated investment monitoring (Diamond, 1984; Boyd and Prescott, 1986), diversification within the financial institutions serves an important role in providing a sufficient loan proceeds to repay a fixed debt claim to depositors, in which well-diversified financial intermediaries reduce their chance of costly financial distress. Similarly, Stiroh (2004) reveals that banks can reduce cyclical variations of profit by shifting its total income toward non-interest income, depending less on general business conditions. To investigate whether income diversification affects bank efficiency levels, Lozano-Vivas and Pasiouras (2010) find that, on average, cost efficiency increases in case non-interest income is used as an output in the global best-practice frontier model. As suggested by the studies of Gamra and Plihon (2011) and Meslier et al. (2014), greater competition in financial markets leads to increasing need for banks to diversify. Banks with various diversification strategies can produce information that enhances their loan making by such activities as securities underwriting, brokerage and other trading services. Indeed, activities that generate non-interest income are believed to be imperfectly associated with those that generate interest income, thereby producing profitable growth and providing a better risk-return trade-off.

Although the diversification plays an important role in the desirable efficiency for a bank, the costs of diversification might are associated with higher income volatility, implying higher risk. This argument is supported by some empirical studies. Notably, DeYoung and Roland (2001) conclude that a shift toward non-interest income is related to higher leverage and increased revenue volatility, which may increase bank earnings' volatility. One possible reason is that commercial banks tend to easily lose clients from fee-based activities because of high witching costs for borrowers associated with lending relationships. Moreover, banks tend to increase operating leverage to additional investment in human resources and technology infrastructure as it shifts towards fee-based activities, leading a high earning's volatility. In a sample of US commercial banks, Morgan and Samolyk (2003) investigate the nexus between geographic diversification and bank performance, and report that diversification is not associated with increased returns or reduced total risk. Similarly, focusing on loan portfolio diversity, Acharya et al. (2006) also find that loan's diversification is not associated with better performance while increasing the risk in Italian banking industry. Stiroh (2006) and Stiroh and Rumble (2006) show that the benefits from diversification are offset by an increase in exposure to non-interest income business, which increases the volatility of equity market returns. More recently, using a sample of small US credit unions, Goddard et al. (2008) find a negative association between diversification and both the unadjusted and risk-adjusted profitability. This is true in particularly in terms of cost and profit efficiency from the study of Berger et al. (2010), who show diversified banks are less profitable than focused Chinese banks.

2.2 Effects of ownership structure on bank efficiency

In addition to bank income diversification, another important dimension of ownership structure is state ownership, foreign ownership versus private ownership structure. Megginson and Netter (2001) present a survey of studies that have provided evidence on the relative performance of state-owned and privately-owned firms.). Reasons for different ownership forms leading to different efficiency levels have been extensively explored in the literature; and the dominant model to consider the effect of ownership utilizes the principal agent framework and public choice theory to highlight the importance of management being constrained by capital market discipline. In few studies of the benefits of state ownership have the efficiency arguments for state ownership been supported (e.g., police and prison ownership, see Hart et al., 1997). In contrast, most studies have found that state ownership is inherently inefficient. Firstly, the agent-principal problem becomes more prominent under state ownership. When there is a separation between ownership and management controls, managers (agents) may pursue their own interests rather than acting in the best interest of owners (principals) (Berle and Means, 1932), which may result in negative effects on performance. Secondly, the free-rider problem also becomes more common. State ownership theoretically means that all citizens are co-owners who in practice have no power and incentive to influence and monitor the management of state banks, leaving governments as the only effective representative (Huibers, 2005). Governments, however, have multiple (often conflicting) goals. Thirdly, soft-budget constraints faced by state banks may induce moral hazard problems leading to poor performance. State banks act as government agents to finance state-owned enterprises (SOEs) based on political preference rather than commercial considerations.[1] When banks are in difficulties, they expect help from governments. Therefore, managers of state banks have the little incentive to minimize costs or maximize profit. Finally, other reasons also explain poor performance of state banks, including the general view of "too big (important) to "fail", the "quiet life" hypothesis, poor monitoring and lack of market discipline (Megginson, 2005).

On the other hand, the most common findings for developing nations are that on average, foreign banks are more efficient than or approximately equally efficient to private domestic banks. Both groups are typically found to be significantly more efficient on average than state-owned banks, but there are variations on all of these findings. To illustrate, some research using data from the transition nations of Eastern Europe finds foreign banks to be the most efficient on average, followed by private domestic banks, and then state-owned banks (Bonin et al., 2005a; b). However, another study of transition nations finds the mixed result that foreign banks are more cost efficient, but less profit efficient than both private domestic and state-owned banks (Yildirim and Philippatos, 2007). A study using 28 developing nations from various regions finds foreign banks to have the highest profit efficiency, followed by private domestic banks, and then state-owned banks (Berger et al., 2004). For cost efficiency, the private domestic banks rank higher than the foreign banks, but both are still much more efficient than state-owned banks. Two studies using Argentine data (prior to the crisis in 2002) find roughly equal efficiency for

[1] For example, Sapienza (2004) finds that the party affiliation of state-owned banks' chairpersons in Italy has a positive impact on the interest rate discount given by state-owned banks in provinces where the associated party is stronger. The empirical results in Dinc (2005) indicate that government-owned banks increase their lending in election years relative to private banks in major emerging markets in the 1990s, and these actions are influenced by political motivations other than differences between privately-owned banks and government-owned banks in efficiency and objective.

foreign and private domestic banks, and that both are more efficient on average than state-owned banks (Delfino, 2003; Berger et al., 2005). A study of Pakistani data finds foreign banks are more profit efficient than private domestic banks and state-owned banks, but all of these groups have similar average cost efficiency (Bonaccorsi di Patti and Hardy, 2005). Finally, a study of Indian banks finds that foreign banks are more efficient on average than private domestic banks (Bhattacharyya et al., 1997).

3. Methodology

3.1 Measuring bank efficiency: Parametric SFA

This study employs the stochastic frontier approach (SFA) to generate cost efficiencies for each bank along the sample during the period under analysis. More specifically, we estimate bank efficiency using the Battese and Coelli (1995)'s SFA model to obtain an unbiased systematic measure of efficiency across countries, based on the assumption that efficiency differences between banking industries are determined by country-specific characteristics.[2] This specification allows us to control for general environmental factors by estimating simultaneously the parameters of the stochastic frontier and the inefficiency model. Particularly, cost efficiency measures how close to the minimum cost a bank is, where the minimum is determined by banks with the best performance in the sample. In its general form, the cost function model can be written as follows:

$$TC_{it} = f_1\left(Y_{it}, W_{it}\right) + v_{it} + u_{it}, v_{it} \sim N\left(0, \sigma_v^2\right), u_{it} \sim N^+\left(\mu_{it}, \sigma_{it}^2\right) \quad (1)$$

where: TC_{it} is total costs for the i^{th} bank in year t, and Y_{it}, W_{it} are the vectors of the output and the price of input, respectively. The u_i represents technical and allocative inefficiency aspects that can be influenced by management, while v_i is the stochastic error term with *i.i.d.* normal distribution represented for other uncontrollable factors. As regards the cost function techniques,

[2] We follow recent cross-country studies (e.g., Dietsch and Lozano-Vivas, 2000; Lozano-Vivas et al., 2002) that account for differences arising from country-specific aspects of technology, macroeconomic conditions, and regulatory conditions by including indicators of these environmental factors in a more comprehensive definition of a common frontier.

the u_{it} error is the non-negative inefficiency effect in the model, having a truncate normal distribution with an observation-specific mean $(\mu_{it} = \delta_0 + z_{it}\delta)$ and variance (σ_{it}^2) which are assumed a function of some determinants (z_{it}) of its pre-truncated distribution. The parameters of equation (1) are estimated by using maximum likelihood (ML) method. We estimate efficiency levels by specifying the commonly-used translog functional form which results in an empirical cost frontier model of the following format:

$$\ln(TC / w_2TA) = \alpha + \sum_{i=1}^{4}\beta_i \ln(Y_i / TA) + \sum_{k=1}\psi_k \ln(W_k / w_2) + \frac{1}{2}\sum_{i=1}^{4}\sum_{j=1}^{4}\beta_{ij}\ln(Y_i / TA)\ln(Y_j / TA)$$
$$+\frac{1}{2}\sum_{k=1}\sum_{m=1}\psi_{km}\ln(W_k / w_2)\ln(W_m / w_2) + \sum_{i=1}^{4}\sum_{k=1}\phi_{ik}\ln(Y_i / TA)\ln(W_k / w_2) + \textit{year dummies}_t$$
$$+\ln u_{it} + \ln v_{it} \qquad (2)$$

where TC is the bank's total costs in a given year; TA is the bank's total assets in a given year; Y_i are outputs; W_k are input prices (w_1: price of capital, w_2: price of fund); and α, β, ψ, ϕ are parameters to be estimated. The translog cost function is estimated using the $(\ln u_{it} + \ln v_{it})$ as a composite error term.

Following Bonin et al. (2005a) and Berger et al. (2009), we choose the following four outputs: total loans *(Y_1)*, other earning assets *(Y_2)*, total deposits *(Y_3)*, and liquid assets *(Y_4)*. In addition, widely consistent with previous studies on bank efficiency we use the following two input prices: price of capital *(w_1)*, calculated as the ratio of non-interest expenses to total fixed assets; and price of funds *(w_2)*, defined by the ratio of interest expenses to total deposits. The total costs *(TC)* of banks are defined as the summation of interest expenses and non-interest expenses. In addition, we impose linear homogeneity restrictions by normalizing by using the price of fund *(w_2)*. Following Jiang et al. (2013), we also normalize total costs and output variables by total assets to control for scale biases and heteroskedasticity. The cost (in)efficiency scores of each bank (INE_i), estimated from the stochastic frontier technique would take a value between one and infinity. However, in order to make our results comparable across banks we follow the same procedure employed by Pasiouras et al. (2009) to calculate the index of cost efficiency as follows: $CE_i = 1/INE_i$. Therefore, efficiency is always positive and it is equal to one for the best practice or zero inefficient bank.

3.2 Measuring bank ownership

The procedure used to calculate a bank's proportion of state ownership is similar to La Porta et al. (2002). That is, the first measure identifies large bolckholder ownership of banks. A large blockholder is any shareholder owning more than 10% of the shares in a bank, and use the 10% threshold from La Porta et al. (1999). Then, we calculate the proportion of government ownership for bank *(GO)* by first multiplying the share of each blockholder shareholder in that bank by the share the government owns in that shareholder, and then sum the resulting products over the shareholders of the bank:

$$GO_{ic} = \sum_{j=1}^{J} s_{ji} s_{gj}; \text{ where } s_{ji} s_{gj} > 0.1, \tag{3}$$

where $c = 1...83$ indexes the 83 countries in the sample, $i = 1...10$ indexes the 10 largest banks in the country, $j = 1... J$ indexes banks' shareholders, s_{ji} is the share of bank i owned by shareholder j and s_{gj} is the share of shareholder j that is owned by a government shareholder. GO_{ic} stands for the total share of bank i in country c that is owned by large government shareholders at the end of each year.

Similar to Dinc (2005), a bank is classified as state-owned if government ownership is at least 20%. The 20% threshold is used here and by Dinc (2005) following the corporate control literature which suggests that 20% ownership is often sufficient to control a company. We use a similar procedure to construct the domestic private (DO_{ic}), and foreign (FO_{ic}) blockholder ownership variables.

3.3 Measuring income diversification

In line with the studies of Stiroh and Rumble (2006) and Sawada (2013), this paper primarily utilizes non-interest income share as an income structure to measure functional diversification of banks. The measure of non-interest income share is defined as the ratio of non-interest income to total operating income, and is expected to capture non-traditional business of banks. The income diversification, *INCDIV*, is measured by constructing Herfindahl–Hirschman Index (HHI) for each bank, in which total operating income is decomposed into two categories: net interest income, *NET*, and non-interest income, *NON*. The non-interest income includes fee and service income, trading income, fiduciary income and other banks' non-interest income shares. Following this procedure, the bank's income diversification is calculated as

$$INCDIV = 1 - \left(NETSHARE^2 + NONSHARE^2 \right), \tag{4}$$

where $NETSHARE = \dfrac{NET}{NET + NON}$ and $NONSHARE = \dfrac{NON}{NET + NON}$ are interpreted as the shares of net interest income and the share of non-interest income from total operating income, respectively. *INCDIV* measures the degree of diversification in a bank's net operating revenue. A higher value indicates a more diversified mix: 0 means that all revenue comes from a single source (complete concentration), while 0.5 is an even split between net interest income and non-interest income (complete diversification).

3.4 Basic model

$$\begin{aligned} Bank\ Efficiency_{i,c,t} = {} & \beta_0 + \beta_1\ INCDIV_{i,c,t} + \beta_2\ NONSHARE_{i,c,t} \\ & + \beta_3\ Ownership\ Structure_{i,c,t} \\ & + \alpha'\ Bank\ Regulation\ Control_{c,t} \\ & + \gamma\ Information\ Sharing_{c,t} \\ & + \lambda'\ Bank\ Controls_{i,c,t} \\ & + \rho'\ Macro\ Controls_{c,t} \\ & + Country\ Dummies + Year\ Dummies + e_{i,j,t}, \end{aligned} \tag{5}$$

where *Bank Efficiency*$_{i,j,t}$ is the cost efficiency scores of bank i in country c in time t. *Bank Efficiency* is always positive and it is equal to one for the best practice or zero inefficient bank. *INCDIV* is the value of income diversification followed the basic HHI-type approach. *NONSHARE* is the share of non-interest income. *Ownership Structure* serves as proxies for ownership types of banks, including government ownership (*D20GO*) and foreign ownership (*D20FO*). *D20GO* is a dummy variable that value one if a bank is state owned (we define ownership using the 20% threshold),[3] *D20FO* is a dummy variable that takes value one if a bank is foreign-owned (private domestically owned is the excluded dummy).

The vector of bank regulation control variables, *Bank Regulation Control*, includes the following variables from Barth et al. (2013) datase: overall capital stringency *(OCS)* and official supervisory power *(OSP)*. While *OCS* reflects the extent of regulatory requirements regarding the amount of capital banks must hold, and deducts the certain market value losses from the determinants of capital adequacy, *OSP* represents the extent to which bank supervisory authorities possess the power to take specific actions against violations of bank regulations for preventing and correcting problems. We also use *Information Sharing* variable to control for the effects of each country's information channel on bank efficiency. *Information Sharing* is defined as a dummy equal to one if a country has either a public or a private registry, and zero otherwise. The vector of bank control variables, *Bank Control*, includes bank size defined as the logarithm of the bank's total assets *(Size);* and bank equity captured by the total equity to total asset ratio *(Equity)*. Furthermore, *Macro Controls* is a vector of macroeconomic controls including economic growth *(GDP)* and inflation *(CPI)*. Finally, *Countries Dummies* is a set of country dummy variables and *Year Dummies* is a set of time dummy variables.

A statistical issue arises, since values of our *Bank Efficiency* in the regression range from 0 to 1, making this dependent variable a truncated distribution. Ordinary least squares (OLS) regression parameter estimates for truncated variables would be biased upwards because OLS assumes a normal and homoskedastic distribution (Maddala, 1983). To resolve this data censor problem, we carry out our regressions using the Tobit maximum likelihood procedure. Use of a Tobit model can handle the characteristics of the distribution of efficiency scores and thus provide unbiased estimates of the coefficients.

[3] We also refer to Micco et al. (2007) and define ownership using the 50% threshold in our robustness test.

It is worth noting that $\hat{\beta}_1$ measures the impact of diversification and $\hat{\beta}_2$, the direct effect of a shift from interest activities to non-interest activities. If income diversity leads to higher efficiency, one would expect $\hat{\beta}_1$ to be positive. We are interested in the relationship between banks' income diversification and efficiency, but it is important to include the *NONSHARE* directly as an independent variable because we would like to control for the correlation between income diversification and non-interest income share.[4] We follow here the methodology developed by Stiroh and Rumble (2006) in order to assess the effects of diversification toward non-interest activities. The impact of a change in non-interest income on efficiency is measured using the first derivative of our dependent variables with respect to non-interest income:

$$\frac{\partial Bank\ Efficiency}{\partial NONSHARE} = \hat{\beta}_1 \frac{\partial INCDIV}{\partial NONSHARE} + \hat{\beta}_2 \qquad (6)$$

The first term on the right-hand side of Eq. (6) measures the effect of a change in the non-interest income share through its effect on diversification. As in Stiroh and Rumble (2006), we refer to this as the indirect effect of a change in non-interest income. As this effect depends both on the sign of $\hat{\beta}_1$ and the magnitude of the non-interest income share, the indirect is calculated accordingly for different levels of non-interest income. Meanwhile, $\hat{\beta}_2$ captures the direct effect of a shift from interest effect. Using a portfolio-style interpretation, $\hat{\beta}_1$ measures the covariance effect, while $\hat{\beta}_2$ measures the variance effect. The net effect, which is the sum of the direct and indirect effects, determines how efficiency varies with an increase in the share of non-interest income.

The dependence, however, between $\hat{\beta}_1$ and $\hat{\beta}_2$ raises econometric issues since *NONSHARE* and *INCDIV* are collinear. Although both estimates may be unbiased, their variance and covariance are overestimated (Chiorazzo et al., 2008). Wald tests need to be conducted to check the joint statistical significance of $\hat{\beta}_1$ and $\hat{\beta}_2$ in the various estimations. Moreover, we also estimate the equation by using only *NONSHARE* to check for robustness.

---

[4] For example, a bank with 0.25 of its non-interest income share and a bank with 0.75 would appear the same value of income diversification, but it implies a very different range of strategies among banks.

3.5 The interrelated dimensions of bank income diversification and ownership

Based on the main implications of income diversification and ownership structure, and allowing for other factors to influence bank's overall efficiency, the basic empirical specification is formulated as follows:

$$\begin{aligned} \textit{Bank Efficiency}_{i,c,t} = {} & \beta_0 + \beta_1\ \textit{INCDIV}_{i,c,t} + \beta_2\ \textit{NONSHARE}_{i,c,t} \\ & + \beta_3\ \textit{INCDIV}_{i,c,t} \times \textit{Ownership Structure}_{i,c,t} \\ & + \beta_4\ \textit{NONSHARE}_{i,c,t} \times \textit{Ownership Structure}_{i,c,t} \\ & + \beta_5\ \textit{Ownership Structure}_{i,c,t} \\ & + \alpha'\ \textit{Bank Regulation Control}_{c,t} \\ & + \gamma\ \textit{Information Sharing}_{c,t} \\ & + \lambda'\ \textit{Bank Controls}_{i,c,t} \\ & + \rho'\ \textit{Macro Controls}_{c,t} \\ & + \textit{Country Dummies} + \textit{Year Dummies} + e_{i,j,t}, \end{aligned} \tag{7}$$

where $\textit{Bank Efficiency}_{i,j,t}$ is the cost efficiency scores of bank i in country c in time t. All other variables are defined in Eq. (5), and we continue to impose the sample restrictions, country and year fixed effects used in the model specifications. Notably, the coefficient on the interaction term $\textit{INCDIV}_{i,c,t} \times \textit{Ownership Structure}_{i,c,t}\ (\beta_3)$ will explain whether the income diversification and ownership enhance or impede bank efficiency. In other words, β_3 indicates the differential in income diversification benefits between government, domestic private and foreign-controlled banks. If one ownership group (i.e., government or foreign-controlled banks) has more benefits of diversification than their private-controlled counterparts, we would expect β_3 to be significant and positive. Similarly, β_4 measures the effects of government, foreign ownership expressed as a difference from the increase exposure to volatile non-interest activities of domestic private banks. If government-controlled banks (or foreign-controlled banks) perform better in mitigating the drawback effect of a shift towards non-interest activities than domestic private banks, the coefficient on the interaction term β_4 would be also expected to be significant and positive.

4. Data

4.1 Data sources

This study examines year-end financial statement data from 2003 through 2012 for 83 countries obtained from BankScope database. Unconsolidated data were selected but where these were not available, we chose consolidated data instead. For each bank in the database, state and foreign ownership information is hand collected from a variety of sources. We first gather information from the section "Shareholder Information" in the BankScope database. When BankScope's shareholder database does not have enough information for us to determine the percentage of state, foreign or domestic private ownership, we use bank ownership information from additional sources as used by La Porta et al. (2002). These sources include the Europa World Yearbook, the Banker's Almanac, Thomson Bank Directory, Asian Company Handbook, the Euromoney Bank Register, Bankers Handbook for Asia, Moody's International Company Data, World Scope Global Disclosure, and the MFC Investment Handbook.

Information on bank regulation and supervision variables was obtained from the World Bank (WB) database developed by Barth et al. (2001) and updated by Barth et al. (2006; 2008; 2013). Furthermore, Specifically, data for the indicator of information sharing were obtained from the Djankov et al. (2007). Finally, data for country-specific variables were collected from the WB database and the International Monetary fund (IMF). Also, we use International Monetary Fund (2012) report to classify countries according to analytical criteria of their development level, in which the sample will be divided into two major groups: developed countries and developing countries.[5] These analytical criteria are based on the compositions of (1) the source of export earnings and other income from abroad named analytical criteria; and (2) the

[5] As used here, the terms "developed countries" and "developing countries" refer to two groups of countries named "advanced economies" and "emerging and developing economies", respectively, in International Monetary Fund (2012) report.

financial criteria focusing on external financing sources and experience with external debt services.[6]

4.2 Efficiency scores

Table 1 provides a summary statistic of variables used in bank efficiency estimations. On average, the commercial banks have a higher amount of their total deposits than total loans. The average total costs of the sample banks is $2.865 billion. The mean values of price of capital and price of funds are about 4.665 and 0.042, respectively. These values are higher than the 2.82 of price of capital reported by Sun and Chang (2011), and are lower the 0.21 of price of funds reported by Berger et al. (2009). Notably, the standard deviations of our output variables are very high, which reflect that there exist the large differences in the bank sizes in the cross-country sample.

[Insert Table 1 here]

We present average *Bank Efficiency* scores by country in Table 2. The *Bank Efficiency* involves minimizing total cost of production for a given output level. Based on our measures in Panel A and B of Table 2, means of the *Bank Efficiency* score in each country range from 34.9 percent to 89.6 percent from year 2003 to 2012, while the overall mean presents at 70.6 percent. These explain that, on average, all banks could have produced their outputs by using 34.9 percent to 89.6 percent of the inputs that they actually consumed during the period 2003 – 2012. The results in Panel C reveal that there is no difference in average bank efficiency between prior and posterior GFC. In contrast, Panel D indicates that cost efficiency in developed markets (73.5 percent) is higher than those of developing markets (69.2 percent), and the difference is statistically significant at the 1 percent level.

[6] Countries are categorized into one of the related groups when their main source of export earnings exceeds 50 percent of total export values on average between 2005 and 2009. Countries are placed in the net debtor category when their current account balance accumulations from 1972 to 2009 are negative. Net debtors are grouped in the external financing category when 65 percent or more of their total debt, on average between 2005 and 2009, is funded by official creditors.

Table 2 also provides descriptive statistics of the government and foreign block ownership by country. During 2003 to 2012, the means of government, domestic private and block foreign ownership of banks for the 83 countries in the sample are 9.31 percent, 25.6 percent and 33.5 percent, respectively. The results in Panel C also show that government ownership of top ten banks has been declining during the aftermath of GFC, although the difference in *GO* between before and after GFC is insignificant. The opposite is true for the cases of domestic private and foreign ownership. After the financial crisis, the average foreign ownership increases about 4.19 percent relative to the prior period, while the difference of private ownership is 1.08 percent (but not statistically significant). It would be not surprising that these changes are consistently influenced by the evolution of the privatization and liberalization process. We also group countries by their economic development in Panel D, and find that both means of government and foreign ownership show higher values for developing countries, while the average private ownership in developing countries presents a significantly lower level than that of developed ones.

We report the mean values of the income diversification and banks' non-interest income share variables disaggregated by a financial crisis, as well as by an economic development. Panel C of Table 2 compares mean values of non-interest income share and bank diversification between before and after GFC. It appears that before the crisis, on average, these values both experience higher levels than those after GFC period. The differences are statistically significant at 1 percent level, indicating a downtrend of bank's activities toward non-interest income. Our univariate results in Panel D show that bank diversification in developing countries tends to be higher than that of developed countries, although it is still questionable to figure out whether the benefits of diversification are improved or reduced by changes in ownership structure mentioned above.

[Insert Table 2 here]

Table 3 shows summary statistics of bank efficiency, ownership structure, income diversification, bank regulations, and bank-level and country-level control variables. The mean value of income diversification in the whole sample is 0.40, while the overall mean of non-interest income share presents at 0.37. On average, the dummy variables of both government ownership (13.47 percent) and foreign ownership (41.74 percent) with the threshold of 20 percent are higher than those of 50 percent threshold (9.13 percent and 33.29 percent, respectively). The mean and standard deviation of the overall capital stringency present at 3.95 and 1.61, respectively, whereas those of official supervisory power index are 10.89 and 2.38. Also, the mean values of log of bank total assets and log of GDP per capita are 3.76 and 4.06, respectively corresponding to the standard deviations of 1.06 and 0.48. These suggest fairly low cross-country variation. Finally, we found that the average value of deflated *CPI* is 119, higher than the value of 100 with base year 2005.

[Insert Table 3 here]

The pair-wise correlation values between independent variables in the pre-crisis period are reported in Table 4. The matrix explaining the correlation between *D20GO* and *INCDIV* is negative and statistically significant, while the correlation between *D20FO* and *INCDIV* shows a positive relationship (although not statistically significant). These correlations explain that banks with high government ownership present a lower level of income diversification than their non-government counterparts, whereas banks with high foreign ownership are not likely to have a greater diversification. A significantly positive association is shown for correlation between *INCDIV* and bank regulatory variables, indicating that the economies with more requirements in bank supervisory and regulatory systems are likely to enlarge their banking diversification. Similarly, *INCDIV* is positively correlated with *Size*, which suggests that banks with larger assets tend to have a higher level of diversification. The opposite is true for the relation between bank diversification and *Equity*. In addition, the positive correlation between *NONSHARE* and *Equity* shows that the higher the ratio of total equity to total assets, the more the share of bank's non-interest income. The matrix correlation also indicates that an increase in *GDP* will increase banks' non-traditional activities, while an increase in domestic inflation *(CPI)* will improve income diversification.

[Insert Table 4 here]

5. Empirical results

5.1 Determents of efficiency

As discussed earlier, to test for the potential effect of the Global Financial Crisis of 2008 in changing the bank's investment behavior and risk exposure, our regressions should be interpreted separately for before and after crisis periods. As banks located in developed and developing economies are likely to have different performance (see Micco et al., 2007), we also split our sample into two country groups. Models 1, 2 and 3 of Table 5 report estimations of the parameters from the Eq. 5 prior GFC by using cost efficiency scores as a dependent variable. The coefficient of income diversification, *INCDIV* is positive and significant in all cases of the pre-crisis period, explaining that increased income diversification enhances bank efficiency. In contrast, the negative coefficients on the share of the non-interest income *(NONSHARE)* across these regressions imply that a larger portion in non-interest income is associated with reduced efficiency. Based on the portfolio framework, the coefficient of *INCDIV* is interpreted as the benefit of diversification from a covariance effect, while that of *NONSHARE* denotes the negative effect from increased exposure to the more non-interest income activities (volatile investments). These results are consistent with the double-edged nature of the trend toward non-interest income reported by Stiroh and Rumble (2006), who suggest that an increase in revenue diversity will lead to higher potential gains for banks, but these benefits are offset by the increased exposure to volatile non-interest income share. This evidence is also similar to the view that banks use up their diversification benefits through increasing their financial leverage or holding less equity capital, hence making more risky loans (Demsetz and Strahan, 1997; DeYoung and Roland, 2001).

Table 5 also reports our baseline results with the differences of bank efficiency across ownership groups. The first model shows that banks with large government ownership tend to have lower cost efficiency than comparable domestic private banks. The effect is quantitatively substantial, explaining that the average state-controlled bank has an efficiency level that is 0.035 points lower than that of the average private-controlled bank. However, we find no statistically significant difference between the bank efficiency of foreign-controlled banks and that of similar domestic private banks. When we look at the effects of ownership structure on bank efficiency across countries, we find only differences in the developing countries, not the developed countries during the pre-crisis period. The result of model 3 shows that state-controlled banks located in developing economies tend to have lower efficiency than their private-controlled counterparts. In developed economies, we find no significant difference in bank efficiency between government, domestic private and foreign-controlled banks. These results are consistent with previous findings that banks with high government ownership tend to be less efficient and less profitable than banks with high private ownership in developing countries (e.g., Bonin et al., 2005a; Berger et al., 2009), but that is not the case in developed countries (Micco et al., 2007).

Models 4, 5 and 6 of Table 5 show the results after the financial crisis. The coefficients on *INCDIV* and *NONSHARE* continue to provide the significantly positive and negative impacts, respectively, on bank efficiency for all these model specifications. These evidences suggest that the benefits of diversification and the dark sides of non-interest exposure are more pronounced even during the financial crisis period. Although income diversification is positively associated with bank efficiency across countries, it shows a lower magnitude of diversification gains in developing countries. Based on our analysis in models 5 and 6, banks in developed economies that experienced a one percent increase in diversification could improve their efficiency about 0.231 percent, higher than that in developing countries (0.114 percent). In contrast, the offsetting effect of non-interest income share on bank efficiency in developed countries (-0.275) is greater than that in developing ones (-0.131). Notably, after the financial crisis, the diversification benefits between developed and developing countries display the opposite magnitudes with those reported in pre-crisis sample. This may be derived from government intervention for the allocation of credit in banking industry, as well as the possible obstacles in operating financial services concerning bank ownership structure, especially in the aftermath of the financial crisis.

We also find different results when we compare the efficiency between foreign-controlled banks and their domestic private counterparts in the aftermath of the financial crisis. There is no difference in cost efficiency between state-controlled and domestic private banks, while foreign-controlled banks tend to have a higher efficiency than comparable private banks in developing countries (model 6 of Table 5). More interestingly, the previous insignificant coefficient of *D20FO* before the financial crisis becomes positively significant in developing countries, while the negative coefficient of *D20GO* becomes statistically insignificant after the crisis period. This indicates that the foreign-controlled banks located in developing countries tend to be more effective in cost management than those of comparable private banks during the crisis aftermath (a result that is consistent with what was found by Micco et al. (2007)).

Notably, the coefficient of foreign ownership dummy in developing countries is very large and indicates that the differential between the cost efficiency of foreign-controlled banks and private-controlled banks more than triples when compared with that of developed countries during the post-crisis period (the two values are 0.066 and 0.020, respectively). On the other hand, the result of *D20GO* also suggests that it is not necessarily true that banks with more government ownership are less efficient than banks with more domestic private ownership and are in the line with Altunbas et al. (2001), who find no evidence that private-owned banks are more efficient and perform better than mutual and state-owned banks in case of Germany. They also argue that the public banks with lower funding costs based on "less interest rate sensitive" retail depositors as a fundamental reason to explain their superior performance over the domestic private banks.

To assess the net effect between positive impact of income diversification and negative impact from the increased non-interest income share, we regard estimates both coefficients together as discussed in Section 3. Table 6 shows results of the indirect, direct and net effect from the bank efficiency regression, regressed at various percentile ranks (10th, 25th, 50th, 75th, and 90th percentile) of non-interest income share.[7] Estimates are based on the result of income diversification regression from the first column and the fourth column of Table 5. The first row of Panel A presents the indirect effect before the financial crisis, which alters monotonically from over 0.002 for a bank with a non-interest income share at the 10th percentile to about 0.001 for a bank at the 90th percentile.[8] The results indicate that banks with relatively smaller non-interest income shares (the 10th and 25th percentile) have greater potential diversification gains from a shift toward non-traditional activities, whereas banks with relatively larger non-interest income shares (the 75th and 90th percentile) have fewer potential diversification benefits. The second row shows the direct effect, which indicates that one percent increase in share of non-interest income is associated with 0.18 percent decline in bank efficiency. The net effect in the final line of Panel A shows that the costs associated with increased income diversification offset the positive gains from a more diversified revenue stream. Interestingly, the potential diversification benefits are significantly smaller when banks tend to be more diversified (the 75th and 90th percentile), explaining that increased shifts toward non-interest income are related to lower bank efficiency.[9] The evidence from net effect confirms again the double-edge nature of the shift toward non-traditional activities: increased income diversification does bring benefits for banks, but these gains from diversify are likely to be offset by the extra costs associated with the more volatile activities. This result supports the strategic focus hypothesis, consistent with the findings of DeYoung and Roland (2001) and Stiroh and Rumble (2006) in earlier periods.

---

[7] The 10th, 25th, 50th, 75th, and 90th percentile correspond to the non-interest income shares of 0.18, 0.27, 0.37, 0.48, and 0.65, respectively for Panel A (before financial crisis), and 0.17, 0.24, 0.32, 0.44, and 0.59 for Panel B (after financial crisis).

[8] Similar to Stiroh and Rumble (2006), the effects are estimated at a 1% increase in the share of non-interest income.

[9] We also report the indirect, direct and net effect of non-interest income share after the financial crisis in Panel B, which the results are almost similar to those of Panel A when the fourth column of Table 5 is used.

5.2 The interrelated dimensions of bank income diversification and ownership

We are now interested in whether the influence of income diversification may vary with different characteristics of countries that have experienced the most considerable changes in ownership structure of commercial banks. In particular, we examine the role of ownership structure in determining the benefits of income diversification. Table 7 presents estimates of regressions with the bank diversification and share of non-interest income variables interacted with dummy government ownership, and with dummy foreign ownership. The coefficients on interaction *INCDIV*D20GO* are significant and negative for both full and subsample cases, indicating that the efficiency of increased diversification is significantly lower for banks having more government ownership. Specifically, models 1 through 3 of Table 7 show that, compared with domestic private banks, a one percentage point increase in income diversity is associated with about 0.155 percentage point lower efficiency level for state-controlled banks. The result is also similar to that obtained in developed countries (-0.286) and developing countries (-0.147), and that is consistent with what was found by Berger et al. (2010) in the regression of cost efficiency. However, the negative effects of government ownership on bank diversification are mitigated by low costs of diversity. All coefficients on *NONSHARE*D20GO* are positive and significant in the pre-crisis period, implying that government-controlled banks perform better in declining the drawback effect of an increased share of non-interest income on bank efficiency than their domestic private counterparts.

When we focus on foreign ownership before the financial crisis, we find that the coefficient on interaction term *INCDIV*D20FO* is negative in the developed countries, but in the developing countries this coefficient is not statistically significant. Model 2 of Table 7 explains that, compared with domestic private banks, foreign-controlled banks located in developed countries tend to have a lower efficiency of income diversification. For developed economies experiencing a one percent increase in income diversification, annual cost efficiency of banks with high foreign ownership is 0.261 percent, lower than that of comparable private banks. In other words, the negative effect of foreign ownership on diversification benefits indicates that foreign-controlled banks seem to be hard to maximize the advantage of management's expertise and reduce agency problems in developed countries. In contrast, the coefficient on *NONSHARE*D20FO* is positive and significant, explaining that foreign-controlled banks can mitigate better the negative impact of an increased share of non-interest activities on bank efficiency than their private-owned banks. This finding is in the line with Berger et al. (2010), who suggest that foreign ownership may play an important role in reducing the bank's diversification discount.

After the financial crisis, most ownership interactions in Table 7 are statistically significant, implying that benefits of diversification and potential risks of non-interest income vary with bank ownership structure. We find that government ownership continues to provide a negative impact on the relation between income diversification and bank efficiency. Results show that cost efficiency of state-controlled banks is lower than cost efficiency in domestic private banks when experiencing an increase in income diversification. Take, for instance, models 5 and 6 of Table 7 reports that the differential in diversification effectiveness between average state-controlled and domestic private banks located in developed countries is approximately -0.325 basis points, while in developing countries the estimated points yield a difference of approximately -0.149 basis points relative to the benchmark of private banks.

It is interesting to note that, the previous coefficient of the interaction *INCDIV*D20FO* is negatively insignificant (-0.202) to become positive and statistically significant (0.110) for the subsample of developing countries after the GFC. The coefficient suggests that, compared with domestic private banks, foreign-controlled banks located in developing countries tend to be more efficient in diversified activities during the post-crisis period. The opposite is true for the foreign-controlled banks in developed countries. One possible reason is that foreign-controlled banks are more exposed to financial markets in developed countries. They tend to be more competitive by using greater communication technology and better risk management while operating in developing countries. These advantages in financial services could favor foreign banks in expanding total leverage for diversification target, and thus enhance their profitability (Claessens et al., 2001). Unlike foreign presence in developed markets, the presence of foreign ownership in developing countries generally represents a monitoring of professionalism at the top management level. Moreover, foreign-owned banks located in developing countries are also often associated with good information networks and wide partnerships, and even have an advantage in affiliation with conglomerates; therefore, their diversified activities can improve the efficiency better than the comparable non-foreign counterparts (Berger et al., 2010).

On the other hand, models 5 and 6 of Table 7 also report that the interaction terms concerning volatile non-interest activities of foreign-owned banks *(NONSHARE*D20FO)* enter a regression positively in developed countries, inversely to a significantly negative coefficient found in developing countries. Not surprisingly, the coefficient of interaction *NONSHARE*D20FO* remains positively significant in the post-crisis sample of developed countries, indicating the role of foreign ownership in mitigating the negative effect of diversified activities that are inherently more volatile. On the contrary, this interaction term shows a negative coefficient (statistically significant at the 5% level) for the subsample of developing countries, explaining that foreign-controlled banks with high degree of non-traditional activities tend to be less effective than their private counterparts. This evidence is also consistent with Pennathur et al. (2012), who show that the foreign banks with a pursuit of fee-based income tend to increases risk, as measured by the earning volatility.

5.3 Robustness tests

In this section, we examine the robustness of our results to an alternative ownership measure. Because we are primarily interested in whether our results are robust to an alternative ownership structure, we replace dummy ownership variables of 20% threshold in previous section with those of 50% threshold. Following Iannotta et al. (2007) and Shen and Lin (2012), we consider a bank as being owned by a large shareholder if the shareholder owning more than 50% of total shares is an individual or company. For this, we set dummy variables, *D50GO* and *D50FO*, attempting to capture the extent of bank controls of government and foreign ownership, respectively (domestic private ownership is the excluded dummy variable).

[Insert Table 8 and 9 here]

We report the estimation results using alternative ownership structure in Table 8 and 9. The findings presented here are similar to the key findings reported in both Table 6 and 7. We continue to find that income diversification still provides a positive association with bank efficiency, whereas the opposite is true for share of non-interest income, suggesting a very robust relationship. The coefficients of government ownership interactions also confirm our prior findings that state-owned banks tend to have a lower benefit of income diversification than comparable private-owned banks, although these banks are likely to have lower costs of diversified activities. Compared to domestic private banks, foreign-owned banks in developed countries are likely to have lower diversification gains, while their presence in developing countries shows the opposite results during the post-financial crisis period. The robustness test once again implies that foreign-owned banks located in developed countries are better in reducing the diversification discount from the shift toward non-interest activities when compared with their domestic private counterparts, and that the opposite is true for the case of developing countries.

6. Conclusion

This paper explores the impact of ownership structure on the relationship between income diversification and bank efficiency using the sample of 83 countries over the period 2003–2012. The cost efficiency scores are estimated by parametric stochastic frontier approach to represent a bank's efficiency. We could summarize our main findings as follows. Firstly, banks with greater income diversification improve their efficiency, even though the diversification gains are offset by the increase exposure to volatile non-interest activities. Secondly, state-controlled banks tend to have lower benefits of diversification than comparable domestic private banks, although an increase in government ownership can help banks to have lower costs of income diversification. Thirdly, foreign-controlled banks located in developed countries are likely to have lower diversification effectiveness than their domestic private counterparts, while in developing countries their participation shows the opposite results during the aftermath of the financial crisis. Finally, banks with foreign-controlled ownership located in developed countries can mitigate better the negative impact of an increased share of non-interest activities on bank efficiency, whereas the opposite is true for their ownership in developing countries.

We provide evidence supporting for the strategic focus hypothesis that commercial banks should be aware of the potential increased costs from a strategy of expanding more non-traditional business lines. Our findings are consistent with the evidence of recent study on the performance–diversification nexus (e.g. DeYoung and Roland, 2001; Stiroh and Rumble, 2006; Berger et al., 2010). Assessing the effects of ownership structure and volatile earnings for financial institutions' efficiency has direct implications in the context of this debate. Because the benefits and dark sides of diversification vary with different forms of bank ownership, as well as with different nation's economic development, our study highlights the importance of designing an appropriate investment strategy and supervisory framework to reduce operation risks and to achieve a better performance for banks.

Table 1
Descriptive statistics of variables used in *Bank Efficiency* estimations.

	Mean	SD	Median	Minimum	Maximum
Interest expenses (in billion US $)	1.647	5.683	0.142	0.000	138.483
Non-interest expenses (in billion US $)	1.218	3.900	0.134	0.000	52.298
Total costs (in billion US $)	2.865	8.840	0.302	0.000	147.100
Outputs (in billion US $)					
Y_1 = Total loans	37.121	110.255	2.888	0.000	1,399.722
Y_2 = Other earning assets	36.111	147.664	1.403	0.000	2,240.273
Y_3 = Total deposits	62.636	200.277	4.364	0.001	2,537.282
Y_4 = Liquid assets	19.811	85.922	0.955	0.000	1,416.301
Input prices					
w_1 = Price of capital	4.665	22.920	1.846	0.073	787.000
w_2 = Price of funds	0.042	0.080	0.032	0.000	3.870

Notes: Price of capital is the ratio of non-interest expenses to total fixed assets. Price of funds is the ratio of interest expenses to total deposits. Total costs are the summation of interest expenses and non-interest expenses. Data source: BankScope, 2003–2012.

Table 2

Measures of bank efficiency, ownership structure, share of non-interest income, and income diversification around the world for the year 2003 –2012. *CE* is cost efficiency estimated by stochastic frontier approach (SFA). *INCDIV* is the value of income diversification followed the basic Herfindahl- type approach. *NONSHARE* is share of non-interest income. Panel A and B show the percentage of assets owned by the government *(GO)*, private domestic *(DO)* and foreign-held block shareholders *(FO)* which is classified by the 10% threshold from La Porta et al. (1999). Panels C and D show the results of tests of mean values across economies experienced the 2008 Global Financial Crisis, and across economic development (developed vs. developing). The economic development classification follows World Economic Outlook reported by International Monetary Fund (2012). Numbers of banks in each country are presented in brackets.

Countries	*CE*	*GO*	*DO*	*FO*	*NON-SHARE*	*INCDIV*

Table 3

Descriptive statistics of independent and control variables used to estimate the impact of income diversification and ownership structure on bank efficiency. *Bank Efficiency* is cost efficiency estimated by stochastic frontier approach. *D20GO (D20FO)* is dummy variable, takes a value of one if the percentage owned by government (foreign) block shareholders of a bank is above the threshold of 20%, zero otherwise. Similarly, *D50GO (D50FO)* is dummy variable, takes a value of one if the percentage owned by government (foreign) block shareholders of a bank is above the threshold of 50%, zero otherwise. *INCDIV* is the value of income diversification followed the basic Herfindahl- type approach. *NONSHARE* is the shares of non-interest income. Bank regulatory variables, including *OCS* and *OSP* represent for overall capital stringency and bank's official supervisory power, respectively. *Size* controls for economy of scale which calculated by log of bank total assets. *Equity* is denoted as the total equity to total asset ratio. *Information Sharing* is defined as a dummy equal to one if a country has either a public or a private registry, zero otherwise. *GDP* is defined as log of Gross Domestic Product (GDP) per capita based on Purchasing Power Parity, while *CPI* is the deflated Consumer Price Index (CPI) for each country with the base year 2005.

Variable	Mean	SD	Median	Minimum	Maximum
Bank Efficiency	0.706	0.193	0.767	0.007	0.973
INCDIV	0.403	0.102	0.436	0.001	0.500

Notes: Significance at 1%, 5% and 10% level is denoted by ***, ** and *. The figures in parentheses indicate *t*-values.

[10] To conserve space, the descriptive statistic for the post-financial crisis period 2008 – 2012 is not reported, but is available upon request.

Table 5

This table reports the differential impact of income diversification on the bank efficiency, which is estimated by Tobit regressions. Statistics are based on an unbalanced panel for the year 2003 – 2007 (before financial crisis) and year 2008 – 2012 (after financial crisis). *D20GO (D20FO)* is dummy variable, takes a value of one if the percentage owned by government (foreign) block shareholders of a bank is above the threshold of 20%, zero otherwise (private domestic ownership is the excluded dummy). *INCDIV* is the value of income diversification followed the basic Herfindahl- type approach. *NONSHARE* is the shares of non-interest income. Bank regulatory variables, including *OCS* and *OSP* represent for overall capital stringency and bank's official supervisory power, respectively. *Size* controls for economy of scale, which is calculated by log of bank total assets. *Equity* is denoted as the total equity to total asset ratio. *Information Sharing* is defined as a dummy equal to one if a country has either a public or a private registry, zero otherwise. *GDP* is defined as log of Gross Domestic Product (GDP) per capita based on Purchasing Power Parity, while *CPI* is the deflated Consumer Price Index for each country with the base year 2005. Models 1 through 3 report the basic regression results that include main independent variables and bank-specific control variables prior the financial crisis, while models 4 through 6 provide regression results after the financial crisis.

Table 6

Estimation of impact of a change in the non-interest income share on bank efficiency. The estimates of the indirect, direct and net effects are based on the results of efficiency regression in the first column of Table 5 for Panel A and second column of Table 5 for Panel B. The coefficients are evaluated at the 10th, 25th, 50th, 75th, and 90th percentile of non-interest income share corresponding to the non-interest income shares of 0.18, 0.27, 0.37, 0.48, and 0.65, respectively for Panel A, and 0.17, 0.24, 0.32, 0.44, and 0.59 for Panel B. Both indirect and indirect effects are estimated effect of a 1% increase in income diversification from a 1% increase in the share of non-interest income. The net effect is measured by sum of indirect and direct effects.

	The percentiles of non-interest income share				
	10th	25th	50th	75th	90th
Panel A – The impact of change in non-interest income share before financial crisis

Table 8

This table reports the differential impact of income diversification on the cost efficiency, which is estimated by Tobit regressions. Statistics are based on an unbalanced panel for the year 2003 – 2007. *D50GO (D50FO)* is dummy variable, takes a value of one if the percentage owned by government (foreign) block shareholders of a bank is above the threshold of 50%, zero otherwise (private domestic ownership is the excluded dummy). *INCDIV* is the value of income diversification followed the basic Herfindahl- type approach. *NONSHARE* is the shares of non-interest income. Bank regulatory variables, including *OCS* and *OSP* represent for overall capital stringency and bank's official supervisory power, respectively. *Size* controls for economy of scale, which is calculated by log of bank total assets. *Equity* is denoted as the total equity to total asset ratio. *Information Sharing* is defined as a dummy equal to one if a country has either a public or a private registry, zero otherwise. *GDP* is defined as log of Gross Domestic Product (GDP) per capita based on Purchasing Power Parity, while *CPI* is the deflated Consumer Price Index for each country with the base year 2005. Models 1 through 2 report the basic regression results that include main independent variables and bank-specific control variables prior the Global Financial Crisis of 2008. Models 3 through 4 show estimated results of developed countries, while models 5 through 6 provide regression results of developing countries.

Table 9

This table reports the differential impact of income diversification on the cost efficiency, which is estimated by Tobit regressions. Statistics are based on an unbalanced panel for the year 2008 – 2012. *D50GO (D50FO)* is dummy variable, takes a value of one if the percentage owned by government (foreign) block shareholders of a bank is above the threshold of 50%, zero otherwise (private domestic ownership is the excluded dummy). *INCDIV* is the value of income diversification followed the basic Herfindahl- type approach. *NONSHARE* is the shares of non-interest income. Bank regulatory variables, including *OCS* and *OSP* represent for overall capital stringency and bank's official supervisory power, respectively. *Size* controls for economy of scale, which is calculated by log of bank total assets. *Equity* is denoted as the total equity to total asset ratio. *Information Sharing* is defined as a dummy equal to one if a country has either a public or a private registry, zero otherwise. *GDP* is defined as log of Gross Domestic Product (GDP) per capita based on Purchasing Power Parity, while *CPI* is the deflated Consumer Price Index for each country with the base year 2005. Models 1 through 2 report the basic regression results that include main independent variables and bank-specific control variables after the Global Financial Crisis of 2008. Models 3 through 4 show estimated results of developed countries, while models 5 through 6 provide regression results of developing countries.

□ □ □ □ □ □ Does Money Illusion Delude Investors? Evidence from Anomalies

Yuna Heo
Department of Finance & Economics, Rutgers Business School
Rutgers University
yunaheo@rutgers.edu

This paper investigates the role of money illusion in the anomaly-based strategies. To the extent that anomalies reflect mispricing, I examine whether money illusion predicts anomaly returns. I find that, following high inflation, anomalies are stronger and the returns on the short-leg portfolios are lower. These findings indicate that money illusion leads to mispricing in the stock market. I explore the source of money illusion-driven mispricing. I find that money illusion negatively predicts forecast errors and dispersion. These results suggest that investors overestimate the upside potential of stock returns following high inflation and are subsequently surprised by the return reversal.

Keywords: Money Illusion, Inflation, Anomalies, Mispricing

JEL Classification: G02, G12, E31

1. Introduction

Whether the inflation, namely money illusion, affects stock prices is a question of long-standing interest to researchers. As early as Fisher (1928) defines money illusion as "the failure to perceive that the dollar, or any other unit of money, expands or shrinks in value", numerous papers have examined the existence of money illusion in the equity market. In early works, equities had often been regarded as a claim against physical assets whose real returns remain unaffected by inflation.[1] However, contrary to the conventional view, many empirical studies find a negative relation between inflation and stock returns.[2]

In recent years, many papers have documented the renewed interests in the existence of money illusion in the capital market. For example, Cohen, Polk, and Vuolteenaho (2005) revisit the issue of money illusion and provide a strong support for Modigliani and Cohn (1979) hypothesis.[3] Brunnermeier and Julliard (2008) find that housing market trends are largely explained by variations in the inflation.[4] These recent studies suggest that money illusion possibly leads to mispricing in the stock market. In this paper, motivated by controversial findings in earlier works and recent renewed interests in money illusion, I investigate the role of money illusion in the stock market by testing anomaly returns.

---

[1] Many researchers thought that the Fisher (1930) hypothesis that a nominal interest rate fully reflects the available information concerning the future values of the rate of inflation might also hold for the stock return-inflation relation. Regarding this, Tobin (1972) described: "An economic theorist can, of course, commit no greater crime than to assume money illusion". See Fehr and Tyran (2001) for the detailed discussion.

[2] For example, see Bodie (1976), Jaffe and Mandelker (1976), Nelson and Schwert (1977), Fama and Schwert (1977), Gultekin (1983), Modigliani and Cohn (1979) Kaul (1987, 1990), and Kaul and Seyhun (1990).

[3] Modigliani and Cohn (1979) propose the hypothesis that stock market investors are subject to inflation illusion. Modigliani and Cohn (1979) assume that the valuations of the assets differ from their fundamental values because of two inflation-induced errors in judgments.

[4] In addition, Sharpe (2002), Ritter and Warr (2002), Campbell and Vuolteenaho (2004), Chen, Lung, and Wang (2009), Lee (2010), Birru and Wang (2014), and Warr (2014) have studies the effect of money illusion in the capital market.

The objective of this paper is to examine whether money illusion plays an important role in affecting the degree of mispricing in the stock market. At the simplest level, money illusion occurs when investors mix real growth rates with nominal discount rates. This valuation error can induce significant impacts in the stock prices. The key explanation of money illusion effects is that, following high inflation periods, money-illusioned investors are overly optimistic for the past performance of equities and excessively extrapolate into the future when they value firms. To the extent that firms' stock price can reflect the views of investors who are most optimistic, a presence of money-illusioned investors can cause a stock price departs from its fundamental value.

I start by testing the relation between money illusion and stock market returns to explore the role of money illusion in the stock market. Consistent with the findings in previous literatures, I find that the money illusion is a negative predictor for stock market returns during the period of 1965-2010. The magnitude of predictability is statistically significant and economically large. In the univariate regression, I find that a one standard deviation increase in money illusion is associated with about 0.5% decline in one month-ahead market returns. In the multivariate regressions, I control for three predictive variables related interest rates and find that the effect of money illusion remains significantly negative.[5] These findings suggest that investors may overestimate the upside potential of stock returns following high inflation periods and subsequently experience negative returns.

To examine whether money illusion leads to mispricing, I entertain the possibility that anomalies at least partially reflect mispricing in the stock market. In previous studies, Stambaugh, Yu, and Yu (2012) explore the role of investor sentiment in a broad set of anomalies in cross-

[5] The three predictive variables are: *T-bill* is the 3-month T-bill rate. *Term* is the difference between yield on 10-year bond and the T-bill. *Default* is the difference between Baa and Aaa-rated corporate bonds.

sectional stock returns.[6] Similar to Stambaugh, Yu, and Yu (2012), I investigate the role of money illusion in the stock market by examining the anomaly-based strategies associated with mispricing. I consider 11 well-documented anomalies in the previous literatures. Theses anomalies include size, value (book-to-market equity), financial distress, net stock issues, earnings quality, gross profitability, returns-on-assets (ROA), investment-to-assets, external financing, and asset turnover. It is worthwhile to emphasize that, while this study shares a similar setting with Stambaugh, Yu, and Yu (2012), I focus on the inflation to investigate whether money illusion affects the degree of mispricing in the stock market.[7] To the best of my knowledge, this is the first paper to examine the relation between money illusion and anomaly returns.

Two main empirical implications are tested to explore the role of money illusion in the stock market. The first hypothesis is that anomalies are stronger following high inflation periods. The first hypothesis indicates that the long-short spread should be larger following high inflation. Consistent with the first hypothesis, I find that each of the long-short anomaly-based strategies presents higher average returns following high inflation. In the predictive regressions, I find the positive relation between money illusion and the long-short spread. These results imply that mispricing is stronger following high inflation periods. The estimate of combination strategy on the benchmark-adjusted returns presents that one standard deviation increase in money illusion is associated with $0.0061 of an additional monthly profit in each long-short spread. Clearly, these

[6] Stambaugh, Yu, and Yu (2012) combine the presence of market-wide sentiment with the Miller (1977) short-sale argument.

[7] Many fundamental mechanisms, including the divergence of opinions and short-sale constraints (Miller (1977), Hong and Sraer (2012)) and sentiment (Baker and Wurger (2006), Stambaugh, Yu, Yuan (2012)), can potentially lead to mispricing in the stock market. In this study, I simply use money illusion as a proxy for mispricing.

findings suggest that money illusion plays an important role in affecting the degree of mispricing in the stock market.

The second hypothesis is that stock returns on the short-leg portfolios should be lower following high inflation. To the extent the anomaly reflects mispricing, the stocks in the short leg should be relatively overpriced compared to the stocks in the long leg. This indicates that the stocks in short leg should be more overpriced following high inflation, as a result, present lower returns. Consistent with the second hypothesis, I find that the short leg of all anomaly-based strategies presents lower excess returns following high inflation periods. The short leg of the combined strategy earns 177 bps less per month following high inflation periods than low inflation periods. In the predictive regressions, I find that the slope coefficients for the short-leg returns of all anomalies are negative. These results suggest that investors overly extrapolate past performance into the future when they value firms and subsequently experience negative returns. The combination strategy implies that one standard deviation increase in money illusion is related to 0.6% decrease in monthly excess return on the short-leg portfolio. These findings clearly provide the evidence that money-illusioned investors overestimate the upside potential of stock returns following high inflation periods.

To better understand the results of this study, I empirically investigate the possible source of money illusion-driven mispricing. I examine two prominent explanations: the risk-based explanation and the behavioral-based explanation. The risk-based explanation argues that the omitted risk factor's premium may explain the required correlation with money illusion. The behavioral-based explanation argues that investors excessively extrapolate on past performance when they value firms and surprised by the subsequent return reversal. I examine the potential for a risk-based explanation by controlling for an additional set of variables. I find that the effect of money illusion remains largely unchanged: the predictive power of money illusion for anomaly returns does not weaken after controlling for macro-variables and firm level predictive variables.[8] In addition, to access the potential for a behavioral-based explanation for previous results, I examine the relation between money illusion and forecast errors and dispersion. I find that money illusion negatively predicts forecast errors and dispersion.[9] The results indicate that investors' ex-ante expectation of future performance was too optimistic and subsequently surprised by the return reversal. This indicates that the behavioral-based explanation may support the results of this study.

Lastly, I extend the exploration of money illusion effects by examining sentiment and other commonly use measure for predicting stock returns. Many previous studies indicate that sentiment captures market-wide impacts in the stock market.[10] I control for the effect of sentiment to investigate whether money illusion plays an additional role in cross-sectional stock returns. I find that the effect of money illusion remains largely unchanged after controlling for sentiment and many additional variables.[11] The results suggest that money illusion can provide the complementary power for cross-sectional stock returns beyond the commonly used variables. Overall, this study contributes to the literatures on money illusion and mispricing by providing novel evidence that money illusion can lead to mispricing in the stock market.

---

[8] The variables are: T-bill as the 3-month T-bill rate, Term as the difference between yield on 10-year bond and the T-bill, Default as the difference between Baa and Aaa-rated corporate bonds, the earnings-to-price ratio, the dividend-to-price ratio, and the equity variance.

[9] The results are consistent with the prediction of Stambaugh, Yu, and Yu (2012) that investors' views must be sufficiently disperse to include rational valuation when sentiment is low.

[10] For example, Baker and Wugler (2006) provide strong evidence that investor sentiment have significant effects on the stock returns. Stambaugh, Yu, and Yu (2012) find evidence that anomaly returns are larger following high levels of sentiment.

[11] I control for an additional set of macro-related variables that seem reasonable to entertain as being correlated with the risk premium. I control for yield premium, term premium, and default premium, earnings-to-price ratio, the dividend-to-price ratio, and the equity variance.

This paper is organized as follows. Section 2 discusses related literatures and develops hypotheses. Section 3 introduces data and presents descriptive statistics. Section 4 reports main results. Section 5 investigates the source of money illusion-drive mispricing. Section 6 examine whether money illusion provides the complementary power to explain the cross-sectional stock returns. Section 7 concludes.

2. Related Literature and Hypothesis Development

2.1 Related Literature

Whether the inflation, namely money illusion, affects stock prices is a question of long-standing interest to researchers. The concept of money illusion was analyzed in detail for the first time by Fisher (1928). As Fisher (1928) defines money illusion as "the failure to perceive that the dollar, or any other unit of money, expands or shrinks in value", numerous papers have examined the existence of money illusion in equity markets. Among many papers, it is worth referring to the survey conducted by Shafir, Diamond, and Tverky (1997). Shafir, Diamond, and Tverky (1997) find that money illusion is a persistent phenomenon among economic and non-economic agents. In a same vein, Fehr and Tyran (2001) present that a presence of money-illusioned agents can cause significant impacts in capital markets.

The relation between stock returns and inflation has been studied for many years. Equities had traditionally been regarded as a hedge against inflation because equities are claims against physical assets whose real returns should remain unaffected by inflation. Numerous researchers thought that the Fisher (1930) hypothesis, which posit that a nominal interest rate fully reflects the available information concerning the future values of the rate of inflation, might also hold for the stock return-inflation relation. However, contrary to the conventional view and the Fisher hypothesis, many empirical studies find a negative relation between inflation and real stock returns.

There is an extensive literature documenting that realized returns are negatively influenced by inflation. (See, for example, Bodie (1976), Jaffe and Mandelker (1976), Nelson and Schwert (1977), Fama and Schwert (1977), and Gulteken (1983)) Several hypotheses have been proposed to explain the observed negative relation between stock returns and inflation.[12] Modigliani and Cohn (1979) propose the inflation illusion hypothesis that stock market investors are subject to inflation illusion. Modigliani and Cohn (1979) assume that the valuations of the assets differ from their fundamental values because of two inflation-induced errors in judgment. To explain the inverse relation, Fama (1981, 1983) proposes the proxy hypothesis. The proxy hypothesis suggests that a rise in expected inflation rationally induces investors to reduce expected future real dividend growth prices and expected real discount rates, subsequently lowers stock prices and realized returns. Later on, Amihud (1996) tests the relationship between unexpected inflation and stock returns in Israel and conclude that his results support only the proxy hypothesis explanation.

In recent years, several papers have documented the renewed interests in the existence of money illusion, suggesting the possibility of money illusion-induced mispricing in capital markets. For example, Ritter and Warr (2002) find that the bull market starting in 1982 was due in part to equities being undervalued, whose cause is cognitive valuation errors of levered stocks in the presence of inflation and mistakes in the use of nominal and real capitalization rates. Campbell and Vuolteenaho (2004) revisit the issue of the stock price-inflation relation based on

[12] Additionally, Geske and Roll (1983) and Kaul (1987) argue that the relationships are driven by links between expected inflation and expected real economic performance. Feldstein (1980) proposes the tax hypothesis to explain the inverse relation between higher inflation and lower share prices. Brandt and Wang (2003) propose the time varying risk aversion hypothesis.

the time-series decomposition of the log-linear dividend yield model and provide strong support for Modigliani and Cohn (1979) hypothesis.[13] Cohen, Polk, and Vuolteenaho (2005) present cross-sectional evidence supporting Modigliani and Cohn's hypothesis by simultaneously examining the future returns of Treasury bills, safe stocks, and risky stocks. Cohen, Polk, and Vuolteenaho (2005) find that money illusion causes the market's subjective expectation of the equity premium to deviate systematically from the rational expectation.

Other recent studies about money illusion have examined earnings forecasts, bubbles, dividend announcements and house prices. Sharpe (2002) find that analysts suffer from money illusion in their forecasts. Chordia ans Shivakumar (2005) find that money illusion causes firms whose earnings are positively related to inflation to be undervalued because investors fail to incorporate the effect of inflation on the earnings growth rate. Focusing on asset bubbles, Chen, Lung, and Wang (2009) find that while inflation illusion can explain the level of mispricing, it does not explain the volatility of mispricing. Brunnermeier and Julliard (2008) test the effect of the Modigliani and Cohn hypothesis on house prices and show that housing market trends are largely explained by variations in the inflation, suggesting that home buyers suffer from inflation illusion.

Given the discussion of numerous literatures, the impact on the economy and stock returns arising from the effects of inflation are indisputable. Motivated by controversial findings in earlier works and recent renewed interests in money illusion, I explore the role of money illusion in the mispricing of stock returns and anomalies.

2.2 Hypotheses Development

[13] Campbell and Vuolteenaho (2004) use the Campbell and Shiller (1988) valuation model to decompose the dividend yield to examine the effect of inflation.

To test whether money illusion plays an important role in affecting the degree of mispricing in the stock market, I entertain the possibility that anomalies at least partially reflects mispricing related to money illusion. In previous studies, combining the impediments to short selling as in Miller (1977), Stambaugh, Yu, and Yu (2012) explore the role of investor sentiment in a broad set of anomalies in cross-sectional stock returns. Similar to Stambaugh, Yu, and Yu (2012), I examine the relation between money illusion and its role in a broad set of anomaly-based strategies.

Two main empirical implications are tested to investigate the effect of money illusion on mispricing. The first implication is that mispricing should be stronger following high inflation. At the simplest level, money illusion occurs when investors mix real growth rates with nominal discount rates. This implies that a presence of money-illusioned investors can cause a stock price depart from its fundamental value. The key explanation of money illusion effects is that, following high inflation periods, money-illusioned investors are overly optimistic for the past performance of equities and excessively extrapolate into the future when they value firms. This valuation error can induce significant impacts in market prices in that a firm's stock price can reflect the view of investors who are overly optimistic. In contrary, during low inflation periods, the most optimistic views about stocks tend to be those of rational investors, and thus mispricing during those periods is less likely. Therefore, the first hypothesis is that anomalies are stronger following high inflation periods. This indicates that the long-short spread should be larger following high inflation. The positive profit on each long-short strategy reflects the unexplained cross-sectional difference in stock returns that constitutes an anomaly.

The second implication is that the stocks in short leg should be more overpriced following high inflation. Stocks in short leg are relatively overpriced compared to the stocks in the long leg. Specially, overpricing becomes more difficult to eliminate with impediments to short selling. If the primary form of mispricing is overpricing, such overpricing can occur for many stocks during high inflation periods. This implies that the stocks in short leg should be more overpriced following high inflation. In this regard, the second hypothesis is that stock returns on the short-leg portfolios should be lower following high inflation. This indicates that investors may overestimate the upside potential of stock returns following high inflation periods and subsequently experience negative returns.

It is worthwhile to emphasize that, while this study shares a similar setting with Stambaugh, Yu, Yuan (2012), I focus on inflation to examine whether money illusion plays an important role in affecting the degree of mispricing. Many fundamental mechanisms, including the divergence of opinions and short-sale constraints (Miller (1977), Hong and Sraer (2011)) and sentiment (Baker and Wurger (2006), Stambaugh, Yu, Yuan (2012)), can potentially lead to mispricing in the stock market. In the current study, I simply use money illusion as a proxy for mispricing.

3. Data

This section describes the data used in this study. I obtained the data from several sources. I compile market returns and S&P 500 returns from CRSP. Four measures of stock market returns are used: the value-weighted raw returns, the value-weighted excess returns, the S&P 500 raw returns, and the S&P excess return. The accounting information is obtained from COMPUSTAT. The sample period is 1965 to 2010. I also conduct sub-sample analysis over period 1970-1990 to ensure the robustness of results.

Inflation, namely money illusion, is defined as the change in Consumer Price Index (CPI) from year $t-1$ to t,

$$Money\ Illusion_t = (CPI_t - CPI_{t-1})/CPI_{t-1}$$

The data for CPI is obtained from the Bureau of Labor Statistics. Figure 1 plots *money illusion* and CPI (Consumer Price Index) from 1965 and 2010. The inflation is relatively high and volatile during 1970-1980. After 2000, the inflation is getting more volatile: The inflation peaked in 2005 once and immediately plummeted. It reached a peak again in 2006 then it crushed in 2008.

Interest rates data including 10-year and 3-month Treasury bills are downloaded from Federal Reserve Economic Data (FRED). I use three predictive variables related to interest rates. I use the excess returns on an index of 10-year bonds issued by the U.S. treasury as a *Term*. I use the excess returns on an index of investment grade corporate bonds as a *Default*. The one-period change in the option adjusted credit spreads for Moody's Baa-rated corporate bonds is used as the investment grade corporate bond rate. To compute excess returns, I use the three-month Treasury bill (*T-bill*) rate as the risk-free rate.

3.1 Descriptive Statistics

Table 1 report the descriptive statistics for the market returns and inflation from 1965 to 2010. Panel A shows that money illusion has an average of 0.35% and a standard deviation of 0.36% monthly. Monthly average of the value-weighted raw return is 0.87% and the monthly average of value-weighted excess returns is 0.43%, with standard deviations of 4.58% and 4.59%. The monthly average raw return on S&P 500 is 0.59% and the excess returns is 0.14%, with standard deviation of 4.42% and 4.43%. Panel B presents the correlations between stock market returns and inflation. All correlations of stock market returns with inflation are negative and the magnitudes are around -10%. This negative relation is consistent with the expected cross-sectional correlation between stock market returns and money illusion.

4. Results

4.1 Univariate Regression

I run predictive regression of one-month-ahead market returns on inflation. Table 2 presents the results of univariate regressions. Panel A reports the results over the periods 1965-2010 and Panel B reports the results over the sub-period 1970-1990. I use four measures of stock market returns: the value-weighted raw returns, the value-weighted excess returns, the S&P 500 raw returns, and the S&P excess return. The independent variable, money illusion, is standardized to have zero mean and unit variance, in order to interpret the economic significance of the predictability.

I find that money illusion is a negative predictor of the stock market returns. The magnitude is economically large: a one standard deviation increase in inflation is associated 0.53% decline in one-month-ahead value-weighted excess returns. For returns on value-weighted raw returns, the coefficient estimate is -0.42%. For returns on S&P 500, the slope estimates are larger and still economically big: -0.56% for S&P 500 excess return and -0.45% for S&P 500 raw return. Turing to Panel B, money illusion more significantly negatively predicts stock market returns for the subsample period with adjusted R^2 varying from 3.4% to 4.5%. The OLS estimates on money illusion are -0.96 % for the value-weighted raw return and -1.05% for the value-weighted excess return monthly. For Returns on S&P 500 excess return, the coefficients are -0.99% for S&P raw return and -1.07% for S&P excess return monthly. In sum, Table 2 indicates that the relation between money illusion and stock market returns is consistently negative.

4.2 Multivariate Regression

To examine whether money illusion has incremental power to predict market returns, I include three predictive variables related to interest rates. The variables are: T-bill is the 3-month T-bill rate. Term is the difference between yield on 10-year bond and the T-bill. Default is the difference between Baa and Aaa-rated corporate bonds.

Table 3 presents the results of multivariate regressions. Panel A reports the results over the periods 1965-2010 and Panel B reports the results over the sub-period 1970-1990. I use four measures of stock market returns: the value-weighted raw returns, the value-weighted excess returns, the S&P 500 raw returns, and the S&P excess return. The independent variable, money illusion, is standardized to have zero mean and unit variance, in order to interpret the economic significance of the predictability. I find that the estimates on money illusion remain negative and significant. The magnitudes of the coefficient on money illusion are almost same in the univariate regression: a one standard deviation increase in Inflation is associated with the 0.4% decrease in one-month-ahead market returns. These results indicate that adding interest variables has little effect on the ability of money illusion to predict returns. In Panel B, I perform sub-period analysis. The results are similar. The adjusted R^2 in the multivariate regressions ranges from 8.9% to 10.1%, higher than those in the univariate regressions. In sum, money illusion remains a negative predictor of stock market returns.

4.3 Money Illusion and Anomaly

I find that money illusion is a negative predictor for stock market returns during the period of 1965-2010. These findings suggest that investors may overestimate the upside potential of stock returns following high inflation periods. The key explanation of money illusion effects is that, following high inflation periods, money-illusioned investors are overly optimistic for the past performance of equities and excessively extrapolate into the future when they value firms. This valuation error can induce significant impacts in market prices.

To test whether money illusion leads to mispricing in the stock market, I entertain the possibility that anomalies at least partially reflect mispricing. In previous studies, Stambaugh, Yu, and Yu (2012) explore the role of investor sentiment in a broad set of anomalies in cross-sectional stock returns. Similar to Stambaugh, Yu, and Yu (2012), I examine the relation between money illusion and anomaly-based strategies.

4.3.1 Anomaly- based Strategy

I consider 11 well-documented anomalies to explore the money illusion-driven mispricing. Theses anomalies include size, value (book-to-market equity), financial distress, net stock issues, earnings quality, gross profitability, ROA (return on assets), investment-to-assets, external financing, and asset turnover. The explanation for each anomaly is as follows:

Size: Banz (1981) first documents the size effect by showing that small firms had higher risk-adjusted returns than large firms during the 1936-1977 period. Essentially, this anomaly indicates that small capitalization stocks outperform large capitalization stocks.

Value: Rosenberg, Reid, and Lanstein (1985) first suggest the value (book-to-market) strategy. This strategy is well-described in Fama and French (1993) that high book-to-market firms earn more than low book-to market firms.

Financial distress: Campbell, Hilscher, and Szilagyi (2008) find that firms with high financial distress have lower subsequent returns. The failure probability (financial distress) is estimated by a dynamic logit model with both accounting and equity market variables.

O-score: Ohlson (1980) O-score yields a similar anomaly to Campbell, Hilscher, and Szilagyi (2008). Ohlson's O-score is measured by the probability of default in a static model using various accounting variables.

Net stock issues: Pontiff and Woodgate (2008) present that there is a negative cross-sectional relation between aggregate share issuance and stock returns. Fama and French (2008) also present that net stock issuers earn negative realized returns.

Earnings quality: Sloan (1996) shows that firms with high accruals earn lower returns than firms with low accruals. Total accruals are calculated as changes in noncash working capital minus depreciation expense scaled by total assets.

Gross profitability: Novy-Marx (2013) finds that more profitable firms have higher returns than less profitable firms. It is calculated by gross profits scaled by assets.

Return-on-assets: Chen, Novy-Marx, and Zhang (2011) show that firms with higher past return on assets earn abnormally higher subsequent returns. Return on assets is measured by earnings before extraordinary items scaled by assets.

Investment-to-assets: Titman, Wei, and Xie (2004) find that higher past investment predicts abnormally lower future returns. Investment-to-assets is measured as the annual change in gross property, plant, and equipment plus the annual change in inventories scaled by the lagged book value of assets.

External financing: Bradshaw, Richardson, and Sloan (2006) find that net overall external financing is negatively related to stock returns. This negative relation suggests that investors may be relatively overoptimistic in forming their earnings expectations for high net external financing firms. External financing is measured by as the net amount of cash a firm raises from equity and debt markets.

Asset turnover: Novy-Marx (2013) find that high asset turnover firms have higher average returns. Asset turnover is often regarded as a proxy of efficiency, which quantify the ability to generate sales. Asset turnover is measured as sales-to-assets.

For each of the 11 anomalies, I examine the strategy that goes long the stocks in the highest-performing decile and short the stocks in the lowest-performing decile. Every portfolio formation on month, I sort stocks into the decile portfolios based on anomaly variables. I then construct a long-short strategy using the extreme decile, 1 and 10, with the long leg being the highest-performing decile and the short leg being the lowest-performing decile.

4.3.2 Anomaly Returns: High vs. Low Inflation

Table 4 presents excess monthly returns on a broad set of anomaly-based strategy following high or low inflation periods. I fist classify returns on each month either a high inflation period or a low inflation period. The high inflation period is one in which the value of money illusion index in the previous month is above the median value for the sample period. The low inflation period is the one below the median value.

The first hypothesis indicates that anomalies are stronger following high inflation periods. This suggests that stocks should earn relatively low (high) returns following high (low) inflation periods. Accordingly, the long-short spread should be larger following high inflation than low inflation. The positive profit on each long-short strategy reflects the unexplained cross-sectional difference in average returns that constitutes an anomaly. Table 4 clearly shows that the average excess returns are lower following high inflation periods. All of the values in 'High-Low' columns are negative and statistically significant. The last three columns in Table 4 present that each of the long-short strategy shows higher average returns following high inflation. All of the values in the last column are positive and statistically significant. The combined long-short spread earns 123 bps per month following high inflation. These results imply that mispricing is stronger following high inflation periods.

The second hypothesis indicates that the stocks in short leg should be more overpriced following high inflation. To the extent that an anomaly reflects mispricing, the profits of the long-short strategy represent relatively greater overpricing of stocks in the short leg. Thus, according to the second hypothesis, the returns on the short leg are lower following high inflation periods. In Table 4, the short leg of all anomaly strategies show a lower excess returns following high inflation periods. All of the values are statistically significant and reject the null hypothesis of no difference between high and low inflation periods. In Table 4, the short leg of the combined strategy earns 177 bps less per month following high inflation periods than low inflation periods. These results indicate that stocks in short leg are relatively overpriced following high inflation. These findings suggest that investors may overestimate the upside potential of stock returns following high inflation periods, inducing the money illusion-driven overpricing.

Overall, the results in Table 4 provide strong support for the first hypothesis and the second hypothesis. This evidence implies the possibility of money illusion-driven overpricing, suggesting that investors excessively extrapolate past performance of stocks and are subsequently experience negative returns.

4.3.3 Predictive Regression

Similar to Stambaugh, Yu, and Yu (2012), I use predictive regressions to examine whether money illusion predicts anomaly returns. The first hypothesis predicts a positive relation between the long-short spread and money illusion. Consistent with this prediction, the estimates for the spreads are positive in both Table 5 and Table 6. In Table 5, ten of 11 anomalies are statistically significant, and one of anomaly, which shows a negative prediction, is not significant. The money illusion index is scaled to have zero mean and unit standard deviation. Therefore, the slope coefficient of 0.0081 for the combination strategy indicates that one standard deviation increase in money illusion is associated with \$0.0081 of additional profit monthly on a long-short strategy with \$1 in each leg. In Table 6, ten of 11 anomalies are statistically significant. The estimate of combination strategy indicates that one standard deviation increase in money illusion is associated with \$0.0061 of an additional monthly profit in each long-short spread.

The second hypothesis predicts a negative relation between the returns on the shot-leg portfolio and the lagged money illusion level. Consistent with this prediction, the slope coefficients for the short-leg returns of all anomalies are negative in both Table 5 and Table 6. In Table 5, all t-statistics are significant. The combination strategy indicates that one standard deviation increase in money illusion is associated with 0.8% decrease in monthly excess return on the short-leg portfolio. In Table 6, ten out of 11 estimates are significant. The combination strategy implies that one standard deviation increase in money illusion is related to 0.6% decrease in monthly excess return on the short-leg portfolio.

In sum, results from predictive regressions reported in Table 5 and Table 6 suggest that money illusion lead to overpricing in the stock market. Overall results are consistent with the findings in Table 2 and Table 3 that investors overestimate the upside potential of stock returns following high inflation periods. The key explanation is that, following high inflation periods, money-illusioned investors are overly optimistic for the past performance of equities and excessively extrapolate into the future when they value firms. These findings indicate money illusion plays an important role in affecting the degree of mispricing in the stock market.

4.3.4 Alternative Money Illusion Index

Overall, the results support the empirical implication that high inflation induces overpricing. This indicates that the money-illusioned investors are overly optimistic following high inflation periods, as a result, produce grater mispricing effects on prices. An alternative explanation for these results is that the money illusion index (i.e. the percentage change of Consumer Price Index) by itself is asymmetric with the period of high inflation. Under this explanation, the mispricing following high inflation periods simply reflect more strong inflation effects during those periods. To address whether the results reflect pricing asymmetry or inflation index asymmetry, I use the alternative measure of money illusion to examine the anomaly returns.

Table 7 presents the results of regressions on the alternative money illusion index. The alternative money illusion index is the inflation expectation, measured by median expected price change next 12 months by Survey of Consumers. The data is obtained from FRED and the source of data is from University of Michigan Inflation Expectation.[14] The sample period is from 1978 to 2010. The alternative money illusion index is scaled to have zero mean and unit standard deviation.

The alternative money illusion index show consistent implications with previous results. In Table 7, ten of 11 anomalies are positive and eight of 11 anomalies are statistically significant.

[14] Web address: http://research.stlouisfed.org/fred2/series/MICH

The estimate of combination strategy indicates that one standard deviation increase in money illusion is associated with $0.0092 of an additional monthly profit in each long-short spread. The results with the alternative money illusion index also support the second hypothesis that money illusion is negatively associated with the returns on the shot-leg. In Table 7, all slope coefficients for the short-leg returns are negative and seven of 11 anomalies are statistically significant. The combination strategy indicates that one standard deviation increase in money illusion is associated with 0.8% decrease in monthly excess return on the short-leg portfolio.

In sum, results from predictive regressions reported in Table 7 show consistent results with Table 5 and Table 6, suggesting that previous results are not driven by asymmetry in inflation index by itself. These results provide a strong support for the possibility of money illusion-driven overpricing that money-illusioned investors overestimate the upside potential of stock returns following high inflation periods.

5. A Source of Money Illusion-Driven Mispricing

In this section, I investigate the source of money illusion-driven mispricing by testing two prominent explanations. The sources of money illusion-driven mispricing are two-fold: One is based on risk and the other one is based on behavioral explanation. The risk-based explanation argues that the stock returns reflect compensation for risk, indicating the risk premium would be correlated with some aspect of macroeconomic conditions. The behavioral-based explanation argues that investors excessively extrapolate on past performance when they value firms and subsequently surprised by the negative returns.

5.1 Risk-Based Explanation

The risk-based explanation argues that the stock returns reflect compensation for risk, indicating the risk premium would be correlated with some aspect of macroeconomic conditions. It is challenging to explain why there is a difference in loadings between long and short legs. To explain this difference, the risk-based explanation suggests the possibility of an omitted risk factor to which each short leg is sensitive but each long leg is not. In this regard, the risk-based explanation argues that the omitted risk factor's premium may explain the required correlation with money illusion.

To access the potential for a risk-based explanation for previous results, I control for an additional set of macro-related variables that seem reasonable to entertain as being correlated with the risk premium. I control for yield premium, term premium, and default premium. The yield premium is the 3-month T-bill rate. The term premium is the difference between yield on 10-year bond and the T-bill. The default premium is the difference between Baa and Aaa-rated corporate bonds. Table 8 reports the results regressing excess returns on money illusion and macro-variables. In Table 8, I find that nine of 11 anomalies are positive and statistically significant. The estimate of combination strategy indicates that one standard deviation increase in money illusion is associated with $0.0050 of an additional monthly profit in each long-short spread. Also, slope coefficients for the short-leg returns are negative in eight out of 11 anomalies. The combination strategy indicates that one standard deviation increase in money illusion is associated with 0.28% decrease in monthly excess return on the short-leg portfolio.

I also control for firm level predictive variables in addition to macro-variables. The firm level predictive variables are earnings-to-price ratio, the dividend-to-price ratio, and the equity variance. Importantly, in Table 9, I find that the predictive power of money illusion for anomaly returns does not weaken after I control for macro-variables and firm level predictive variables. In

Table 9, ten of 11 anomalies are positive and statistically significant. The estimate of combination strategy indicates that one standard deviation increase in money illusion is associated with \$0.0042 of an additional monthly profit in each long-short spread. Also, slope coefficients for the short-leg returns are negative in nine out of 11 anomalies and nine of 11 anomalies are statistically significant. The combination strategy indicates that one standard deviation increase in money illusion is associated with 0.2% decrease in monthly excess return on the short-leg portfolio.

To summarize the findings in Table 8 and Table 9, the results suggest that the effect of money illusion remains largely unchanged after control for additional variables. The coefficient and *t*-statistics are consistent with the main results in Table 5 and Table 6, in which the additional variables are not included.

5.2. Behavioral-Based Explanation

The behavioral-based explanation argues that investors may overestimate the upside potential of stock returns following high inflation periods, inducing the money illusion-driven mispricing. The key explanation of money illusion effects is that, following high inflation periods, money-illusioned investors are overly optimistic for the past performance of equities and excessively extrapolate into the future when they value firms.

To access the potential for a behavioral-based explanation for previous results, I investigate the relation between earnings forecast and money illusion. To examine the relation between forecast errors and money illusion, I first obtain the 12-month-ahead target-price forecasts for all individual analysts from the I/B/E/S database and aggregate the target-prices for each calendar month. Then, I obtain the actual stock prices realized in 1-year from the CRSP database, and define a variable forecast errors as the absolute value of the percentage difference between the realized stock price and the 1-year-ahead target price forecast. In addition, I obtain firms' financial accounting information from the COMPUSTAT database and calculate the log total assets, financial leverage, market-to-book ratio, ROA, and R&D-to-asset ratio. This approach is consistent with the analyst forecast literature.

I begin my analysis to fit regression specifications using forecast errors and money illusion with year and month fixed effects. I control for other factors being documented in prior research that can also influence analyst forecast behavior, such as firm size (log total assets), profitability (ROA), leverage (asset to equity ratio), growth opportunity (market to book ratio), and investment (R&D expense to asset ratio). Table 10 reports results of regressing forecast errors on money illusion index. I break down the sample to two subsamples: high-performance firms and low-performance firms. I find the negative coefficients on money illusion for the high-performance firms. This result indicates that investors' ex-ante expectation of future performance was too optimistic compared with the realized performance. Overall, results suggest that money-illusioned investors tend to overestimate the upside potential of stock returns following high inflation periods.

To clarify the role of dispersion in investors' views, I examine the relation between forecast dispersion and money illusion. The forecast dispersion is defined as the standard deviation of all analyst forecasts of 1-year-ahead target-price scaled by the average target-price for each firm. Table 11 reports results of regressing forecast errors on money illusion index. I find the negative coefficients on money illusion index. These results indicate that investors' views are more dispersed following low inflation. The results are consistent with the prediction of Stambaugh, Yu, and Yu (2012) that investors' views must be sufficiently disperse to include rational valuation when sentiment is low.

In sum, I find that money illusion negatively predicts forecast errors and forecast dispersion. These results suggest that money-illusioned investors are overly optimistic for the past performance of equities and excessively extrapolate into the future when they value firms.

6. Money Illusion, Sentiment, and Cross-Sectional Stock Returns

Overall, the results suggest that money-illisioned investors excessively extrapolate past performance into future and are subsequently experience return reversal. These findings are consistent with previous literatures by Delong, Shleifer, Summers, and Waldman (1990), Baker and Wurgler(2007) and Stambaugh, Yu, and Yu (2012). In this section, I extend the exploration of money illusion effects by examining sentiment and other commonly use measure for predicting stock returns.

Baker and Wugler (2006) provide strong evidence that investor sentiment have significant effects on the stock returns. Moreover, Stambaugh, Yu, and Yu (2012) find evidence that anomaly returns are larger following high levels of sentiment. These previous studies indicate that sentiment captures market-wide impacts in the stock market. Thus, to investigate whether money illusion plays an important and complementary role in cross-sectional stock returns, I control for the effect of sentiment first. The sentiment index is obtained from Baker and Wurgler (2006). Table 12 reports results of regressing benchmark-adjusted anomaly returns on money illusion index and Baker and Wugler sentiment index. The sentiment index is scaled to have zero mean and unit standard deviation. The results in Table 12 are consistent with the findings in Stambaugh, Yu, and Yu (2012). Each anomaly is stronger following high levels of sentiment and is mainly due to the overpricing of short legs.

Importantly, focusing on the coefficient, b_1, where money illusion is used as the explanatory variable, I find that the predictive power of money illusion for anomaly returns does not weaken after I control for the sentiment index. In Table 12, nine of 11 anomalies are positive and statistically significant. The estimate of combination strategy indicates that one standard deviation increase in money illusion is associated with $0.0073 of an additional monthly profit in each long-short spread. Also, slope coefficients for the short-leg returns are negative in ten out of 11 anomalies and nine of 11 anomalies are statistically significant. The combination strategy indicates that one standard deviation increase in money illusion is associated with 0.7% decrease in monthly excess return on the short-leg portfolio. These results suggest that money illusion has the complementary power for predicting anomaly performance, indicating that money illusion provides new information beyond investor sentiment.

In addition to sentiment index, I control for an additional set of macro-related variables that seem reasonable to entertain as being correlated with the risk premium. I control for yield premium, term premium, and default premium. The yield premium is the 3-month T-bill rate. The term premium is the difference between yield on 10-year bond and the T-bill. The default premium is the difference between Baa and Aaa-rated corporate bonds. I also control for firm characteristic variables. They are earnings-to-price ratio, the dividend-to-price ratio, and the equity variance. Table 13 reports the results regressing excess returns on money illusion, sentiment, macrovariables, and other firm characteristic variables. In Table 13, focusing on the coefficient, b_1, I find that nine of 11 anomalies are positive and statistically significant. The estimate of combination strategy indicates that one standard deviation increase in money illusion is associated with \$0.0067 of an additional monthly profit in each long-short spread. Also, slope coefficients for the short-leg returns are negative in nine out of 11 anomalies. The combination strategy indicates that one standard deviation increase in money illusion is associated with 0.49% decrease in monthly excess return on the short-leg portfolio.

In sum, the effect of money illusion remains largely unchanged after controlling for sentiment and additional variables. These results suggest that money illusion plays an important role in affecting the degree of mispricing in the stock market and provides the complementary power to explain the cross-sectional stock returns.

7. Simple Model

In the presence of money illusion and short-sale constraints, the potential disagreement between investors can lead overpricing. To the extent that judgment fallacies may affect some investors but not others, or may differ across investors, heterogeneity of investor beliefs can be sustained as an equilibrium phenomenon, and this in turn can affect asset prices in surprising ways. One characteristic of the asset market is that different investors may interpret the same information in different ways. Much of the public information such as inflation is subjective in nature and open to different interpretations by investors. To better understand the interactions among inflation, beliefs, and asset prices, I suggest a theoretical model that highlights overpricing of stock returns.

7.1 Set up

This model is a simple variation on the Harrison and Kreps (1978) and Morris (1996) model of speculative pricing in asset markets, where the key maintained assumption are risk neutral investors, adequate liquidity, and short-selling constraints. To set up asset market to test the theory of money illusion-driven overpricing, I impose short sales constraints and endow investors with a lot of liquidity so that liquidity constraints do not bind.

7.2 Investors and Heterogeneous Beliefs

Assume that all investors use a common Bayesian updating rule, based on the true stochastic process generating the signals. q is common knowledge and all investors update using Bayes rule.

Let π_t be the common posterior that the state of the world is A after S_t is revealed in period t. [15] Given ρ_t, the common posterior if $s_t = \alpha$ is

$$\pi_t(\rho_t | s_t = a) = \frac{q\rho_t}{q\rho_t + (1-q)(1-\rho_t)}$$

and the common posterior if $s_t = b$ is

$$\pi_t(\rho_t | s_t = b) = \frac{(1-q)\rho_t}{(1-q)\rho_t + q(1-\rho_t)}$$

Given that the asset pays off 1 in state A and 0 in state B, and given that all investors are risk neutral, this common posterior at period t is also the valuation of the asset at period t. In this

[15] There are two possible states of the world, A and B. The probability of A being world is ρ. Nature chooses the state of the world. There is an asset market with $t+1$ trading periods and i risk-neutral investors. There is one type of asset in this market that pays off H per unit if A is the state of the world and L(<H) per unit if B is the state of the world. Investors observe either a sequence of public signals, one at the beginning of each trading period after the first. I assume the signals are generated by a stochastic process that is independent across periods, conditional on the state. If $\omega = A$, then $s_t = a$ with probability $q>0.5$ and $s_t = b$ with probability 1-q. Likewise, when $\omega = B$, $s_t = b$ with probability $q>0.5$ and $s_t = a$ with probability 1-q. In the initial period, investors receive no information about the state of the world. Since the asset pays off only in state A, I refer to a signal $s_t = a$ as high inflation and a signal $s_t = b$ as low inflation.

model, each investor thinks her own belief is correct. Investors have own expectations about the distribution of future prices, and disagree about the fundamental value of asset.

I consider a continuum of investor types characterized by the parameter $\theta \in [0, \infty]$. An investor with type θ_l will treat a public signal (i.e. inflation) as if it had the informational equivalent of θ independent signals, each of informativeness q. Thus, θ_l measures how much investor i under-react ($\theta_l < 1$) or over-react ($\theta_l > 1$) to the public signal, relative to q. Over-reaction to signals is sometimes referred to neglect, and under-reaction is sometimes referred to as conservatism.

Let π_t be investor i's posterior that the state of world is A after st is revealed in period t. This updated posterior after observing $s_t = A$ for an investor of type θ_l is:

$$\pi_{lt}^{\theta l}(\rho_{lt} | s_t = A) = \frac{q^{\theta l}\rho_{lt}}{q^{\theta l}\rho_{lt} + (1-q)^{\theta l}(1-\rho_{lt})}$$

and after observing $s_t = B$ is

$$\pi_{lt}^{\theta l}(\rho_{lt} | s_t = B) = \frac{(1-q)^{\theta l}\rho_{lt}}{(1-q)^{\theta l}\rho_{lt} + q^{\theta l}(1-\rho_{lt})}$$

7.3 Equilibrium Price and Overpricing

I maintain the assumptions of binding short sale constraints and sufficient liquidity among the investors to hold all the assets. Under these assumptions, I can apply the logic of the Morris (1996) model to characterize the equilibrium price dynamics in our model. Given the way I have defined different investors' types, and given that the initial prior belief is 0.5, the private posterior and equilibrium prices will depend only on the investor types, the period number, t, and the number of signals, $h \leq t$. Thus, I can denote the current belief of investor type θ_l by

$$\pi_{it}^{\theta_i}(h) = \frac{q^{\theta_i h}(1-q)^{\theta_i(t-h)}}{q^{\theta_i h}(1-q)^{\theta_i(t-h)} + q^{\theta_i(t-h)}(1-q)^{\theta_i h}}$$

Define $\pi_t^*(h) = \max_{i\in I}\{\pi_{it}^{\theta_i}(h)\}$ to be the most optimistic belief amongst the investors at period *t* about A being the state of the world. The corresponding θ type for the investors with the most optimistic belief is denoted θ^*. The price of the asset period t given the history of public signals must be equal to the highest expect return of holding it to the next period *t+1* in equilibrium.

Let $\varphi_t^*(h)$ be the most optimistic belief about the likelihood of good news being announced in period *t+1*, after h good news signals and *t-h* bad news signals,

$$\varphi_t^*(h) = \pi_t^*(h)\left(\frac{q^{\theta^*}}{q^{\theta^*}+(1-q)^{\theta^*}}\right)+(1-\pi_t^*(h)\left(\frac{(1-q)^{\theta^*}}{q^{\theta^*}+(1-q)^{\theta^*}}\right)$$

Note investors can only update their beliefs and asset valuations based on the sequence of signals revealed so pricing depends upon the signals revealed and expectations about future signals. The θ type with the most optimistic belief about the state of the world being A also has the most optimistic belief about the next guess being A. Now I can specify the equilibrium price

$$P_t(h) = \varphi_t^*(h)P_{t+1}(h+1) + \left(1-\varphi_t^*(h)\right)P_{t+1}(h+1)$$

Therefore, I can define the speculate overpricing, $\alpha_t(h) = P_t(h) - P_t^*(h)$. *h* is the number of guesses about the high pay off state being realized. The speculative overpricing is the amount by which the price exceeds the maximal valuation of all investors. This overpricing is the different between the price and the most optimistic valuation. The price would reflect only the belief of the most optimistic investor or possible exceed the valuations of all of the investors when there is a speculative premium.

Recall that a continuum of investor types is characterized by the parameter $\theta \in [0, \infty]$. Following Morris (1996), I compare the price in each period to the investors' valuations and derive several results. A permanent optimist has the highest probabilistic belief of A being the state of the world out of all investors for every continuation sequence of signals (high inflation) until the end of the market. Accordingly, speculate overpricing, $\alpha_t(h) \equiv P_t(h) - P_t^*(h)$, is the amount by which the price exceeds the maximal valuation of all investors.

This implies that overpricing is more likely during high-inflation. The main prediction of theoretical model is that, following high inflation periods, the most optimistic views about stocks tend to be overly optimistic, as a result, stocks tend to be overpriced. In contrary, during low inflation periods, the most optimistic views about stocks tend to be those of rational investors, and thus overpricing during those periods is less likely. This would be consistent with the money illusion-driven overpricing for the short portfolio stocks.

8. Conclusion

In this study, I investigate whether money illusion deludes investors, as a result, leads to mispricing in the stock market. Numerous researches have examined the existence of money illusion in the capital market and find that the impact of money illusion is crucial on the economy. Motivated by early works and recent renewed interests in money illusion, I examine whether inflation plays an important role in affecting the degree of mispricing in the equity market.

To the extent that anomalies reflect mispricing, I test whether money illusion predicts anomaly returns. I find that anomalies are stronger and the returns on the short-leg portfolio of each anomaly are lower following high inflation periods. These findings indicate that money-illusioned investors overestimate the upside potential of stock returns following high inflation and subsequently experience the return reversal. To the best of my knowledge, this is the first paper to examine the relation between money illusion and anomaly returns.

Furthermore, I explore the source of money illusion-driven mispricing. I find that money illusion negatively predicts forecast errors and dispersion. The findings imply that, following high inflation periods, investors are overly optimistic for the past performance of equities and excessively extrapolate into the future when they value firms. This indicates that the behavioral-based explanation may support the results of this study.

I extend the exploration of money illusion effects by examining sentiment and other commonly use measure for predicting stock returns. I find that the effect of money illusion remains largely unchanged after controlling for many additional variables. The results suggest that money illusion can provide the complementary power for cross-sectional stock returns beyond the commonly used variables. Overall, this study contributes to the literatures on money illusion and mispricing by providing novel evidence that money illusion can lead to mispricing in the stock market.

Figure1. Money Illusion and CPI (Consumer Price Index)

This figure plots *money illusion* and CPI (Consumer Price Index) from 1965 and 2010. *money illusion* is defined as the percentage change in CPI. The data for CPI is obtained from the Bureau of Labor Statistics.

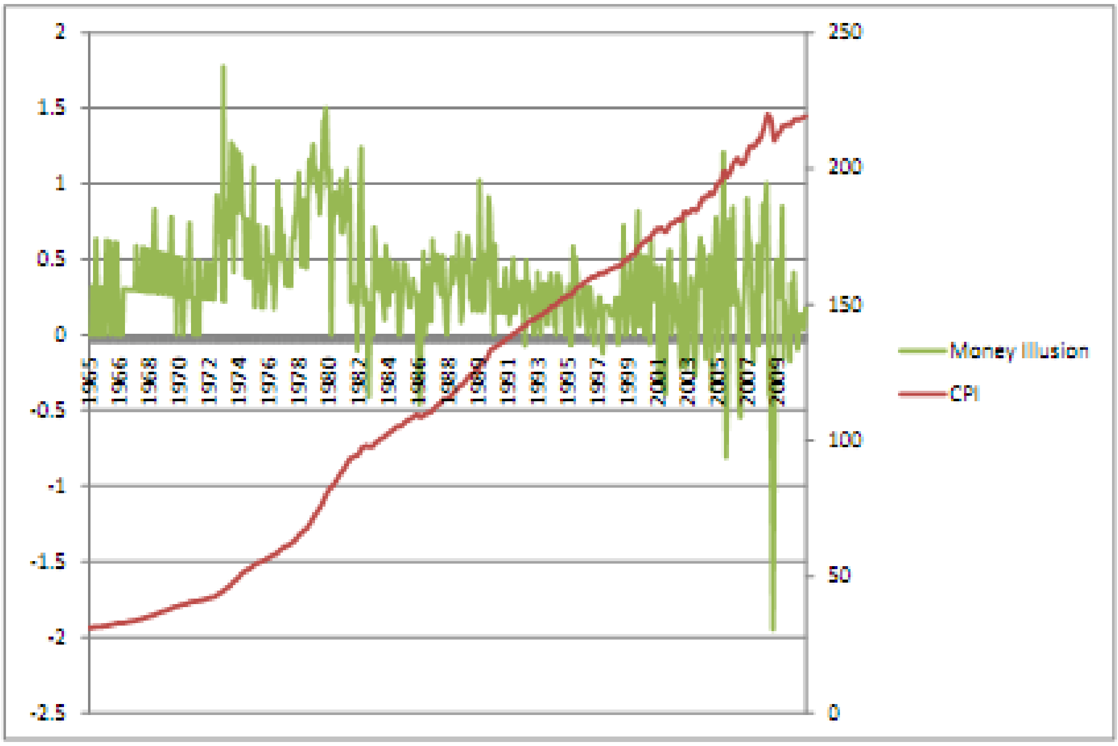

Table 1. Descriptive Statistics for Money Illusion and Stock Market Returns

The table reports the descriptive statistics for money illusion and stock market returns. Four measures of stock market returns are used: the value-weighted raw returns, the value-weighted excess returns, the S&P 500 raw returns, and the S&P excess return. Stock market returns are computed monthly. Money illusion is defined as the percentage change in Consumer Price Index (CPI) from year *t-1* to *t*. The sample period is from 1965 to 2010.

Panel A: Descriptive Statistics			
Variable	Mean	Std.dev	Median
Money Illusion	0.0035	0.0036	0.0030
Value-weighted raw returns	0.0087	0.0458	0.0122
Value-weighted excess returns	0.0043	0.0459	0.0077
S&P 500 raw returns	0.0059	0.0442	0.0087
S&P 500 excess return	0.0014	0.0443	0.0048

Panel B: Correlation				
Variable	Value-weighted raw returns	Value-weighted excess returns	S&P 500 raw returns	S&P excess return
Value-weighted raw returns	1			
Value-weighted excess returns	0.9986	1		
S&P 500 raw returns	0.9858	0.9844	1	
S&P 500 excess return	0.9843	0.9858	0.9985	1
Money Illusion	-0.0930	-0.1157	-0.1033	-0.1268

Table 2. Univariate Regression: Money Illusion and Stock Market Returns

The table reports the predictive regression of one-month-ahead stock market returns on the inflation. Panel A report the results for the full sample period 1965-2010 and Panel B reports results for the subsample period 1970-1990. Four measures of stock market returns are used: the value-weighted raw returns, the value-weighted excess returns, the S&P 500 raw returns, and the S&P excess return. Money illusion is defined as the percentage change in Consumer Price Index (CPI) from year *t-1* to *t*. The inflation variable is standardized to have zero mean and unit variance. *t*-statistics are in parenthesis with ***, ** and * indicating its statistical significant level of 1%, 5% and 10% respectively.

Panel A: 1965-2010

Table 4. Anomaly Returns: High vs. Low Inflation

This table reports excess monthly returns on a broad set of anomaly-based strategies. I classify returns each month as following either a high-inflation or a low-inflation month. A high-inflation month is one in which the value of the money illusion index in the previous month is above the median value of sample period, and a low-inflation month is below the median values. *t*-statistics are in parenthesis.

Anomaly	Long leg			Short leg			Long-Short

Table 7. Predictive Regressions: Alternative Money Illusion Index and Benchmark-adjusted Returns on Long-Short Strategie

The table reports estimates of b in the regression

$$R_{i,t} = a + bE_{t-1} + cMKT_t + dSMB_t + eHML_t + u_t,$$

where $R_{i,t}$ is the excess return in month t on either the long leg, the short leg, or the difference. E_t is the inflation expectation, measured by median expected price change next 12 months by Survey of Consumers. The data is obtained from FRED and the source of data is from University of Michigan Inflation Expectation. The sample period is from 1978 to 2010. t-statistics are in parenthesis.

□ □ □ □ □ □ Governance of Private Universities: A Socio-Economic Cost and Benefit Analysis

Do Ba Khang
Faculty of Economics and Commerce
Hoa Sen University
Ho Chi Minh City, Vietnam
khang.doba@hoasen.edu.vn

This paper reviews and applies the general theories developed in the extensive nonprofit organization literature to private nonprofit universities. The primary objective is to identify significant socio-economic roles that may help explaining the long and growing existence of this type of universities in many countries in the world. Given the characteristics of higher education, it is found that nonprofit universities fill the demand gaps neglected by the public and for-profit private universities, provide the needed (although not perfect) protection for the students and their sponsors from potential exploitative behavior by the people in control of privately owned universities, create new opportunities to mobilize additional developmental resources to supplement the public funds and private capitals, improve productivity and quality in both private and public universities through increased competition and spillover, and establish attractive environment for academic and other socially minded professionals to pursuit social missions in higher education. The paper also explores some inherent weaknesses of the nonprofit status of universities that include possible increase of agency cost and decrease of operational efficiency. The analysis provides and also rationalizes a conceptual framework for policy implications at both government and university levels to maximize potential benefits while limiting the costs of this increasingly important sector in higher education.

Keywords: Higher education; university governance; nonprofit; non-distribution constraint; private universities; cost and benefit analysis.

1. Introduction

Despite the vast research literature accumulated over past few decades on nonprofit organizations, the governance issues of private universities, especially regarding the distinction between for-profit and nonprofit universities have attracted little interest in academia. Although nonprofit universities could be considered as a subsector in the larger sector of general nonprofit organizations, one may wonder if the specific characteristics of higher education have any bearing on the governance choice and behavior of private nonprofit universities. The large variation in the proportions of private universities, both nonprofit and for-profit, in different parts of the world also raise the question whether what may explain the existence and development of different governance status of private universities.

This conceptual paper aims at exploring the possible social and economic roles of nonprofit universities as well as the implications of this governance choice on their behavior. The key research questions are as follows:

- What are the benefits nonprofit universities can bring to society? (Do such benefits explain the existence of nonprofit universities in parallel with public and for-profit universities?)
- What are the inherent weaknesses of this choice of governance and how are they expressed in the differences in the behavior of nonprofit universities relative to for-profit universities?
- What are the policy implications (at government level as well as the university level) of such characteristics of the nonprofit status in higher education?

The answers to these questions rely on salient characteristics of higher education and applications of general theories developed in the nonprofit organization literature. For social entrepreneurs – and to a certain extent, for managers, professoriate and staff – working in higher education, this essay will provide rational justification for their choice toward nonprofit status. For policy makers, especially those in developing countries, where the emerging private and nonprofit university sector is relatively fragile, a balanced analysis on the benefits and possible weaknesses of the nonprofit governance status of private universities can help formulating effective policy to support and regulate this important subsector of the higher education market. In addition testable hypotheses can be drawn from this conceptual study for future empirical researches.

The next section describes the various theories developed in the literature to explain the needs and benefits of nonprofit organizations, and explains how they can be applied in higher education market to the case of nonprofit universities. In the following section I discuss the inherent weaknesses of the nonprofit status, again by applying the general theories developed for nonprofit organizations to private universities. Finally the policy implications, both at government and university levels, will be explored to develop a healthy nonprofit higher education sector.

2. Benefits of nonprofit governance form of private universities

Higher education (also called tertiary or postsecondary education) is commonly understood as a large and diverse area of services that includes continuing education, vocational and professional diploma programs, associate-degree programs, regular and professional undergraduate education, liberal art education, post-graduate and doctoral education. This diversity itself is probably the most salient characteristic of the higher education, with the implication that the institutions providing such services may vary greatly from training centers focused in short-term non-degree programs to local community colleges to large national research universities offering large variety of programs to a huge and diverse student body. For simplicity, we will call all such institutions "universities".

It is well accepted that a private university, or any private provider of social services, is called nonprofit if it "is barred from distributing its net earnings, if any, to individuals who exercise control over it" (Hansmann 1980, p.838), a condition commonly called "non-distribution constraint". Several authors have developed various theories to explain the role of non-distribution constraint, and consequently of the existence of nonprofit organizations (see for example, Salamon and Anheier 1998, Weisbrod 1977, 1989, Hansmann 1980, 1987, Rose-Ackerman 1996, Hirth 1997). These theories will be briefly reviewed below and then applied to explain the potential benefits of nonprofit governance status of private universities, taking into account specific characteristics of higher education services. The explanations can be divided into three groups: the demand-side, the supply-side and the competition theories.

2.1. *Demand-side theories*

As in many sectors of economy, it is commonly accepted that private universities, for-profit or not, provide higher education services to meet the demand not fulfilled by public universities. The reason for this unmet demand is not necessarily lack of resources from government for higher education since one may observe the existence of private universities even in wealthy industrialized countries, with increasing role despite economic growth. Instead, Weisbrod (1977, 1989) argued that when the demand for a service is heterogeneous, which is typically the case of demand for higher education in most countries, the public sector is designed to serve the need of the majority of the population only, and thus leaving certain needs of different (political, cultural, religious and historical) minority groups to be served by the private sector.

The key question here is that why do we need the services of private nonprofit universities. In other words, why we cannot simply rely on the higher education services of for-profit private universities to fill the gap left over by the public universities, just like many other service sectors in the economy (transportation, utilities, telecommunication, etc.)? The answer to this question could be two-fold. First, even with advanced technology in education, there are many traditional areas in higher education (e.g. liberal art education, basic research education, humanity and social science education, etc.) where the operating expenses are high and the benefits to the students are intangible and only observable in long terms. As consequence, most for-profit universities will simply avoid to provide services in these areas as it is difficult to charge tuition high enough to recover the cost, let alone to earn the needed profit required. This implies that, in these areas of higher education, the gaps left over by public universities are also abandoned by for-profit universities, and could only be filled by nonprofit ones (Hansmann 2012). Second and more importantly, Hansmann (1980, 1987) proposed a general "contract failure theory" that could explain the need for nonprofit organizations even in markets where for-profit firms already provide their services. According to Hansmann, for a private firm to provide goods and services with maximum efficiency, certain market conditions should be met: (a) customers can evaluate the product and prices before making decision; (b) customers can reach clear agreement with the chosen firm on quantity, quality and price; (c) customers can determine if the firm complies with agreement or not; and (d) customers can penalize the firm if it did not. When some of these conditions are not met, either due to the circumstance where the services of the organization are purchased or consumed, or to the nature of the services themselves, the firm has both the incentive and the opportunity to take advantage of customers by providing less service to them than was promised and paid for. In such situations, called "contract failure" by Hansmann or more generally "market failure" (Vlassopoulos 2009, Valentinov 2011, Young 2013) a nonprofit firm providing the same goods and services offers consumers the advantage that, owing to the non-distribution constraint, those who control the organization are constrained in their ability to benefit personally from providing low-quality services and thus have less incentive to take advantage of their customers than do the managers of a for-profit firm.

One can argue that, higher education and especially its major and most traditional elements (that is, under- and post-graduate education), exhibit typical "contract failure" characteristics. In fact, the complexity of higher education services makes it extremely difficult for the "customers" (students or parents) to accurately evaluate the quality and potential benefits of the education they receive, and if its values are worth the price (tuition) they pay. Given the nature of higher education, a student may only realize the full value of the education he or she receive years or even decades after graduation. By that time, if the student is dissatisfied with the education he or she received, the chance of penalize the university is practically nil. Moreover, as the students are in the early stage of their career, their tuition is most likely covered by someone else (parents, scholarship donors, student loan providers, etc.) who is in even less position to assess the quality and value of the education received by the students. The situation is aggravated with the information asymmetry commonly found in higher education: the service providers have significantly more information than all other stakeholders about the quality and cost of the education provided (Hansmann 1996, Valentinov 2011, James 2011, Titova & Shutov 2014). Thus, the nonprofit governance form defined by the "non-distribution constraint" presents a (limited) protection for the students (and those who pay for their study) from potential exploitative behavior of those in the control of the universities by at least reducing their incentive to do so.

Exceptions to this "contract failure theory" can be found in certain areas of higher education like vocational and professional programs, corporate training programs, etc. where a healthy for-profit sector has emerged and grown in the past few decades. On the other hand, in traditional undergraduate education over the past few years, together with the rise of for-profit universities, there are ample reported empirical evidences of malpractices by these universities in US, especially in recruitment approach, poor quality and financing with public funds (see for example the Harkin Report, US Senate Committee on Health, Labor & Pensions 2012). These "predatory education" practices include: 1. providing an educational experience that results in net harm to students; 2. harmful rent-seeking behavior; 3. securing student enrollment through fraud or deception; 4. securing student enrollment through misrepresentation, nondisclosure, and questionable business practices that do not amount to outright fraud; and 5. capitalizing on the absence of legal remedies (James 2011). These findings support the merits of the "contract failure theory" as well as the benefits of the nonprofit status in higher education.

2.2. *Supply-side theories*

From the supply side, Rose-Ackerman (1996) argued that in most societies there are groups of people who are motivated by ideology (generalized beliefs in certain social values) or simple altruism to contribute money and time to help other people. She also cited a study by Hodgkinson & Weitzman (1994) that contribution to education makes the second largest percentage of total household contributions to charity in US, after only donations to religious organizations. Thus, in higher education the nonprofit universities may respond to the need of these altruists and "social entrepreneurs" by reducing their fear that their gift could be converted to private gain, or by avoiding the bureaucratic barriers commonly found in public sector. In this sense nonprofit universities provide opportunities to supplement public funds and private capitals with additional resources in society to develop higher education to serve the overall need of the population. Valentinov (2008) extended Rose-Ackerman's theory to imply that the relevant stakeholders of nonprofit organizations need the non-distribution constraint because they can then better enhance their utility of being involved in pursuing the non- profit mission. This way, the preferences to non-profit mission and the freedom to pursue relevant ideologies and beliefs complement the restriction imposed by non-distribution constraint.

The general "social entrepreneur" theory of Rose-Ackerman and the neo-classical arguments by Valentinov for nonprofit sector could have a direct implication on nonprofit universities that goes beyond mobilizing additional financial resources in the society to serve the higher education needs unmet by the public universities and for-profit universities. In fact, the majority of the academic faculty in universities may arguably be considered as altruistic professionals who pride themselves in their services of the society through creating and disseminating knowledge. For this faculty, the monetary motivations may be secondary to the academic freedom and the professional recognition, by the society and public in general, and by their peers in particulars. As consequence, they cannot generally accept the work environment of for-profit universities where faculty self-governance is absent and professors are merely employees contracted to teach in most cost-effective way standardized courses designed to maximize profits for some shareholders. This way, nonprofit universities provide this faculty better environment to pursue a career of pushing the boundary of knowledge and disseminating it to generations of students (Hansmann 2012). In fact, Valentinov (2008) and Handy & Katz (1998) even argued that, for academic professionals, these environmental factors may substitute monetary incentive and allow for self-selecting those committed to the nonprofit mission of the university.

2.3. *Competition theories*

Without profit motive, the nonprofit universities operate with similar objectives with public universities in higher education market. Thus, they provide the diversity needed to foster a healthy competition with public universities for the best students and the best faculty. This competition in turn promotes high quality in education and research in both sectors (Levin, 2008).

In the relationship with for-profit universities, it is commonly observed that quality of education provided by nonprofit universities is better than that provided by for-profit universities at equivalent tuition range. However, the benefits of nonprofit universities on a mixed higher education market where both nonprofit and for-profit universities operate are often higher than these observable quality differences between the two sectors. Indeed, the formal competition theory developed by Hirth (1997) for mixed market with quality competition and information asymmetry can be applied to higher education market to imply a spillover impact of nonprofit universities. According to this theory, with adequate enforcement of non-distribution constraint, when the presence of nonprofit universities increases, the poorly informed customers (as most students are) will be disproportionately attracted by the assurance of protection provided by the non-distribution constraint to the for-profit sector, leaving the for-profit university market with a higher ratio of better-informed customers, forcing the for-profit universities to increasingly deliver the quality promised to their customers. Eventually, when nonprofit universities dominate the market, the quality of both sectors will converge *because* of the presence of nonprofit universities. As consequence, the quality differences between the two subsectors *understate* the real benefits of nonprofit universities that have originally created this convergence.

In fact, according to Hirth, the response of for-profit universities to the competition from nonprofit universities is more complex and could happen in two ways. First, they may be forced to increase the quality to stay in the business and deliver what they promise to the students. Second, they may also move out from the area where quality education provision is not profitable. In the first case, we have the spillover effect explained above. In the second case, the for-profit universities will leave a larger part of the market demand for nonprofit universities to fill up.

The analysis above gives rise to several hypotheses that may be tested empirically across nations the way Salamon and Anheier (1996) did for general nonprofit organizations. Some of these hypotheses are summarized below.

- The greater the public spending by government on higher education, the smaller presence of private universities (nonprofit and for-profit included).
- There is a segmentation among the private universities: for-profit universities are concentrated more on vocational education and corporate training, while liberal art education and fundamental research are provided mostly by nonprofit universities.

- Academic faculty in nonprofit universities practice higher degree of self-governance and academic freedom than those in for-profit universities.
- Nonprofit universities have larger percentage of their income from donation and endowment compared with for-profit ones.

3. Costs of nonprofit governance form of private universities

The benefits of nonprofit universities in providing higher education services do not come without costs although these costs are usually intangible and non-cash. Two types of costs have been identified in relevant literature: agency costs to ensure the compliance with the non-distribution constraint and the nonprofit mission, and costs of decreased efficiency.

3.1. *Agency costs*

Applying the well-known principal-agent model of Jensen & Meckling (1976) to nonprofit universities, one may readily accept that the role of agent will be played by the university administrators. However, the role of the principals is less clear as, in place of owners, there could be many key stakeholders with different interests: students, academic staff, donors, community and government. Although these stakeholders are usually represented in governing boards, these boards are ultimately not accountable to these stakeholders and they are generally self-perpetuating instead of elected (Glaeser, 2003). Thus, comparing with for-profit firms, the agency problems as defined by Jensen & Meckling (1976) may include not only the gaps between these stakeholders as principals and the administrators as agents, but also the gaps of interests among these stakeholders themselves, and the gaps between these stakeholders and their representatives. As consequence, the agency cost, defined as the sum of the costs to the principals to monitor the agents, the bonding costs to the agents, and the residual loss, will be higher than that in equivalent for-profit universities.

In more practical terms, several authors (e.g. Brekke 2011, Glaeser & Shleifer 2001, Herbst & Prufer 2011, Valentinov 2006) argue that the "non-distribution constraint" cannot completely prevent those in control of nonprofit universities from shirking the net earnings for their own pocket in the forms of unusually high salaries, perquisites[1], contracts with firms controlled by family members, etc. The board, not being elected by stakeholders and not facing competition, could also be manipulated by the administration. The resulting need for increased regulatory control both in policy and enforcements in turn leads to increased costs of auditing and ensuring the transparency (in particular, financial transparency)[2].

---

[1] "Perquisites" is defined as non-pecuniary compensation "involving different types of improvement in the working environment, such as lower effort levels, free meals, shorter workdays, longer vacations, better office facilities, etc." (Brekke et al. 2011, p.3)

[2] Fishman (2006) observed, however, that it was a misconception that there has been an increase of contemporary wrong doing and scandal in the nonprofit sector. For example reported that between 1995-2002 there were only 152 reported incidents of misconducts out of over 50,000 nonprofits in NY state, US.

3.2. *Inefficiency*

One implication of the agency problem in nonprofit universities is the lack of clear and unique measurement of performance to guide the university administrators. In fact, while the for-profit universities' administrators are motivated by a single profit motive, management of nonprofit universities faces multiple goals that reflect the conflicting interests of different key stakeholders: quality and value-to-money for students, community and public services for the public and government, academic reputation and freedom for faculty, mission-effectiveness and sustainable growth for donors, etc. It is often argued that this lack of strict and clear performance criteria, combined with less incentive to minimize cost due to the "non-distribution constraint", will render nonprofit universities less efficient than for-profit universities (see for example Hansmann 1996). However, empirical evidences indicated that this concern about operational efficiency "while not entirely misplaced, are easily exaggerated" (Hansmann 1996, p.249).

Hansmann (1996) identified another type of inefficiency in general nonprofit organizations: their sluggishness in responding to changes in demand. Applying Hansmann's arguments to higher education, one can observe that when demand increases or new demand emerges, nonprofit universities may not be able to set up or grow quickly enough to match, either due to the lack of access to equity capital or the lack of incentives from university administrators, or both. Similarly, when demand declines, nonprofit universities may also be slow in reducing their outputs correspondingly or to withdraw entirely. The reasons in this case may include legal constraints for nonprofit universities to withdraw or transfer its capitals dedicated to its original missions, and, again, the lack of incentive from management to downscale their university. The problem is compounded by the fact that, while for-profit universities have to maintain return on capital equal or above the market rate in order to survive, nonprofit universities can continue operating indefinitely just with zero net rate of return.

4. Policy implications

The policy implications of the analysis above will be discussed first at the level of the government, and then at the university level. From macro perspective, we can safely say that the primary goals of the government intervention toward the nonprofit sector of the higher education market are to create conditions for establishment and operation of nonprofit universities and to allow them to fulfill the socially beneficial roles expected as well as to minimize the weaknesses inherent in this governance status. At the university level, the primary goal will be to maximize the potential benefits usually established in the mission statement of the university, and also to minimize the inefficiency and agency cost inherent in the nonprofit governance status.

4.1. *Government's roles*

Given the significant public benefits nonprofit universities can bring to society, the government should create enabling environment for setting up and operating nonprofit universities. At the same time, since most of the benefits from nonprofit universities stem from non-distribution constraint, the government should also play the role of public guarantor to enforce the non-distribution constraint at these universities.

The first environment factor in the support to nonprofit universities starts with the recognition of the needs and potential benefits of this government form, which should happen at the highest level of the government to guide the policy formulation efforts, and then be promoted to the public through open scientific and public debates and forums. Such recognition, together with the assurance by the non- distribution constraint that is enforceable by law, would provide the necessary inputs to solicit donations and voluntary works to set up and sustain nonprofit universities. In countries where the sector is just emerging, a more important enabling factor, however, is an appropriate legal framework that should at least include a legal definition of the nonprofit status for private universities that is consistent with non-distribution constraint; and a provision for the governance of such a university through a board of trustee that is responsible to protect the nonprofit status by enforcing the non-distribution constraint, and the public-benefit mission of the university. In addition, such legal framework should facilitate the creation of new nonprofit universities, at least relatively to creating for- profit universities. The conversion from for-profit status to nonprofit status should also be treated by law favorably to enhance achieving social goals. At the same time, it should be made difficult, even practically impossible, to change back from the nonprofit status to for-profit status, to prevent maneuvering to avoid non-distribution constraint for personal gains. Similarly, when an nonprofit university is dissolved, its asset should be prohibited from being distributed to individuals or for-profit firms.

In countries with more mature nonprofit sector, financial supports to nonprofit universities are provided either in direct subsidies or through differential treatments of nonprofit universities, especially with tax privileges. Direct supports to nonprofit universities could be either financial grants or provision of subsidized land or infrastructure. Given the fact that the nonprofit university sector is expected to supplement the limited resources of the state to serve the public needs in higher education, such direct subsidies could be limited in size, of ad hoc nature and probably difficult to guarantee in law. Tax exemptions are usually considered as more popular ways to support nonprofit universities or nonprofit organizations in general for two reasons:

- Provision of tax breaks or tax reductions for nonprofit universities will not impose direct financial burden on state;
- The implementation power of such policies is vested in the tax authority which is best positioned to check and enforce the non-distribution constraint and the nonprofit status of the these universities (Hines et al. 2010).

Among the tax treatments applicable to support nonprofit universities, income tax exemption on donations plays an especially important role in allowing the nonprofit universities to mobilize further resources untapped in society for meeting the higher education needs. Hirth (1997) argued that the tax exemption on donations could be even more useful as normally the donors may have good understanding of, and some control on, how the nonprofit universities serves the community and public interests according to its missions, and thus adding another mechanism to enforce the non-distribution constraint and protect the nonprofit status of the university.

In addition to financial supports, the government may provide the academic staff of nonprofit universities with non-monetary incentives such as international collaboration opportunities and professional or public recognition, especially for their research and community services. Academic freedom and self-governance are also environmental factors conducive to mobilize socially minded academics to join nonprofit universities and fulfill its social missions.

Compared with supporting roles to nonprofit universities, the need for interventions by the government in regulating the nonprofit universities is less clear. The main reason for this apparent contradiction is that too much intervention from government may impair the autonomy of university and therefore be counter-productive. The primary regulating role (which at the same time is also a supporting one) of the government to nonprofit universities is to ensure that non-distribution constraint is properly enforced. Without much interference with the university's operations and autonomy, this can be achieved by having a clear internal governance structure in the university and have the governing board liable under law to protect the nonprofit mission and the non-distribution constraint. The government can also enhance the effect of non-distribution constraint in protecting the customers (students, parents and donors) by reducing the information asymmetry through two major sets of instruments: 1. Transparency and accountability requirements with mandatory reporting from the boards and administrations of nonprofit universities and regular or occasional auditing by government agencies; 2. Setting up public or independent agency to collect, compile the information from the universities and disseminate to the public in useful and consumable format.

Contrary to the enforcement of non-distribution constraint, the role of government in controlling the quality of the nonprofit universities is more controversial. While in many developing countries, the governments exercise a great power in directly auditing and controlling the quality of education provided by private universities, nonprofit or for-profit alike, the experiences from US and developed countries show that better results in guaranteeing and improving higher education quality could be achieved by

- Accreditation system implemented by associations of universities without intervention of the state;
- Competition among the universities, especially for the best faculty and students (Hansmann 2012, Levin 2008).

Thus, the role of the government in this area may better be indirect and limited to facilitate setting up – and, if necessary, to monitor – such independent accreditation system as well as to create conditions to allow for high mobility by student and academic staff among all universities and thus foster competition in the higher education market.

4.2. *Internal governance structure*

As discussed above, the best – and least expensively – way to enforce the non-distribution constraint critical in creating the benefits of nonprofit universities is with an appropriate internal governance structure of the universities. With the absence of owners represented by boards of directors in for-profit universities, the common and tested governance structure observed in most nonprofit universities is the dual system consisting of a board of trustees and a professional management team hired by the board. The non-distribution constraint is then protected by giving the board, as the highest authority of the university, the power of appointing and controlling the management and of setting policies for the university, but no executive power which is vested in the professional management. In the same spirit, the board members are normally uncompensated (or at the very least, the compensation should only nominal, and cannot be related to the university's performance). The Board is perpetuated and has fiduciary duty to ensure that the management will perform in line with the original mission and for the best interest of the organization. To overcome the efficiency problems caused by lack of management incentive discussed above, the board may establish policy to link compensation of management and employees to the performance as long as such policy serves the interest of organization. Such duality of the system implies that the Board and the Management should be separated, with the Rector or President of the university is only ex officio member of the Board, and Board members should not be employed by the university (or enrolled as student of the university).

The governance board of nonprofit universities should be made liable under law to protect the non- distribution constraint conditions and the nonprofit mission of the university. The board should be responsible in monitoring the performance of the university, especially cost control measures by administration. The administration of the nonprofit universities should also report and be accountable to the board, the tax authorities and the concerned government agencies with regular reports on compliance with the non-distribution constraint and the nonprofit charter of the university. Stakeholders should be encouraged to report deviations from the non-distribution constraint, and incompliance should be appropriately penalized.

In addition to performance-based compensation system, nonprofit universities may set up fringe benefit systems that promote the self-selecting mechanism to ensure that the right types of socially-minded people will join and work for the university. For example, Handy and Katz (1998, p. 258) suggested that "offering an academic wage package consisting of less cash but more research funding and facilities, increases the likelihood that research-minded professors will self-select. This strategy can work even if a devoted manager values a dollar of fringe benefit at less than a dollar in cash."

5. Conclusion

This paper reviews the theories developed in the nonprofit organizations literature and applies them to the private nonprofit university sector with view of specific characteristics of higher education. The conceptual analysis highlights many significant roles of nonprofit universities that may help explaining the long and growing existence of the sector in many countries in the world. In fact, nonprofit universities fill the gap of higher education demand in society that is neglected by the public and for- profit private sector. Given the information asymmetry evident in higher education sector, the status- defining non-distribution constraint provides the needed (although not perfect) protection for the students and their sponsors from potential exploitative behavior of for-profit private universities by reducing the incentives of the people in control of these universities. The nonprofit universities also create new opportunities to mobilize additional resources to supplement the public funds and private capitals by ensuring private donors that their contributions will be used to the intended purpose. In particular, the nonprofit status is attractive to academic professionals as it provides the foundation for the cherished autonomy and academic freedom often absent in public universities and for-profit universities. The presence of nonprofit universities in the higher education market also promotes the improvements of productivity and quality in both private and public universities by increasing the competition for students and faculty. Moreover, nonprofit universities are proven to have spillover impact in mixed higher education market, increasing the quality of the services of the for-profit universities to converge to that of nonprofit universities.

These positive impacts of nonprofit universities, on the society in general and on the higher education market in particular, depend on the level of enforcement of non-distribution constraint. In fact, if non- distribution constraint is easily circumvented, many for-profit universities may adopt the strategy to disguise as nonprofit ones to gain access to both the students and the support of the government and public and thus driving out honest nonprofit universities. To a lesser extent, the non-distribution constraint might be bypassed with exceptional perquisites, substantially weakening possible positive impacts. Thus, it is critical to have a clear legal framework and appropriate internal check-and-balance mechanism to ensure that the non-distribution constraint is reinforced without interference by government in the universities' operations. Tax privileges for donations to nonprofit universities, transparency requirements, independent accreditation and conditions for students and faculty mobility are found to be constructive ways government can encourage development of this critical sector. In addition to government's roles, separating the control role of the board of trustees from the executive power of the administration of the nonprofit universities, with appropriate compensation policy for the latter are means to ensure both the non-distribution constraint and needed incentive for performance. The conceptual analysis in this paper also provides empirically testable hypotheses for future research.

1. Introduction

1.1 Information Technology (IT) for Financial Services

The finance services industry involves a broad range of organizations such as banks, credit card companies, insurance companies, consumer finance companies, stock brokerages, investment funds and some government sponsored enterprises. The industry represents a significant share of the global market. Information technology (IT) in the financial service industry is considered as an indispensable tool for productivity as well as competitiveness in the market. The IT spending in financial service industry grows constantly across different industry verticals (banking, insurance, and securities and investments). The impact directly from the use of advanced IT brings on financial services industry is on the rise.

The structure of the industry has changed significantly in the last two decades as companies, which are not traditionally viewed as financial service providers, have taken advantage of opportunities created by technology to enter the market. New technology-based services keep emerging. These changes are direct result of the interaction of technology with the industrial environment, such as economic atmosphere, societal pressures, and the legal/regulatory environment in which the financial service industry operates. The effects of IT on the internal operations, the structure and the types of services offered by the financial service industry have been particularly profound (Phillips et al, 1984;Hauswald and Marquez, 2003; Griffiths and Remenyi, 2003). IT technology has been and continues to be both a motivator and facilitator of change in the financial service industry, which ultimately leads to competitiveness of the industry. The change is in particular radical after 1991 when World Wide Web was invented by Tim Berners-Lee and his group for information sharing in the community of high energy physics. It was later introduced to the rest of the world, which subsequently changed the face of how people doing business today.

Informational considerations have long been recognized to determine not only the degree of competition but also the pricing and profitability of financial services and instruments. Recent technological progress has dramatically affected the production and availability of information, thereby changing the nature of competition in such informationally sensitive markets. Hauswald and Marquez (2003) investigate how advances in information technology (IT) affect competition in the financial services industry, particularly credit, insurance, and securities markets. Two aspects of improvement in IT are focused: better processing and easier dissemination of information. In other words, two dimensions of technology progress that affects competition in financial services can be defined as advances in the ability to process and evaluate information, and in the ease of obtaining information generated by competitors. While better technology may result in improved information processing, it might also lead to low-cost or even free access to information through, for example, informational spillovers. They show that in the context of credit screening better access to information

decreases interest rates and the returns from screening. On the other hand, an improved ability to process information increases interest rates and bank profits. Hence predictions regarding financial claims' pricing hinge on the overall effect ascribed to technological progress. Their results conclude that in general financial markets informational asymmetries drive profitability.

The viewpoint of Hauswald and Marquez is adopted in this work. Assuming competitors in the dynamics of financial market possess similar capacity, the informational asymmetries can be created sometimes only between seconds and now are possible to be achieved through the outperformance of underlying IT platforms.

1.2 Competitiveness through IT Performance

Following the computing evolution in financial services, it was a centralized process to begin with and gradually decentralized into a distribution of practical trading application logic across service networks. Financial services have tradition of doing most of its heavy lifting financial analysis in overnight batch cycles. However, in securities trading it cannot satisfy the need due to its ad hoc nature and requirement of fast response.

New computing paradigms, Grid computing and Cloud computing were subsequently emerged in the last decade. The Grid computing was initially incorporated into the core context of a well referenced Atkins' report of National Science Board of US, namely"Revolutionizing Science and Engineering Through Cyberinfrastructure" (Atkins et al, 2003), which lays down a visionary path for future IT platform development of the world. One may observe this trend from statistics from Google Trend regarding the global Search Volume and global News Reference Volume of key phrases of "Cluster Computing", "Grid Computing", "Cloud Computing" and "Big Data" (Fig. 1), which represents four main stream computing paradigms in high end quantitative analysis.

Cluster Computing is a group of coupled computers that work closely together so that in many respects they can be viewed as though they are a single computer. They are connected with high speed local area networks and the purpose is usually to gain more compute cycles with better cost performance and higher availability. The Grid Computing aims at virtualizing scalable geographically distributed computing and observatory resources to maximize compute cycles and data transaction rates with minimum cost. Cloud Computing is more of recent development owing to the similar technology used in global information services providers, such as Google, Amazon … etc. The Cloud is referred to as a subset of internet if to be explained in a simplest fashion. Within the cloud the computers also talk with servers instead of communicating with each other similarly to that of Peer to Peer Computing (Milojicic et al, 2002). There are no definitive definitions for the above terminology. However, people tend to view Clusters as one of foundational components of Grids, or Grids as a meta-cluster on wide area networks. This is also known as horizontal integration. The Cloud virtualizes further the compute, store and network in an utility sense and provides an interface between users and Grids. We refer to Foster et al (2008) and Yelick (2011) for a comparison. This perspective considers Grids as a backbone of Cyberinfrastructure to support the Clouds. Similarly, in early days of development of Grids there is a so called "@HOME" style PC Grids (Korpela et al, 2001), which are exactly working on at least ten of thousands of PCs, in which owners of PCs donate their CPU times when their machines are in idle. The PC Grids can be specifically categorized as Clouds.

Fig. 1 shows that there is a gradually drop in the curve of search volume for Grid Computing and Cluster Computing, and many surges, grows but a recent quick drop on Cloud Computing since its introduction in mid-2007. The new rising technology is Big Data (Bughin et al, 2010), which implies a paradigm shift from compute centric, network centric gradually to data centric computing. However, the size of the search volume strongly relates to the degree of maturity of each computing paradigm. This is obvious in cluster computing. Clusters are the major market products, either in supercomputers from big vendors, such as IBM, HP, SGI and NEC…etc, or from aggregation of PCs in university research laboratories. Fig. 1 also implies constant market need for high end computing. The performance and security issues are fundamental to general distributed and parallel computing, which also remain as a challenge to Cluster, Grid, Cloud and Big Data (Lauret et al, 2010, Ghoshal et al 2011, Ramakrishnan et al 2011). Performance models in compute based grid, which is also cloud-like, environment are adopted in this work. The general definitions of Grid and Cloud Computing will be introduced and briefly compared. To tackle the core performance issue Grids are chosen to demonstrate how fundamental financial calculations can be improved, hence leverage the financial service.

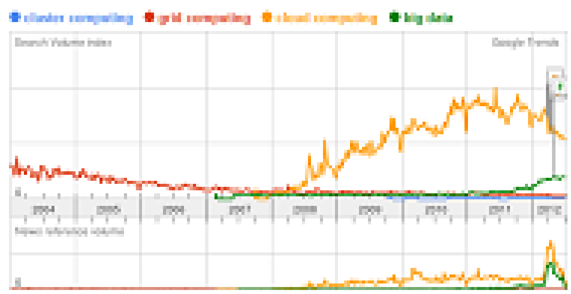

Fig. 1 The trend history from Google Trend according to global Search Volume and global News Reference Volume, in which the alphabetic letters represent the specific events that relate to each curve.

Grid computing, following by cloud computing as shown in Fig 1, has been matured to serve as a production environment for finance services in recent years. Grid computing is well suited to the challenge posed by the capital markets practices. In this study the core computing competence for financial services will examined and how underlying algorithms for financial analysis can take advantage of Grid environment scrutinized. One of the most popular practiced algorithms is Monte Carlo Simulation (MCS) and it will be specifically used in our cases study for calculations of option pricing and for value at risk (VaR) in risk management.

Three grid platforms are carefully chosen to exploit the performance issue for financial services. The first one is traditional grid platform with heterogeneous and distributed resources. Usually digital packets are connected via optical fibers. For long distance, depending on network traffics, it will produce approximately 150~300 microseconds (mm) latency across Pacific Ocean. This is the physical constrain of light speed when traveling through the fiber channels. Therefore, even in split second packets can still travel to anywhere in the world. The Pacific Rim Applications and Grid Middleware Assembly (PRAGMA) grid is a typical example, which linked with 14 countries and 36 sites. The system is highly heterogeneous. The computer nodes mounted to PRAGMA grid range from usual PC clusters to high-end supercomputers. The second one is a special Linux, or DRBL, PC cluster. It converts system into a homogenous Linux system and exploits the compute cycles of the cluster. The intention is to provide dynamic and flexible resources to cope better with uncertainty of the traders' cycle demand. Finally, PC grid is chosen to demonstrate finance services that can be effectively conducted through a Cloud-based computing. The usefulness of PC Grid is based on the fact that 90% of CPUs time of PCs were in idled status.

2 Performance Enhancement

In this section two types of Grid systems, compute intensive and data intensive respectively, are introduced. The classification of the types is based on various grid applications. Traditionally, the grid systems provides a general platform to harvest, or to scavenge if used only in idle status, compute cycles for a collection of resources across boundaries of institutional administration. In real world most applications are in fact data-centric. For example in a trading center, it collects tick-by-tick volume data from all related financial markets and is driven by informational flows, hence typical data-centric. However, as noted in Section 3.2.1 the core competence still lies on the performance enhancement of the IT system. The following two subsections are will gives more details of compute intensive as well as data intensive grid systems by a survey of current development of Grids specifically for financial services. In some cases, e.g. high frequency data with real time analysis, two systems have to work together to get better performance. Our emphasis will be more on compute intensive grid system.

2.1 High End Computing Technology

2.1.1 Definitions of High End Computing

Grid was coined by Ian Foster (Foster and Kesselman, 2004) who gave the essence of the definitions as below

> "The sharing that we are concerned with is not primarily file exchange but rather direct access to computers, software, data, and other resources, as is required by a range of collaborative problem solving and resource-brokering strategies emerging in industry, science, and engineering. This sharing is, necessarily, highly controlled, with resource providers and consumers defining clearly and carefully just what is shared, who is allowed to share, and the conditions under which sharing occurs. A set of individuals and/or institutions defined by such sharing rules form what we call a *virtual organization*."

The definition is centered on the concept of virtual organization, but it is not explicit enough to explain what the grid is. Foster then provide additional checklist as below to safeguard the possible logic pitfalls of the definition. Hereby, Grid is a system that:

1) *coordinates resources that are not subject to centralized control*

A Grid integrates and coordinates resources and users that live within different control domains—for example, the user's desktop vs. central computing; different administrative units of the same company; or different companies; and addresses the issues of security, policy, payment, membership, and so forth that arise in these settings. Otherwise, we are dealing with a local management system.

2) *using standard, open, general-purpose protocols and interfaces*

A. Grid is built from multi-purpose protocols and interfaces that address such fundamental issues as authentication, authorization, resource discovery, and resource access. As I discuss further below, it is important that these protocols and interfaces be *standard* and *open*. Otherwise, we are dealing with an application specific system.

3) *to deliver nontrivial qualities of service.*

A Grid allows its constituent resources to be used in a coordinated fashion to deliver various qualities of service, relating for example to response time, throughput, availability, and security, and/or co-allocation of multiple resource types to meet complex user demands, so that the utility of the combined system is significantly greater than that of the sum of its parts.

The definition of Grid thus far is well accepted and has been stably used up to now. The virtual organization (VO) has strong implication of community driven and collaborative sharing of distributed resources. The advance of development of optical fiber network in recent years plays a critical role of why Grids can be a reality. It is also the reason why now the computing paradigm shift to distributed/Grid computing.

Additionally, perhaps the most generally useful definition is that *a grid consists of shared heterogeneous computing and data resources networked across administrative boundaries.* Given such a definition, a grid can be thought of as both an access method and a platform, with grid middleware being the critical software that enables grid operation and ease-of-use.

The term "cloud computing" has been used to refer to different concepts, models, and services over the last few years. The definition for cloud computing provided by the National Institute of Standards and Technology (NIST) is well received in the IT community, which defines cloud computing as *a model for enabling convenient, on-demand network access to a shared pool of configurable computing resources (e.g., networks, servers, storage, applications, and services) that can be rapidly provisioned and released with minimal management effort service provider interaction* (Peter Mell and Tim Grance, 2011). The model gains popularity in the industry for its emphasis on pay-as-you-go and elasticity, the ability to quickly expand and collapse the utilized service as demand requires. Thus new approaches to distributed computing and data analysis have also emerged in conjunction with the growth of cloud computing. These include models like MapReduce and scalable key-value stores like Big Table (Chang et al 2006).

From the high end computing perspective, Cloud computing technology allows users to have the ability to get on-demand access to resources to replace or supplement existing systems, as well as the ability to control the software environment. Yet the core competence still lies on the performance of financial calculation and further of the transactions of financial processes. This work will focus on the core competence in financial calculation based on Grid environment. Grid computing technology will be used to explain how the core financial calculations can be significantly accelerated in various distributed and parallel computing environments. The calculation models in this work can be easily migrated to pure cloud environments.

2.1.2 Essence of IT Technology

To realize the above goal, it needs to handle technically inter-operability of middleware that is capable of communicating between heterogeneous computer systems across institutional boundaries. The movement of Grid began in 1996 by Ian Foster and Kesseleman(2004). Before their development, another branch of high performance computing that focuses on connecting geographically distributed supercomputers to achieve one single grand task had been developed by Smarr and Catlett (1992). They coined such a methodology as metacomputing and their query has been how can we have infinite computing power under the physical limit, such as Moore's Law. However, it remains to be less useful because its limit goal on pursuing top performance without noticing practical use in real world. The idea lives on and generates many tools dedicated to high performance/throughput computing, such as Condor (Litzkow, Livny and Mutka, 1988), Legion(Grimshaw and Wulf, 1997) and UNICORE (Almond and Snelling,1999). Condor, as suggested by the name of the project, is devised to scavenge a large clusters of idle workstations. Legion is closer to the development of world-wide virtual computer. The goal of UNICORE is even much simpler and practical. It was developed due to Germany government decided to consolidate their 5 national supercomputer centers into a virtual one to reduce the management cost, and need a software tool to integrate them, hence the UNICORE. These tools were successful under their development scope. However they fail to meet the first and the second items in Foster's checklist in the previous section.

The emergency of Grids follows the similar path as that of Condor and Legion at the first place, which development aims at resources sharing in high performance computing. However, its vision in open standards and the concept of virtual organization allows its development go far beyond merely cluster supercomputers together. It gives a broader view of resources sharing, in which it is not only limited to the sizable computing cycles and storage space to be shared, but also extended virtually to calculable machines that are able to hook up to the internet, such as sensors and sensor loggers, storage servers, computers etc. Since 1996, Foster and his team have been developing software tools to achieve the purpose. Their software Globus Toolkit (Foster and Kesselman, 2004) is now a de facto middleware for Grids. However, the ambitious development is still considered insufficient to meet the ever growing complexity of grid systems.

As mentioned earlier that grid based on open specifications and standards, they allow all stakeholders within the virtual organization/grid to communicate with each other with ease and enable ones more to focus on integrated value creation activities. The open specifications and standards are made by the community of Open Grid Forum (OGF), which plays as a standard body and made, discussed and announced new standards during regular OGF meetings. Grid Specifications and Standards include Architecture, Scheduling, Resource Management, System Configuration, Data, Data movement, Security, Grid Security infrastructure. In 2004, OGF announced Globus Toolkit version, which adopt both the open standard of grid, Open Grid Services Architecture (OGSA), and the more widely adopted World Wide Web standard, Web services resrouce framework (WSRF), which ultimately enable grids to tackle issues of both scalability and complexity of very large grid systems.

2.2 Compute Intensive IT Systems

The recent development of computational finance based on grids is hereby scrutinized and remarks given. Our major interest is to see if the split second performance is well justified under the grid architecture. Also, real time issue with real market parametric data should be used as input for practical simulation. In addition, issues of inter-system, inter-disciplinary, geographically distribution of resources and the degree of virtualization are crucial to the success of such a grid. The chosen projects are reviewed and discussed as follow:

1.) PicsouGrid:
This is a French Grid Project for Financial Service. It provides a general framework for computation Finance and targets on applications of options trading, options pricing, Monte Carlo simulation, aggregation of statistics etc (Stokes-Rees et al, 2007). The key for this development is the implementation of the middleware ProActive. ProActive is an in-house Java library for distributed computing developed by INRIA Sophia Antipolis, France. It provides transparent asynchronous distributed method calls and is implemented on top of Java RMI. It is also used in commercial applications. It also provides fault tolerance mechanism. The architecture is shown in Fig. 2, which is very similar to most of grid applications apart from the software stack used. The option pricing was tested in an approximately 894 CPUs. The underlying computer systems are heterogeneous. The system is used for metacomputing. As a result, the system has to specifically design to orchestrate and to synchronize and re-synchronize the whole distributed processes for one calculation. Once the grid system require synchronization between processes, which imply stronger coupling of algorithm of interest, the performance will be seriously affected. There is no software treatment to solve such problems and should be tackled by physical infrastructure, e.g. optical fiber network with Layer 2 light path.

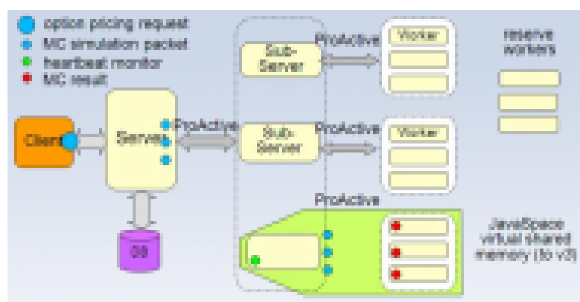

Fig. 2 Architecture of PicsouGrid for option pricing based on Monte Carlo simulation (Stokes-Rees, 2007).

2.) FinGrid:
FinGrid stands for Financial Information Grid. Its study includes components of bootstrapping, sentimental analysis and multi-scale analysis, which focusing on information integration and analysis, e.g. data mining. It takes advantage of the huge collection of numerical and textual data simultaneously to emphasize the study of societal issues (Amad et al, 2004, Ahmad et al, 2005, Gillam et al, 2005). The architecture of FinGrid is shown in Fig. 3. It is a typical 3 tiers system, in which the first tier facilitates the client in sending a request to one of the services: Text Processing Service or Time Series Service; the second tier facilitates the execution of parallel tasks in the main cluster and is distributed to a set of slave machines (nodes) and the third tier comprises the connection of the slave machines to the data providers. This work focuses on small scale and dedicated grid system. It pumps in real and live numerical and textual data from say Reuters and performs real

time sophisticated data mining analysis. This is a good prototype for Finanical grid. However, it will encountered similar problem as that of PicsouGrid if it is to scale up. The model is more successful in automatically combining real data and the analysis.

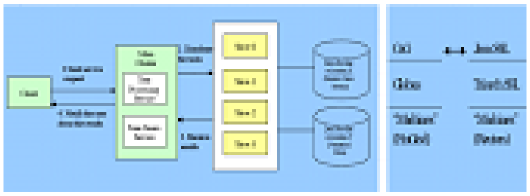

Fig. 3 The architecture of Financial Information Grid (FinGrid).

3.) IBM Japan collaborates with life insurance company and adopt PC grids concept to scavenge more compute cycles (Tanaka, 2003):

In this work an integrated risk management system (see Fig. 4) is modified, in which the future scenarios of red circle of Fig. 4 are send via Grid middleware to a cluster of PCs. According to the size of the given PCs, the number scenarios are then divided in a work balanced manner for each PC. This is the most typical use of compute intensive grid systems and a good practice for production system. However, the key issues that discussed in the above two cases cannot be answered in this study. Similar architecture can also be found in EGrid (Leto et al, 2005).

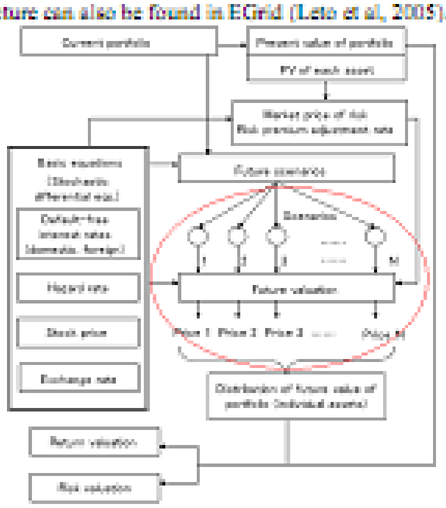

Fig. 4 Architecture of Integrated Risk Management System (Tanaka, S. 2003).

4.) UK e-Science developed a grid service discovery in the financial markets sector focusing on integration of different knowledge flows (Bell and Ludwig, 2005).

From application's viewpoint, business and technical architecture of financial service applications may be segmented by product, process or geographic concerns. Segmented inventories make inter silo re-use difficult. The service integration model is adopted and a loosely coupled inventory – containing differing explicit capability knowledge. Three use cases were specifically chosen in this work to explore the use of semantic searching:

Use-case 1 – Searching for trades executed with a particular counterparty

Use-case 2 – Valuing a portfolio of interest rate derivative products

Use-case 3 – Valuing an option based productThe use-cases were chosen to provide examples of three distinct patterns of use – aggregation, standard selection and multiple selection. The architecture (see Fig. 5) is bound specifically with the user-cases. The advantage for grid in this case is that it can be easily tailored into specific user need to integrate different applications, which is a crucial strength of using grid.

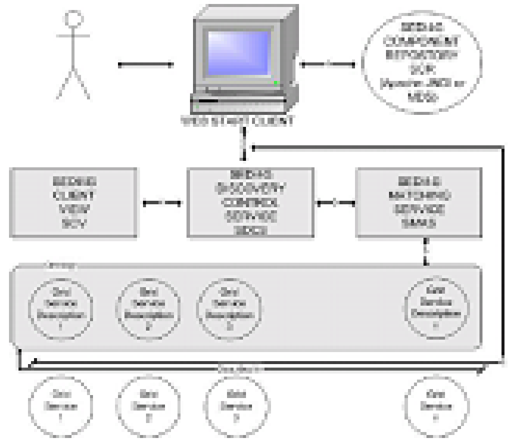

Fig. 5 The Semantic Discovery for Grid Services architecture (SEDI4G) (Bell and Ludwig 2005).

2.3 Data Intensive IT Systems

Grid in Financial Services from the perspective of web Services towards Financial Services Industry. The perspective is more on transactional side. Once the bottleneck of compute cycle is solved, the data-centric nature will play the key role again. The knowledge flows back to the customized business logic should provide the best path for users to access the live data of interest. There is no strong focus of development on this data intensive grid system. Even in FinGrid, which claims in streaming live data for real time analysis, the data issue remains part of compute grids. However, the need for dynamic data management is obvious as mentioned in (Amad et al, 2004). Hereby, we like to introduce and implement a dynamic data management software Ring Buffer Network Bus (RBNB) Dataturbine to serve such a purpose.

RBNB Dataturbine was used recently to support global environmental observatory network, which involves linking with ten of thousand of sensors and is able to obtain the observed data online. It meets grid/cyberinfrastructure (CI) requirements with regard to data acquisition, instrument management, and state-of-health monitoring including reliable data capture and transport, persistent monitoring of numerous data channels, automated processing, event detection and analysis, integration across heterogeneous resources and systems, real-time tasking and remote operations and secure access to system resources. To that end, streaming data middleware provides the framework for application development and integration.

Use cases of RBNB Dataturbine include adaptive sampling rates, failure detection and correction, quality assurance and simple observation (see Tilak et al, 2007). Real-time data access can be used to generate interest and buy-in from various stakeholders. Real-time streaming data is a natural model for many applications in observing systems, in particular event detection and pattern recognition. Many of these applications involve filters over data values, or more generally, functions over sliding temporal windows. The RBNB DataTurbine middleware provides a modular, scalable, robust environment while providing security, configuration management, routing, and data archival services. The RBNB DataTurbine system acts as an intermediary between dissimilar data monitoring and analysis devices and applications. As shown in Fig. 6 a modular architecture are used, in which a source or "feeder" program is a Java application that acquires data from an external live data sources and feeds it into the RBNB server. Additional modules display and manipulate data fetched from the RBNB server. This allows flexible configuration where RBNB serves as a coupling between relatively simple and "single purpose" suppliers of data and consumers of data, both of which are presented a logical grouping of physical data sources. RBNB supports the modular addition of new sources and sinks with a clear separation of design, coding, and testing (ref. Fig. 6). From the perspective of distributed systems, the RBNB DataTurbine is a "black box" from which applications and devices send data and receive data. RBNB DataTurbine handles all data management operations between data sources and sinks, including reliable transport, routing, scheduling, and security. RBNB accomplishes this through the innovative use of memory and file-based ring buffers combined with flexible network objects. Ring buffers are a programmer-configurable mixture of memory and disk, allowing system tuning to meet application-dependent data management requirements. Network bus elements perform data stream multiplexing and routing. These elements combine to support seamless real-time data archiving and distribution over existing local and wide area networks. Ring buffers also connect directly to client applications to provide streaming-related services including data stream subscription, capture, rewind, and replay. This presents clients with a simple, uniform interface to real-time and historical (playback) data.

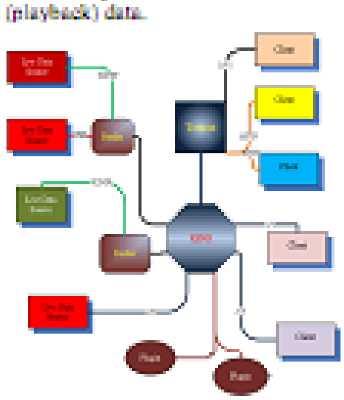

Fig. 6 RBNB DataTurbine use-scenario for collaborative applications.

3 Distributed and Parallel Financial Simulation

In the previous sections, we address issues of incorporating IT technology for financial competitiveness and derive that the core lies on the performance of IT platform, providing the competitors in the market have similar capacity and equally informed. Grid technology, as the leading IT development in high performance computing, is introduced as the cutting edge IT platform to meet our goal. Many companies have adopted similar technology of Grids with success as mentioned in Section 1. There are also increasing research interests, which result in the work discussed in Section 2.3. Better performance, however, cannot be achieved by merely using a single architecture as observed in the cases of Section 2.3. The architecture obviously has to be specifically chosen for the analysis of interest. Simultaneously, the analysis procedures have to be tailored into the chosen architecture for performance fine tune.

In this section, we will introduce and discuss analysis procedures of financial simulation and how to tailor the analysis procedures into grid architectures by distribution and parallelism. The popular calculations for option pricing and for value at risk (VaR) in trading practice are used to serve the purpose. The calculation is based on Monte Carlo simulation, which is chosen not only because it is a well received approach due to the absence of straightforward closed form solutions for many financial models, but also a numerical method intrinsically suited to mass distribution and mass parallelism. The success of Monte Carlo simulation lies on the quality of random number generator, which will be discussed in details at the end of the section.

3.1 Financial Simulation

There are wide variety of sophisticated financial models developed, to name a few, ranging from analysis in time series, fractals, nonlinear dynamics and agent-based modeling to applications in optional pricing, portfolio management and market risk measure etc (Schmidt, 2005), in which option pricing and VaR calculations of market risk measure can be considered crucial and one of the most practiced activities in market trading.

3.1.1 Option Pricing

An option is an agreement between two parties to buy or sell an asset at a certain time in the future for a certain price. There are two types of options:

Call Option: A call option is a contract that gives the right to its holder (i.e. buyer) without creating an obligation, to buy a pre-specified underlying asset at a predetermined price. Usually this right is created for a specific time period, e.g., six months, or more. If the option can be exercised only at its expiration (i.e. the underlying asset can be purchased only at the end of the life of the option) the option is referred to as an European style Call Option (Or European Call). If it can be exercised any date before its maturity, the option is referred to as an American style Call Option (or American Call).

Put Option: A put option is a contract that gives its holder the right without creating the obligation, to sell a pre-specified underlying asset at a predetermined price. If the option can be exercised only at its expiration (i.e. the underlying asset can be sold only at the end of the life of the option) the option is referred to as a European style Put Option (Or European Put). If it can be exercised any date before its maturity, the option is referred to as an American style Put option (or American Put).

To price options in computational finance, we use the following notation: K is the strike price; T is the time to maturity of the option; S_t is the stock price at time t; r is the risk-free interest rate; μ is the drift rate of the underlying asset (a measure of the average rate of growth of the asset price); σ is the volatility of the stock; V denotes the option value. Here is an example to illustrate the concept of option pricing. Suppose an investor enters into a call option contract to buy a stock at price K after three months. After three months, the stock price is S_t. If $S_t > K$ then one can exercise one's option by buying the stock at price K and by immediately selling in the market to make a profit of $S_T - K$. On the other hand, If he $S_T - K$ to be buy the stock. Hence, we see a call option to buy the stock at time T at price K will get payoff $(S_T - K)^+$,where $(S_T - K)^+ \equiv \max(S_T - K, 0)$ (Schmidt, 2005; Hull, 2003).

3.1.2 Market Risk Measurement based on VaR

Market risks are the prospect of financial losses , or gains, due to unexpected changes in market prices and rates. Evaluating the exposure to such risks is nowadays of primary concern to risk managers in financial institutions. Until late 1980s market risk were estimated through gap and duration analysis (interest rates), portfolio theory (securities), sensitivity analysis (derivatives) or scenarios analysis. However, all these methods either could be applied only to very specific assets or relied on subjective reasoning.

Since the early 1990s a commonly used market risk estimation methodology has been the Value at Risk (VaR). A VaR measure is the highest possible loss L incurred from holding the current portfolio over a certain period of time at a given confidence level (Dowd, 2002)

$$P(L > VaR) \leq 1 - c \qquad (1)$$

where c is the confidence level, typically 95%, 97.5% or 99% and P is cumulative distribution function. By convention, $L = -\Delta X(\tau)$, where $\Delta X(\tau)$ is the relative change (return) in portfolio value over the time horizon τ. Hence, large values of L correspond to large losses (or large negative returns).

The VaR figure has two important characteristics: 1) it provides a common consistent measure of risk across different positions and risk factors and 2) it takes into account the correlations or dependencies between different risk factors. Because of its intuitive appeal and simplicity, it is no surprise that in a few years Value at Risk has become the standard risk measure used around the world. However, VaR has a few deficiencies, among them the non-subadditivity – a sum of VaR's two portfolios can be smaller than the VaR of the combined portfolio. To cope with these shortcomings, Artzner et al proposed an alternative measure that satisfies the assumptions of a coherent risk measure. The Expected Shortfall (ES), also called Expected Tail Loss (ETL) or Conditional VaR, is the expected value of the losses in excess of VaR:

$$ES = E(L|L > VaR) \qquad (2)$$

It is interesting to note, that although new to the finance industry – Expected Shortfall has been familiar to insurance practitioners for a long time. It is very similar to the mean excess function which is used to characterize claim size distribution, see (Cizek et al, 2004)

The essence of the VaR and ES computations is estimation of low quantiles in the portfolio return distributions. Hence, the performance of market risk measurement methods depends on the quality of distribution assumptions on the underlying risk factors. Many of the concepts in theoretical and empirical finance developed over the past decades, including the classical portfolio theory, the Black-Scholes-Merton option pricing model and even the RiskMetrics variance-covariance approach to VaR rest upon the assumption that asset returns follow a normal distribution. The assumption is not justified by real market data. Our interest is more on the calculation side. For interested readers we refer further to (Weron, 2004).

3.2 Monte Carlo Simulations

3.2.1 Monte Carlo and Quasi-Monte Carlo Methods

In general, Monte Carlo (MC) and Quasi-Monte Carlo (QMC) methods are applied to estimate the integral of function $f(x)$ over $[0,1]^d$ unit hypercube where d is the dimension of the hypercube.

$$I = \int_{[0,1]^d} f(x)dx \qquad (3)$$

In MC methods, I is estimated by evaluating $f(x)$ at N independent points randomly chosen from a uniform random distribution over $[0,1]^d$ and then evaluating average

$$\hat{I} = \frac{1}{N}\sum_{i=1}^{N} f(x_i) \qquad (4)$$

From the law of large numbers, $\hat{I} \to I$ as $N \to \infty$. The standard deviation is

$$\sqrt{\frac{1}{N-1}\sum_{i=1}^{N}(f(x_i) - I)^2} \qquad (5)$$

Therefore, the error of MC methods is proportional to $N^{-1/2}$.

QMC methods compute the above integral based on low-discrepancy (LD) sequences. The elements in a LD sequence are "uniformly" chosen from $[0,1]^d$ rather than "randomly". The discrepancy is a measure to evaluate the uniformity of points over $[0,1]^d$. Let $\{q_n\}$ be a sequence in $[0,1]^d$, the discrepancy D_N^* of q_n is defined as follows, using Niederreiter's notation (Niederreiter, 1992).

$$D_N^*(q_n) = \sup_{B \in [0,1]^d} \left|\frac{A(B, q_n)}{N} - v_d(B)\right| \qquad (6)$$

Where B is a subcube of $[0,1]^d$ containing the origin, $A(B, q_n)$ is the number of points in q_n that fall into B, and $v_d(B)$ is the d -dimensional Lebesgue measure of B. The elements of q_n is said uniformly distributed if its discrepancy $D_N^* \to 0$ as $N \to \infty$. From the theory of uniform distribution sequences (Kuipers and Niederreiter, 1974), the estimate of the integral using a uniformly distributed sequence $\{q_n\}$ is $\hat{I} = \frac{1}{N}\sum_{n=1}^{N} f(q_n)$, as $N \to \infty$ then $\hat{I} \to I$. The integration error bound is given by the Koksma-Hlawka inequality:

$$\left|I - \frac{1}{N}\sum_{n=1}^{N} f(q_n)\right| \leq V(f)\, D_N^*(q_n) \qquad (7)$$

where $V(f)$ is the variation of the function in the sense of Hardy and Krause (see Kuipers and Niederreiter, 1974), which is assumed to be finite.

The inequality suggests a smaller error can be obtained by using sequences with smaller discrepancy. The discrepancy of many uniformly distributed sequences satisfies $O((\log N)^d/N)$. These sequences are called lowdiscrepancy (LD) sequences (Chen et al, 1006). Inequality (7) shows that the estimates using a LD sequence satisfy the deterministic error bound $O((\log N)^d/N)$.

3.2.2 Monte Carlo Simulations for Option Pricing

Under the risk-neutral measure, the price of a fairly valued European call option is the expectation of the payoff

$E[e^{-rT}(S_T - K)^+]$. In order to compute the expectation, Black and Scholes (1973) modeled the stochastic process generating the price of a non-dividend-paying stock as geometric Brownian motion:

$$dS_t = \mu S_t dt + \sigma S_t dW_t \qquad (8)$$

where W is a standard Wiener Process, also known as Brownian motion. Under the risk-neutral measure, the drift μ is set to $\mu = r$.

To simulate the path followed by S, suppose the life of the option has been divided into n short intervals of length $\Delta t (\Delta t = T/n)$, the updating of the stock price at $t + \Delta t$ from t is (Hull, 2003):

$$S_{t+\Delta t} - S_t = r S_t \Delta t + \sigma S_t Z \sqrt{\Delta t} \qquad (9)$$

Where Z is a standard random variable, i.e. $Z \sim (0,1)$. This enables the value of $S_{\Delta t}$ to be calculated from initial Value S_t at time Δt, the value at time $2\Delta t$ to be calculated from $S_{\Delta t}$, and so on. Hence, a completed path for S has been constructed.

In practice, in order to avoid discretization errors, it is usual to simulate $\ln S$ rather than S. From Itô's lemma, the process followed by of (9) is (Bratley and Fox, 1988):

$$d\ln S = \left(r - \frac{\sigma^2}{2}\right)dt + \sigma dz \qquad (10)$$

so that

$$\ln S_{t+\Delta t} - \ln S_t = \left(r - \frac{\sigma^2}{2}\right)dt + \sigma Z\sqrt{\Delta t} \qquad (11)$$

or equivalently:

$$S_{t+\Delta t} = S_t \exp\left[\left(r - \frac{\sigma^2}{2}\right)dt + \sigma Z\sqrt{\Delta t}\right] \qquad (12)$$

Substituting independent samples $Z_1, \cdots, Z_n$ from the normal distribution into (12) yields independent samples $S_T{}^{(i)}$, $i = 1, \cdots, n$, of the stock price at expiry time T. Hence, the option value is given by

$$V = \frac{1}{n}\sum_{i=1}^{n} V_i = \frac{1}{n}\sum_{i=1}^{n} e^{-rT}\max\left[S_T{}^{(i)} - K, 0\right] \qquad (13)$$

The QMC simulations follow the same steps as the MC simulations, except that the pseudo-random numbers are replaced by LD sequences. The basic LD sequences known in literature are Halton (1960), Sobol (1967) and Faure (1982). Niederreiter (1992) proposed a general principles of generating LD sequences. In finance, several examples have shown that the Sobol sequence is superior to others. For example, Galanti and Jung (1997) observed that "the Sobol sequence outperforms the Faure sequence, and the Faure marginally outperforms the Halton sequence. In this research, we use Sobol sequence in our experiments. The generator used for generating the Sobol sequence comes from the modified algorithm 659 of Joe and Kuo (2003).

3.2.3 Monte Carlo Bootstrap for VaR

Monte Carlo simulation is applicable with virtually any model of changes in risk factors and any mechanism for determining a portfolio's value in each market scenario. But revaluing a portfolio in each scenario can present a substantial computational burden, and this motivates research into ways of improving the efficiency of Monte Carlo methods for VaR.

The bootstrap (Efron, 1981; Efron and Tibshirani, 1986) is a simple and straightforward method for calculating approximated biases, standard deviations, confidence intervals, and so forth, in almost any nonparametric estimation problem. Method is a key word here, since little is known about the bootstrap's theoretical basis, except that (a) it is closely related to the jackknife in statistic inferring; (b) under reasonable condition it gives asymptotically correct results; and (c) for some simple problems which can be analyzed completely, for example, ordinary linear regression, the bootstrap automatically produces standard solutions.

The bootstrap method is straightforward. Suppose we observe returns $X_i = x_i$, $i = 1, 2, \cdots, n$, where the X_i are independent and identically distributed (iid) according to some unknown probability distribution F. The X_i may be real valued, two-dimensional, or take values in a more complicated space. A given parameter $\theta(F)$, perhaps the mean, median, correlation, and so forth, is to be estimated, and we agree to use the estimate $\hat{\theta} = \theta(\hat{F})$, where $\hat{F}$ is the empirical distribution function putting mass $1/n$ at each observed value x_i. We wish to assign some measure of accuracy to $\hat{\theta}$.

Let $\sigma(F)$ be some measure of accuracy that we would use if F were known, for example $\sigma(F) = SD_F(\hat{\theta})$, the standard deviation of $\hat{\theta}$ when $X_1, X_2, \cdots, X_n \sim F^{(iid)}$. The bootstrap estimate of accuracy is $\hat{\sigma} = \sigma(\hat{F})$ is the nonparametric maximum likelihood estimate of $\sigma(F)$. In order to calculate $\hat{\sigma}$ it is usually necessary to employ numerical methods. (a) A bootstrap sample $X_1^*, X_2^*, \cdots, X_n^*$ is drawn from $\hat{F}$, in which each X_i^* independently takes value x_j with probability $1/n$, $j = 1, 2, \cdots, n$. In other words, $X_1^*, X_2^*, \cdots, X_n^*$ is an independent sample of size n drawn with replacement from the set of observations $\{x_1, x_2, \cdots, x_n\}$. (b) This gives a bootstrap empirical distribution function $\hat{F}^*$, the empirical distribution of the n values $X_1^*, X_2^*, \cdots, X_n^*$, and a corresponding bootstrap value $\hat{\theta}^* = \theta(\hat{F}^*)$. (c) Steps (a) and (b) are repeated, independently, a large number of times, say N, giving bootstrap values $\hat{\theta}^{*1}, \hat{\theta}^{*2}, \cdots, \hat{\theta}^{*N}$. (d) The value of $\hat{\sigma}$ is approximated, in the case where $\sigma(F)$ is the standard deviation by the sample standard deviation of the $\hat{\theta}^*$ values, where

$$\hat{\mu} = \frac{\sum_{j=1}^{N} \hat{\theta}^{*j}}{N} \qquad (14)$$

And

$$\hat{\sigma}^2 = \frac{\sum_{j=1}^{N}\left(\hat{\theta}^{*j} - \hat{\mu}\right)^2}{N - 1} \qquad (15)$$

3.3 Distribution and Parallelism based on Random Number Generation

Financial variables, such as prices and returns, are random time dependent variables. Wiener process plays the central role in modeling. As shown in (8) and (9) for approximating the underlying prices $S_{t+\Delta t}$, or the bootstrap samples of return X_i^*, The solution methods involve basic market parameters, drift μ, volatility σ and risk-free interest rate r, current underlying price S or return X, strike price K, and Wiener process, which is related to time to maturity Δt and standard random variable Z, i.e. $\Delta W = Z\sqrt{\Delta t}$. Monte Carlo methods simulate this nature of the Brownian motion directly. It follows Wiener process and approximates the standard random variable Z by introducing pseudo iid random number into each Wiener process. When the simulation number is large enough, e.g. if n in (13) is large enough, the mean value will approach the exact solution. The large number for n also implies the performance problems are the key problems for Monte Carlo methods. One the other hand, the *iid* property of the random number Z shows possible solution to tackle the performance problem through mass distribution and/or parallelism. The solution method centers on the random number generation.

The techniques of random number generation can be developed in a simple form through the approximation of a d-dimensional integral, e.g. (3). Mass distribution and parallelism required solutions of for large dimension. However, most modern techniques in random number generation have limitations. In this study, both tradition pseudo random number generation and high dimensional low discrepancy random number generator are considered.

Following Section 3.2.1 better solution can be achieved by making use of Sobol sequences, which were proposed by Sobol (1967). A computer implementation in Fortran 77 was subsequently given by Bratley and Fox (1988) as Algorithm 659. Other implementations are available as C, Fortran 77, or Fortran 90 routines in the popular Numerical Recipes collection of software. However, as given, all these implementations have a fairly heavy restriction on the maximum value of d allowed. For Algorithm 659, Sobol sequences may be generated to approximate integrals in up to 40 dimensions, while the Numerical Recipes routines allow the generation of Sobol sequences to approximate integrals in up to six dimensions only. The FinDer software of Paskov and Traub (1995) provides an implementation of Sobol sequences up to 370 dimensions, but it is licensed software. As computers become more powerful, there is an expectation that it should be possible to approximate integrals in higher and higher dimensions. Integrals in hundreds of variables arise in applications such as mathematical finance (e.g., see Paskov and Traub(1995)). Also, as new methods become available for these integrals, one might wish to compare these new methods with Sobol sequences. Thus, it would be desirable to extend these existing implementations such as Algorithm 659 so they may be used for higher-dimensional integrals.We remark that Sobol sequences are now considered to be examples of (t, d)-sequences in base 2. The general theory of these low discrepancy (t, d)-sequences in base b is discussed in detail in Niederreiter (1992). The generation of Sobol sequences is clearly explained in Bratley and Fox (1988). We review the main points so as to show what extra data would be required to allow Algorithm 659 to generate Sobol sequences to approximate integrals in more than 40 dimensions. To generate the j th component of the points in a Sobol sequence, we need to choose a primitive polynomial of some degree s_j in the field $\mathbb{Z}_2$ that is, a polynomial of the form

$$x^{s_j} + a_{1,j}x^{s_j-1} + \cdots + a_{s_j-1,j}x + 1, \qquad (16)$$

where the coefficients $a_{1,j}, \cdots, a_{s_j-1,j}$ are either 0 or 1.

We use these coefficients to define a sequence $\{m_{1,j}, m_{2,j}, \cdots\}$ of positive integers by the recurrence relation

$$\begin{aligned} m_{k,j} &= a_{1,j}m_{k-1,j} \oplus 2^2 a_{2,j}m_{k-2,j} \oplus \cdots \\ &\oplus 2^{s_j-1}a_{s_j-1,j}m_{k-s_j+1,j} \oplus 2^{s_j}a_{s_j,j}m_{k-s_j,j} \\ &\oplus m_{k-s_j,j} \end{aligned} \qquad (17)$$

for $k \geq s_j + 1$, where $\oplus$ is the bit-by-bit exclusive-OR operator. The initial values $m_{1,j}, m_{2,j}, \cdots, m_{s_j,j}$ can be chosen freely provided that each $m_{k,j}$, $1 \leq k \leq s_j$ is odd and less than 2^k. The "direction numbers" $\{v_{1,j}, v_{2,j}, \cdots\}$ are defined by

$$v_{k,j} \equiv \frac{m_{k,j}}{2^k} \qquad (18)$$

Then $x_{i,j}$, the j th component of the ith point in a Sobol sequence, is given by

$$x_{i,j} = b_1 v_{1,j} \oplus b_2 v_{2,j} \oplus \cdots \qquad (19)$$

where b_l is the lth bit from the right when i is written in binary, that is, $(\cdots b_2 b_1)_2$ is the binary representation of i. In practice, a more efficient Gray code implementation proposed by Antonov and Saleev (1979) is used; see Bratley and Fox (1988) for details. We then see that the implementation in Bratley and Fox (1988) may be used to generate Sobol sequences to approximate integrals in more than 40 dimensions by providing more data in the form of primitive polynomials and direction numbers (or equivalently, values of $m_{1,j}, m_{2,j}, \cdots, m_{s_j,j}$). When generating such Sobol sequences, we need to ensure that the primitive polynomials used to generate each component are different and that the initial values of the $m_{k,j}$'s are chosen differently for any two primitive polynomials of the same degree. The error bounds for Sobol sequences given in Sobol (1967) indicate we should use primitive polynomials of as low a degree as possible. We discuss how additional primitive polynomials may be obtained in the next section. After these primitive polynomials have been found, we need to decide upon the initial values of the $m_{k,j}$ for $1 \leq k \leq s_j$. As explained above, all we require is that they be odd and that $m_{k,j} < 2^k$. Thus, we could just choose them randomly, subject to these two constraints. However, Sobol (1988) introduced an extra uniformity condition known as Property A. Geometrically, if the cube $[0,1]^d$ is divided up by the planes $x_j = 1/2$ into 2^d equally sized subcubes, then a sequence of points belonging to $[0,1]^d$ possesses Property A if, after dividing the sequence into consecutive blocks of 2^d points, each one of the points in any block belongs to a different subcube. Property A is not that useful to have for large d because of the computational time required to approximate an integral using 2^d points. Also, PropertyA is not enough to ensure that there are no bad correlations between pairs of dimensions. Nevertheless, Property A would seem a reasonable criterion to use in deciding upon a choice of the initial $m_{k,j}$. The numerical results for Sobol sequences given in Section 4 suggest that the direction numbers obtained here are indeed reasonable. Otherways of obtaining the direction numbers are also possible. For example, in Cheng and Druzdzel (2000), the initial direction numbers are obtained by an interesting technique of minimizing a measure of uniformity in two dimensions. This technique may alleviate the problem of bad correlations between pairs of dimensions that was mentioned above. Sobol (1967) showed that a Sobol sequence used to approximate a d dimensional integral possesses Property A if and only if

$$\det(V_d) = 1 \pmod 2, \qquad (20)$$

where V_d is the $d \times d$ binary matrix defined by

$$V_d = \begin{bmatrix} v_{1,1,1} & v_{2,1,1} & \cdots & v_{d,1,1} \\ v_{1,2,1} & v_{2,2,1} & \cdots & v_{d,2,1} \\ \vdots & & \ddots & \vdots \\ v_{1,d,1} & v_{2,d,1} & \cdots & v_{d,d,1} \end{bmatrix} \qquad (21)$$

with $v_{k,j,1}$ denoting the first bit after the binary point of $v_{k,j}$. The primitive polynomials and direction numbers used in Algorithm 659 are taken from Sobol and Levitan (1976) and a subset of this data may be found in Sobol (1967). Though it is mentioned in Sobol (1967) that Property A is satisfied for $d \leq 16$, that is, $\det(V_d) = 1 \pmod 2$ for all $d \leq 16$, our calculations showed that Property A is actually satisfied for $d \leq 16$. As a result, we change the values of the $m_{k,j}$ for $21 \leq j \leq 40$, but keep the primitive polynomials. For $j \geq 41$, we obtain additional primitive polynomials. The number of primitive polynomials of degree s is $\phi(2^s - 1)/s$, where ϕ is Euler's totient function. Including the special case for $j = 1$ when all the $m_{k,j}$ are 1, this allows us to approximate integrals in up to dimension $d = 1111$ if we use all the primitive polynomials of degree 13 or less. We then choose values of the $m_{k,j}$ so that we can generate Sobol sequences satisfying Property A in dimensions d up to 1111. This is done by generating some values randomly, but these are subsequently modified so that the condition $\det(V_d) = 1 \pmod 2$ is satisfied for all d up to 1111. This process involves evaluating values of the $v_{k,j,i}$'s to obtain the matrix V_d and then evaluating the determinant of V_d. A more detailed discussion of this strategy is given in the next section. It is not difficult to produce values to generate Sobol's points for approximating integrals in even higher dimensions.

The following figures is the two dimensional plots of high dimension Sobol sequences of Joe and Kuo with $d = 1000$. It is compared with pseudo random number generation. The number of sampling points is 3000. In Fig. 7 pseudo random number is plotted in comparison with that of quasi-random number of Sobol. The leading dimensions 1 and 2 of Sobol sequences are used. The improvement is immense. In order to understand more of the nature of Sobol sequences, we chose prime dimensional numbers 499, 503, 991 and 997 respectively as suggested by Joe and Kuo. The results are plotted in Fig. 8 and Fig. 9. It is found that there are stronger correlations between Sobol sequences of non-adjacent dimensions in the fashion of the dimensional comparison of their randomness. Larger numbers of sampling points, e.g. 10,000, are also tested and the patterns persist. It implied the violation of *iid* assumption and may incur problems in mass distribution and parallelism, in which each process the random number is generated independently without knowing what other processes are doing. The dependency may deteriorate the quality of randomness. Nevertheless, in our numerical experiments there are no significant differences found thus far.

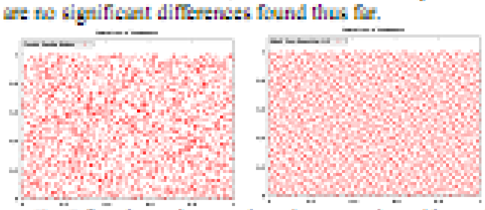

Fig. 7 Pseudo random number plot comparing with quasi-random number of Sobol for dimensions 1 and 2.

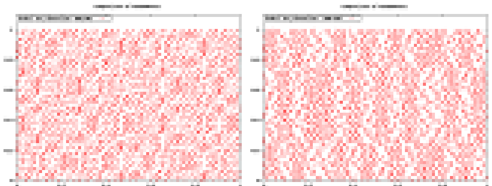

Fig. 8 Comparison of adjacent dimensions in Quasi-random number Sobol sequence. The dimensions are chosen according to prime numbers. There are high discrepancy found in higher dimensions of Sobol sequence modified by Joe and Kuo (2003).

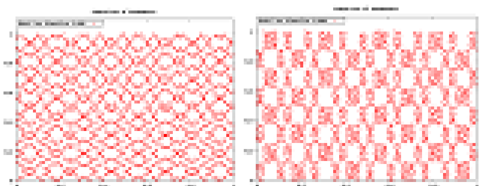

Fig. 9 Comparison of non adjacent dimensions. High discrepancy is found in their correlations and forms clusters of islands in the distribution.

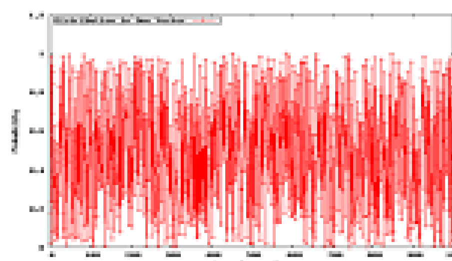

Fig. 10 The distribution of probability in directional vector $v_{i,j}$ of Sobol sequences at i=3000 with $j \in \{1, \cdots, 1000\}$. The mean of the distribution is 0.491357, which approaches the mean of the normal distribution 0.5.

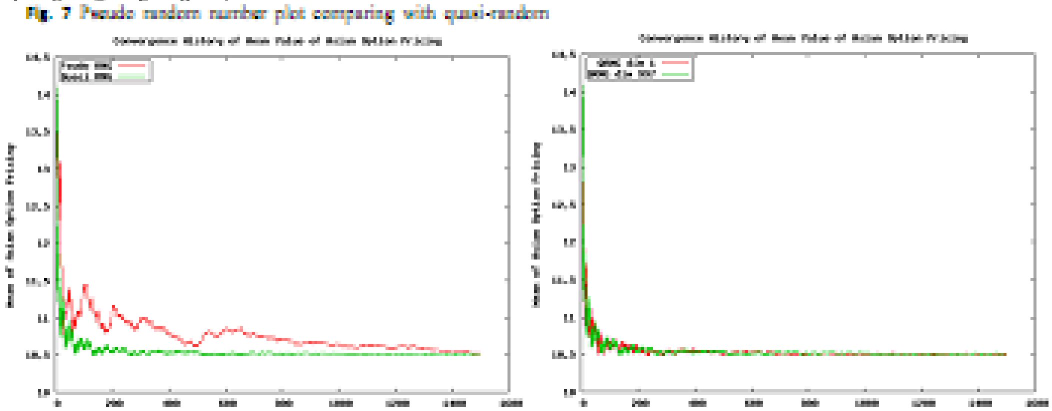

Fig. 11 The convergence history of the mean value of Asian option pricing with risk-free interest rate r=0.1, underlying asset spot price S=100, strike price X=100, duration to maturity T=1 and volatility σ =0.3: The comparison is based

on a single dimension of the extended high-dimensional Sobol sequences. The quasi random number generator (QRNG) outperforms pseudo random number generator. The test also is conducted to compare the convergence history between different dimensions in Sobol sequences and found all perform consistently as shown in the right figure, in which the low dimension and high dimension are chosen for the comparison.

4 Cases Study and Discussions

4.1 Cases Study

Asian Options and Rainbow Options

To demonstrate what the grid computing can contribute to the financial service in a significant manner, two kinds of popular options, Asian options and rainbow options, are chosen for Monte Carlo pricing model. Asian options have payoffs that depend on the average price of the underlying asset such as stocks, commodities, or financial indices. However, there is no exact closed-form formula existed for these popular options. Rainbow options, also known as basket options, is referred to an entire class of options which consist of more than one underlying asset. Rainbow options are usually calls or puts on the best or worst of the underlying assets, or options which pay the best or worst of the assets. They are excellent tools for hedging risk of multiple assets. The rainbow options are therefore used for our bootstrap calculations of VaR.

Parallelization, Distribution and Message Passing Interface (MPI)

MPI is a library specification for message passing, proposed and developed as a standard by a broadly based committee of vendors, developers and users (Snir et al, 1996). MPI was designed for high performance on both massively parallel machines and on distributed clusters. The MPI standard is nowadays widely accepted and used in the community of high performance computing.

The basic MPI functions are point-to-point pair-wise message passing for send and for receive. Collective communications are also provided for ease of use as well as better performance. These communication methods, when used in supercomputers, do facilitate the parallelization of numerical methods that require both heavy compute cycles and stronger dependency between parallel processes.

Recent development of supercomputer, affected by the popularity of cluster computing in PCs, tends to be designed hierarchically scalable. Further extension of clusters of supercomputers can be regarded as initial concept of grids (see Section 2). The use of MPI is straightforward in this kind of hardware architecture and interlink of networks. There is always an obvious physical limitation in this architecture, which is also proportional to the limitation of the investment of governmental research funding. People tend to use mass distribution of computers, mostly PCs, which linked loosely in internet cloud. The terminology cloud is often used in networking community to show that in internet there is no specific network path from one computer to another. MPI working in such an environment is expected to be inefficient and unstable, e.g. high network latency induced packet lost in long distance real time communication. In the following sections three specific platforms, including local clusters, geographically distributed large clusters, and PC grids with ten of thousand PCs connected in the cloud, will be used for the financial calculations to demonstrate benefits in using grids.

Empirical Study for Data Grid System

In order to demonstrate the usefulness of grid system, in particular in data-intensive application, the real market data are used, including daily from iShares (Morgan Stanley Capital International) MSCI Taiwan Index (ETF) and Taiwan Stock Exchange Center (TSEC) weighted index, extracted specifically from May 31, 2005 to May 31, 2008, and 30 days tick-by-tick trading data from Taiwan Futures Exchange Center (TAIFEX).

4.2 Grid Platforms Tests

The various grid platforms are carefully chosen to demonstrate the performance issue in finance services, which include a small diskless remote boot Linux (DBRL) PC clusters, large scale and geographically widely distributed test-bed the Pacific Rim Applications and Grid Middleware Assembly (PRAGMA) compute grid, and a densely distributed at-home style PC grid, which resembles the clouding computing.

4.2.1 Diskless Remote Boot Linux (DRBL) Cluster

DRBL is an in-house program of National Center for High-Performance Computing (NCHC) and was an original software product developed by Steven Shiau and his group under the auspice of National Knowledge Innovation Grid (KING) of Taiwan. It was developed initially as a centralized system management tool aiming at small and median size of PC clusters. It is nowadays recognized internationally as one of the most advanced mass backup solutions. Here DRBL is used as an alternative scavenger for compute cycles of spare clusters. When needed, it converts systems of PC clusters into an aggregated and homogenous Linux system, simultaneously with a mass backup of the original systems, and recovery back the original systems once the need satisfied. The most popular use is to convert a PC classroom into a compute linux cluster. In such a case, compute cycles of the clusters can be fully exploited. In a grid environment, this is a perfect case to resources scale-up when in contingent need and once the situation relieved resources will be released correspondingly. Such a dynamic feature can be beneficial for the financial services.

The schematic of DRBL system can be shown in Fig. 12, where DRBL duplicates image files of an operational system, e.g. Linux kernel, via network to the clients. The clients' original operational systems are not used. The clients are therefore temporarily turned into dedicated compute resources, which also provide additional security to financial data.

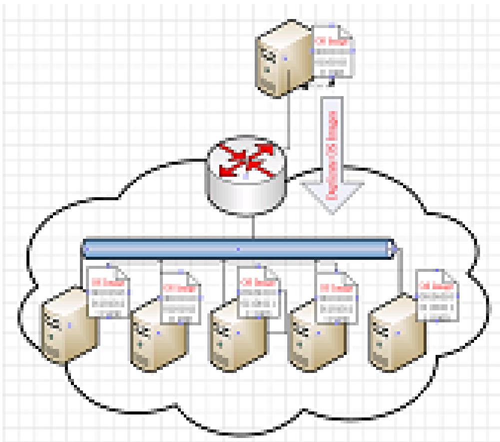

Fig. 12 The schematic of DRBL system: DRBL duplicates image files of operational system via network to the clients, in which the clients' original operational systems are untouched. Therefore, the clients are temporarily turned into dedicated compute resources, which also provide additional security to financial data.

The test case here involves Monte Carlo simulations on Asian option pricing, on rainbow option pricing and on a bootstrap VaR calculation respectively (see Section 3.2). The market parameters are given as risk-free interest rate r=0.1, underlying asset spot price S =100, strike price X=100, duration to maturity T=125 and volatility σ =0.3. For the rainbow options a linear weighted combination of 4 underlying assets is assumed with underlying prices of S_i=100, 110, 120, 130 and the corresponding weightings of volatility σ_i = 0.3, 0.4, 0.5, 0.6. The correlation matrix is taken to be

$$\rho_{ij} = \begin{pmatrix} 0.5 & 0.4 & 0.5 \\ 0.4 & 0.3 & 0.4 \\ 0.5 & 0.4 & 0.6 \end{pmatrix}.$$

The calculation of the VaR uses the same 4 dimensional rainbow options with additional expectation of return 0.07, 0.08, 0.09 and 0.10 respectively. They are calculated in DRBL cluster as well as benchmarked with two cluster-based supercomputers in NCHC. The results are shown in Table 1 and Table 2.

Table 1 Comparison of performance between DRBL-based PC platform with 32 nodes, FORMOSA II of NCHC with a batch job of 32 nodes and IBM Cluster 1350 with a batch job of 32 nodes. The PCs are 20 XEON 2.6 GHz and 4GB RAM.

	DRBL Cluster	FORMOSA II	IBM Cluster 1350
Asian Option Pricing (AOP)	81	49	24
Rainbow Option Pricing (ROP)	329	197	98
VaR Calculation (based on ROP w/ Bootstrap)	322	194	97

Unit: micro-secs per Monte Carlo path. Averaged from 1000,000 Monte Carlo paths.

Table 2 Comparison of Speedup ratios based on the calculations in Table 1.

	DRBL Cluster	FORMOSA II	IBM Cluster 13 50
Asian Option Pricing (AOP)	28.68	29.46	30.16
Rainbow Option Pricing (ROP)	27.31	28.59	29.34
VaR Calculation (based on ROP w/ Bootstrap)	27.20	28.10	29.10

Unit: Speedup Ratio:CPU(non-parallel single node)/CPU(parallel single node)

In Table 1, instead of giving a total wall clock time of the calculation with some given numbers of Monte Carlo simulations or paths, a more useful averaged single Monte Carlo simulation based on 1,000,000 simulations is used to demonstrate the performance when different system architectures are used. The results show that the traditional big irons, i.e. supercomputers, still outperform the cluster. Yet, considering there are no extra cost invested in the computing resources and still obtain compute cycle in a sizable manner, the approach is appealing to be further developed in to a fully operational production system.

4.2.2 Pacific Rim Applications and Grid Middleware Assembly (PRAGMA) Grid

The Pacific Rim Applications and Grid Middleware Assembly (PRAGMA), founded in 2002, is an open international organisation that focuses on a variety of practical issues of building international scientific collaborations in a number of application areas. PRAGMA Grid is established by the resources and data computing working group of Group as a global grid testbed for benchmarking the interoperability of grid middleware and the usability and productivity of grids. The PRAGMA Grid consists of physical resources as well as system administration supports from 29 institutions across 5 continents and 14 countries. It is an instantiation of a useful, interoperable, and consistently available grid system that is neither dictated by the needs of a single science domain, nor funded by a single national agency. It does not have uniform infrastructure management, yet robust and supports a wide range of scientific applications. The software stack of the system is shown in Fig. 12.

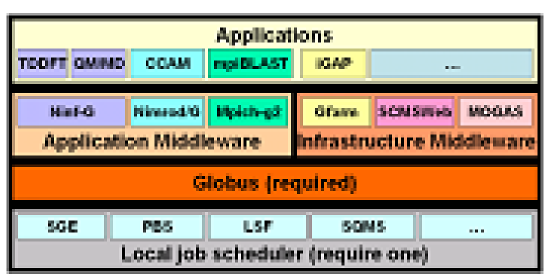

Fig. 13 Software stack developed in the PRAGMA grid.

The PRAGMA grid successfully tackle the issues of distance and time zone differences among sites, lack of infrastructure tools for heterogeneous global grid, non-uniform system and network environments, and diverse application requirements. For more technical details both in theory and practice we refer to (Abramson et al, 2006).

Table 3 Comparison of performance between Group A, which consists of 13 nodes from NCHC and 15 from UCSD, and Group B, which consists of 122 nodes collectively from UCSD, AIST, NCHC and Osaka University. The details of resources are referred to (http://pragma-goc.rocksclusters.org/pragma-doc/resources.html).

	Group A.	Group B
Asian Option Pricing (AOP)	68	56
Rainbow Option Pricing (ROP)	278	234
VaR Calculation (based on ROP w/ Bootstrap)	271	229

Unit: secs/per Monte Carlo path. Averaging from 1000,000 Monte Carlo paths

Table 4 Comparison of Speedup ratios based on the calculations in Table 3.

	Group A.	Group B
Asian Option Pricing (AOP)	25.24	107.98
Rainbow Option Pricing (ROP)	25.81	110.34
VaR Calculation (based on ROP w/ Bootstrap)	25.63	110.09

Unit: secs/per Monte Carlo path. CPU(non-parallel single node)/CPU(parallel single node)

Following the similar test case in Section 4.2.2, but extended the platform with a collection of clusters across institute boundaries. The common job submission is executed via a homogeneous middleware Globus Toolkit. We demonstrate the usefulness of the platform by grouping compute resources across national boundaries and still achieve good performance. The results are shown in Table 3 and Table 4.

4.2.3 At-Home Style PC Grid

While the continued penetration of personal computers and the remarkable improvement of CPU processing speed, 80 to 90 percent of most PCs' processing power is untapped, according to a study. This does not mean that many PCs remain turned off, but that the capacity of the CPU, the brain of the PC, is not fully utilized. In case the CPU is more extensively used when a task requiring an enormous number of operations, such as three-dimensional graphical processing, is assigned, it sits idle most of the time during word processing and Internet browsing because CPU processing speeds are much faster than the speeds of input from the keyboard or the communication line.

This fact led to the idea of virtually gathering the power of idle CPUs to use as a computer resource. In other words, this means networking numerous computers to make them work like a single high performance computer, and assigning complex processing tasks to it. The assigned task will be divided into a myriad of small tasks and allocated to individual computers on the grid-like network. Even when increasingly faster CPUs, the power of PCs are not comparable to those of supercomputers, but in a networked environment where individual PCs simply process complex task in parallel, PCs can deliver surprisingly high performance. This is the core concept of CP grid computing, and it came into a reality several years ago.

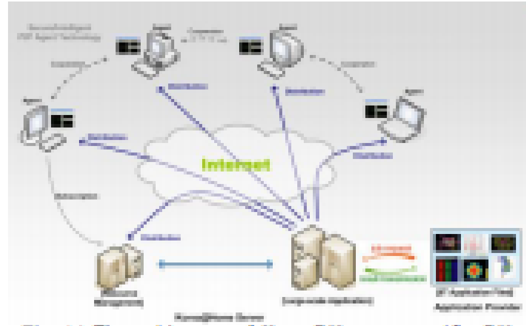

Fig. 14 The architecture of Korea@Home, a specific @Home style PC Grid used in our case study (Jun-Weon Yoon, 2008).

Table 5 Summary of the case for the PC Grid calculations.

Asian Option Pricing	Statistics
Number of Monte Carlo Path	1,000,000 x 10,000
The running period (1) (Wall clock time)	28h 51m (104911s)
Number of jobs	10,000
CPU time per job	28"30s
Total running time (2) (Wall clock time)	4 days 14h 31m (397919 s)
Speedup ratio $\frac{(2)}{(1)}$	3.79

The commoditization and the increased processing speed of PCs leads the growth of idle CPU power. This will facilitate the construction of PC grid computing system along with improvement of communication environment by broadband connectivity (Chen et al, 2006). In practice, a PC Grid platform Korea@Home (or K@H) is used in our study. Its architecture is shown in Fig. 14. The is based on MS Windows. Asian option pricing is used to demonstrate the performance of the system, in which the number of iterations is taken to be 1,000,000. The duration to maturity is further divided by 10,000 periods, which push the system to run on the mass parallel system of K@H. To tackle this scale, or even larger scale for all kinds of possible scenarios in real trading practice, an off line distributed and parallel approach is adopted. The total number of Monte Carlo simulation is 1,000,000 x 10,000. It was divided into 10,000 jobs and each job consists of 1,000,000 Monte Carlo simulations. The market parameters are given as above.

The results demonstrated here are not as good as expected (see Table 1). It shows that the speedup ratio is only 3.79. In this test, K@H further divides the jobs into 10 groups. Each group was send and run in a sequential fashion, which causes the low speedup ratio. However, if one looks into the executed CPU time for each job, our assumption is still valid. We simulated the result in a small cluster with the same scenario and Monte Carlo paths. The result shows 90% speedup can be easily achieved.

4.2.4 RBNB Data Grid

RBNB DataTurbine in market data streaming is implemented here (See Fig. 11), in which the real data from iShares MSCI Taiwan Index (ETF) and TSEC weighted index from May 31, 2005 to May 31, 2008 and 30 days tick-by-tick trading data from Taiwan Futures Exchange Center (TAIFEX) are used and open in different file-based online channels from the RBNB DataTurbine. The purpose is to dynamically manage the high frequency market data and connect the data with analysis applications on the fly. The system implemented up to date is for large scale dynamic and static data management.

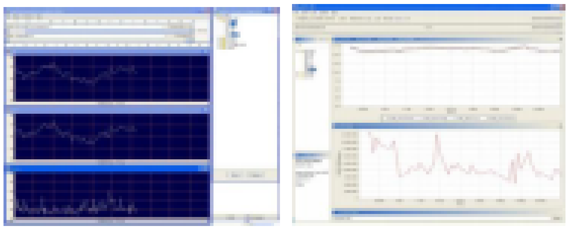

Fig. 15 RBNB DataTurbine streaming open for data channels of iShares MSCI Taiwan Index (ETF) and TSEC weighted index from May 31, 2005 to May 31, 2008, and 30 days tick-by-tick trading data from Taiwan Futures Exchange Center (TAIFEX). (real data plot in collaboration with Ebbe et al, 2007).

5 Conclusions

Securities trading is one of the few business activities where a few seconds processing delay can cost a company big fortune. The growing competitive in the market exacerbates the situation and pushes further towards instantaneous trading even in split second. The key lies on the performance of the underlying information system. Following the computing evolution in financial services, it was a centralized process to begin with and gradually decentralized into a distribution of actual application logic across service networks. Financial services have tradition of doing most of its heavy lifting financial analysis in overnight batch cycles. However, in securities trading it cannot satisfy the need due to its ad hoc nature and requirement of immediate response. A new computing paradigm, Grid computing, aiming at virtualizing scale-up distributed computing resources, is well suited to the challenge posed by the capital markets practices.

In this study we revisit the theoretical background of how performance will affect the market competition. The core concept lies on information asymmetry. Due to the advance of IT, even in split second it will be a matter of win or lose in real market practice. After establish the motivation we review recent grid development specifically used for finance service. Monte Carlo simulations are chosen not only because of its popularity in real world, but also its nature of so call "fine grain" or mass parallelism approach. The success of Monte Carlo simulations lies on better random number generators. The well recognized Sobol sequences as a quasi random number generator are carefully studies to ensure the quality of Monte Carlo simulations when employed for mass parallelism. Then some popular basic option pricing models, collectively Asian option pricing, rainbow option pricing and VaR calculation with constant market parameters, are introduced as drivers to introduce more details of grids for better finance service. Finally, we test various grid platforms, based on the methodology of mass parallelism and mass distribution, with the drivers. The real market data are also used, but at this stage they are only used to demonstrate the dynamic data management, in which grids can offer better.

During this study, we encountered system architect Koschnick from Zürcher Kantonalbank of Switzerland (Koschnick, 2008). Coincidentally, the system they plan to migrate from big irons is the similar system to that of DRBL with additional virtual local area networks (VLAN) for security. The system is used for overnight batch job as well as real time trading practice. It is confirmed that for the years to come, financial services providers will adopt more grid or grid-based technology to enhance their competitiveness.

Our future work will be following the current work: continuously using the current grid platforms and extending them to the use high-frequency real market data. Along the track of this development, we will also develop sophisticated Monte Carlo based option pricing and risk management based on tick-by-tick daily market information.

□ □ □ □ □ □ The Impact of Free Trade Agreement on Trade Flow of Goods in Vietnam

Nguyen Quang Huy
Vietnam-Netherlands Programme for M.A. in Development Economics
University of Economics Ho Chi Minh City
Vietnam
huy.nq@vnp.edu.vn

This study analyzes the effect of free trade agreement on Vietnam’s trade flow of goods by establishing gravity model for 185 countries between 1990 and 2012. Basing on the theoretical foundation and previous empirical papers, the FTA is expected to have positive relationship with trade flow of member countries. In details, two countries being in a same FTA will trade much more than those without in a same FTA. The results from the current study also find out that FTA’s estimated coefficients are consistently positive. The empirical results from all estimation models are consistent with each other in term of sign of FTA’s coefficient. For policy implication, the study proposes that FTA is a good trade policy for Vietnam because it can help to improve the export value among FTA members. However, FTA does not impact on trade outflow only, but it also has effect on other aspects of Vietnam economy such as wage structural, investment. Those issues are beyond the objective of this study.

Keywords: Free Trade Agreement, gravity model, total bilateral trade, export.

1 Introduction

According to World Trade Organization, Vietnam is now official member of eight free trade agreements which are signed and into force; and, Vietnam is also launching negotiation with a number of countries and economic groups to establish other free trade agreements such as TPP, ASEAN-EU FTA. On the one hand, free trade is espoused in improving the trade and welfare of signing countries. This belief is developed from the absolute advantage by Adam Smith, comparative advantage by David Ricardo, Heckscher-Ohlin model by Eli Heckscher and Bertil Ohlin to Paul Krugman with economies of scale and product differentiation. On the other hand, Viner (1950) not only accepted the gain from free trade but he also pointed out the loss if countries build trading blocs. The "trade diversion" is the terminology for the diverting trade from countries to countries. Therefore, question should be asked is how trade flow of Vietnam is affected by her free trade agreements.

Empirically, there are a vast number of papers investigating the relationship between free trade agreement and bilateral trade. Hur, Alba &Park (2009) conducted a research to evaluate the Hub-and-Spoke problem in free trade agreements by using panel data analysis of 96 countries from 1960 to 2000; and concluded that in spite of the existing of overlapping free trade agreement, export also increased. Other relevant paper by Baier & Berstrand (2009), that gives comprehensive contribution to the empirical model to investigate the effect of free trade agreement on international trade flow, also found the positive linkage. However, Aitken (1972) did an empirical research on trade creating and trade diverting after the establishment of EEC and EFTA. He found that EEC increased trading value of member countries significantly by trade creating and trade diverting, whereas the effect of EFTA is not considerably because of trade diverting. Besides, Bhavish, Jugurnath, Stewart & Brooks (2007), conducted a research on ASEAN FTA, APEC, CER, MERCOSUR and NFTA. The authors asserted that ASEAN FTA, CER increase its members' trade significantly, while MERCOSUR, NFTA and APEC created the trade diversion. As a result, the demand for study for international trade effect on specific context needs a critical exploration. Relating to Vietnam context, papers analyze the linkage between free trade agreement and trade flow in Vietnam is limited. For instance, Thai (2006) used gravity model to calculate the trade between Vietnam and twenty-three European countries. The paper found the determinants in trading such as economic characteristics, exchange rate volatility and the demand of destination. However, free trade agreement is not mentioned in the paper because Vietnam and those countries have not signed Free trade Agreement yet. Other paper investigates the impact of ASEAN Free Trade Agreement (AFTA) on Vietnam's economy is by Fukase & Martin (2001). The authors concluded that impact of AFTA is not significant. Agricultural sector gets benefit from that free trade because of exporting opportunity to ASEAN market, while some other industries is hurt and need to be protected due to ASEAN competitors. Therefore, this study will analyze the role of free trade agreement on trade flow of goods in Vietnam by applying gravity model for panel of 184 countries over the period 1990-2012. The study is carried out by using Fixed Effect model proposed by Baier & Bergstrand (2007), Sample Selection model by Helpman et al (2008), and Poisson Pseudo Maximum Likelihood model by Tenreyro & Silva (2008).

2 Free trade agreement

After establishing trading bloc, member countries can shift import from higher-taxed suppliers to lower-no taxed suppliers; and, domestic goods are substituted by member's low-cost goods. Johnson (1974) stated these above movements will balance the increasing-welfare. Lipsey (1957) and Bhagwati (1971) defined the trade diversion as the change in the locus of production from initial lower supplier to higher member suppliers. Trade creation is defined as the increase in trade between member countries. Johnson (1974) argued that trade diversion can give a transfer from locus of production which negatively impact on welfare, and create a substitution effect which positively impact on welfare. Furthermore, Michaely (1976) asserted that trade liberalization impacts on the trade pattern of signing countries in three ways. First effect is the increase in new trade flow between bloc's members. Secondly, reducing trade barrier can divert the import from non-member suppliers to member suppliers. Finally, the change in term of trade is an attributable to a rise in demand of substitute commodity.

Chaney (2008) stated that the change in trade flow due to trade barrier shock can be explained through two mechanisms. The first mechanism is the intensive margin which is the increase in exporting volume of incumbent firms. The second one is the extensive margin which is the change in the number of exporter in different sectors. In general, trade barrier reduction such as free trade agreement between two countries leads to the change in the number of good each firm exports, and new exporters can enter the market. Crozet and Koenig (2010) confirmed the theory in heterogeneous firms established in Chaney (2008). The paper disintegrated effect of trade cost on trade flow in to intensive margin and extensive margin as follow:

$$\varepsilon_{\tau_j}^{M} = \varepsilon_{\tau_j}^{EXT} + \varepsilon_{\tau_j}^{INT} \qquad (2.1)$$

Where $\varepsilon_{\tau_j}^{M}$ is the total trade cost elasticity of trading value

$\varepsilon_{\tau_j}^{EXT}$ is the trade cost elasticity of external margins

$\varepsilon_{\tau_j}^{INT}$ is the trade cost elasticity of internal margins

Crozet and Koenig (2010) concluded that the change in trade flow due to fluctuation in trade cost varied across the industries. In details, the reducing in trade barrier impacts on trade level greater in homogenous industries than more heterogeneous industries. Extensive margin effect can dominate the intensive margin effect in industry with high differentiated product. Moreover, Helpman, Melitz, and Rubinstein (2008) stated that the profitability of firm export is higher if the importing countries' demand is higher, and lower trade costs. On the other hand, firm will not export if the profit of firm is negative. That can explain the zero value in export between two countries. He showed the primary bias in estimating impact of trade barrier on trade flow is attributed to ignoring extensive margin effect. The reducing in trade friction may not only lead to the expansion of trade between existent country pairs, but also to create new trading partners.

3 Gravity model for free trade agreement

Aitken (1973) is the first author which applied the theory of gravity model in order to estimate the effect of European Economic Community (EEC) and European Free Trade Association (EFTA) on the import and export of member countries. In his model, he proposed a number of indicators for conceptions in the theoretical model. The dependent variable was export value. The independent variables were Free trade agreement, Income of exporting countries, Income of Importing countries, Distance between trading partners. Those indicators have been used by latter researches on observing the impact of FTA on trade flow of countries.

Trade flow

In empirical papers, there are three indicators for trade flow between countries. Firstly, McCallum (1995) used the shipment value from one country to other country as the representative for trade flow. In his paper, he analyzed the impact of trade border effect in the trade between The United States of America (USA) and Canada. The idea of research is that within-provincial trade of Canada is greater than the trade with USA's states, or foreign trade. By applying the gravity model as follow:

$$x_{ij} = a + by_i + cy_j + ddist_{ij} + eDUMMY_{ij} + u_{ij} \tag{2.2}$$

Where x_{ij} is the total export from region i to region j

Anderson and Wincoop (2003) examined the results obtaining from McCallum (1995). The authors argued that the result is overestimated because it omitted trade resistance variables which are called multilateral resistance terms (MRTs). Anderson and Wincoop (2003) proposed a new estimated model as follow:

$$x_{ij} = \frac{y_i y_j}{y^w}\left(\frac{t_{ij}}{\prod_i P_j}\right)^{1-\sigma} \tag{2.3}$$

The model also used the export from countries i to j as the dependent variable for trade flow. The differences with McCallum (1995) are the variables $\prod_i$, and P_j, the multilateral resistance terms. The meaning of MRTs is that it indicated the average price of export country to the rest of the world's price. The definitions of MRTs are as follow:

$$\prod_i = \left(\sum_j \left(\frac{t_{ij}}{P_j}\right)^{1-\sigma} \theta_j\right)^{1/_{1-\sigma}} \tag{2.4}$$

$$P_j = \left(\sum_i \left(\frac{t_{ij}}{\prod_i}\right)^{1-\sigma} \theta_i\right)^{1/_{1-\sigma}} \tag{2.5}$$

Baier and Bergstrand (2007) conducted a research to estimate the impact of FTA on trade flow. The paper used data of 96 countries around the world from 1960 to 2000. In his estimation model, the trade flow between i and j is the export value from i to j divided by the GDP deflator to obtain real trade flow. Hur, Alba, and Park (2010) applied the gravity model proposed by Baier and Bergstrand (2007) to find out the hub-spoke effect of FTA using data on 96 countries around the world throughout 40 years from 1960. In the model, dependent variable is real exporting value, the nominal exporting value divided by GDP deflator. However, Yang and Martinez-Zarzoso (2014) estimated whether ASEAN-China Free Trade agreement is trade creation or trade diversion. In the paper, current export level in US dollar represent for trade flow concept in international trade.

On the other hand, Jugurnath, Stewart, and Brook (2007) did not exploit the export value as an indicator for trade flow. Instead of that, current import value is use as a dependent variable in the model. The reason is that country often strictly reports its import value for the tax purpose, so the import value is more correct than export value.

Free Trade Agreement

The primary effect of FTA on trade flow is through the elimination of trade tariffs, so many research papers has analyzed trade cost as a tool for evaluation the impact of FTA. Anderson and Wincoop (2003) use the following measurement:

$$t_{ij} = b_{ij} d_{ij}^{p} \tag{2.6}$$

b_{ij} indicates the border effect in his analysis. The variable will take the value of 1 if two regions is in same country, otherwise, it is equal to one add trading tax. Although the paper did not mention about FTA, the paper has been applied by later researcher. Baier and Bergstrand (2007) estimated the impact of FTA on trade flow of countries by using variable FTA as a dummy variable. The variable FTA took value of 1 of exporter and importer are in the same free trade area, unless FTA was equal to 0. The paper use panel data and fixed effect estimation to find the FTA's coefficient, and the result showed that there is positive relationship between FTA and trade flow. Basing on Baier and Bergstrand (2007), Jugurnath, Stewart, and Brooks (2007) also used FTA as dummy variable in their paper. However, the paper not only estimated the impact of FTA on trade flow, but also intent to find the trade diversion and trade creation effect of FTA. Therefore, they set up more dummies variable to separate the diversion and creation effect in trade. The model is as follow:

$$\log IMPORT_{ij} = aX + \sum_{k=1} \alpha RTA_{ik} RTA_{kj} + \sum_{k=1} \alpha RTA_{ki} + \sum_{k=1} \alpha RTA_{kj} \tag{2.7}$$

In the model, i is the importing country, j is exporter, and k indicates the Regional Trade Agreement (RTA) k. Unlike in Baier and Bergstrand (2007), there are separate RTAs for two countries to analyze the trade creation and trade diversion of RTAs. The paper concluded that regional trade agreement of ASEAN, CER are trade creation while APEC, MERCOSUR, and NAFTA have a tendency to increase trade within regional member or may be trade diversion. Furthermore, Yang and Martinez-Zarzoro (2014) estimated the relationship between ASEAN-China (ACFTA) on trade flow of member countries. The model of paper set up three types of FTA dummy variables. The first FTA variable is equal one if both export and import countries are in same FTA. This variable showed the trade increase between member countries as the effect of ACFTA. The second dummy FTA is equal 1 if exporter is in the ACFTA, and importer is not in ACFTA. The final dummy FTA is equal 1 if only importer is in ACFTA. FTA dummy variable is applied to measure free trade agreement effect in Hur, Alba, and Park (2010). Objectives of the paper are to answer two questions. The first question is the effect of FTA on trade by using dummy variable FTA as in Baier and Bergstrand (2007). The second question is the hub and spoke nature of FTA. Data covered 96 countries in the world in 40 years from 1960. By applying fixed effect panel data in estimation, the paper pointed out that the increase in export of countries which are in same free trade agreement.

In conclusion, indicator for Free Trade Agreement is the dummy variable taking value of 1 if two countries is in same FTA, otherwise, FTA equal to 0. The coefficient of FTA variable is expected to be positive

Income of exporting and importing countries

Aitken (1973) took the nominal GDP of exporting and importing countries as measurement of income concept in international trade. This indicator for income has been accepted by other empirical papers. Anderson and Wincoop (2003) chose the gross domestic production as a proxy for income of trading countries. The nominal gross domestic production also used in paper of Jugurnath, Stewart, and Brooks (2007). However, Baier and Bergstrand (2007) divided nominal GDP by the GDP deflator in order to obtain real GDP. There was no clear argument between choosing nominal GDP or real GDP as an indicator for income. In all mentioned papers, both income of exporting country and importing countries have been found to impact positively on the trade flow.

Distance

The development of information technology and transportation infrastructure has leaded to a decrease in transport cost between countries, yet the question arose is whether the distance effects on trade flow is important or not. Disdier and Head (2008) analyzed the distance effect on trading between two countries. The paper collected 1467 coefficients of distance on trade flow from the estimation of 103 papers, and then found out that the change in the value of distance elasticity of trade flow. The authors stated that the mean effect of distance is approximate 0.9 meaning that 10 percent increase in the distance of two countries; the trade value will decrease 9 percent.

Carrère and Schiff (2005) conducted a paper to answer for puzzle in distance of trade. In the paper, the authors decomposed the components of transport cost into non-distance trade cost whose costs do not related to distance of goods export, and distance cost. By analyzing the transport cost of data from 150 countries between 1962 and 2000, Carrere and Schiff (2005) stated that the decision on how much to trade to foreign countries locating at varied distance depends on the combination of non-distance cost and distance cost. Although the paper did not solve which costs can be dominance factors, the measurement showed that the distance's role in trade is rose throughout the period.)

Relating to measure distance variable in empirical study, Baier and Bergstrand (2007) measured the distance variable by the distance between economic center of countries, while Yang and Martinez-Zarzoso (2014) estimate the distance variable by calculating the great circle distance from capital of exporting countries to capital of importing countries. In both papers, the expected impact of distance on trade flow is negative.

Exchange rate

The role of exchange rate in international trade is an ongoing argument within empirical studies. Rose and Wincoop (2001) did a research on the effect of currency union on European countries on the trade flow. The paper used Economic and Monetary Union (EMU) as an indicator for no exchange rate volatility in international trade. In the paper, if the EMU impacts positively on the trade flow of member countries, the exchange rate volatility has negative relationship on export and import value. By using data on trade of 200 countries from 1970 to 1995, the paper applied gravity model adding EMU dummies variable for estimation. The result indicated that the trade between EMU countries is higher than those without in EMU. In detail, EMU increased trade within European countries approximately 250% to 400%. Rose and Wincoop (2001) posed the importance of currency barrier in trade flow. McKenzie (2002) conducted a paper reviewing previous researches on the risk of exchange rate's effect to trade. The papers also found out the conclusion supporting Rose and Wincoop (2001); the result is that exchange rate volatility impact negatively on international trade, yet the degree of impact varying among the paper. The explanation for this problem came from the issue in measuring exchange rate volatility. There are many techniques to calculate the value of the fluctuation in exchange rate between countries; however, the author suggested that the application of Autoregressive Conditional Heterogeneity (ARCH) can produce the efficient and consistent result of exchange rate volatility. Recently, Al-Rashidi and Lahiri (2013) used heterogeneous firm-selection model to estimate that relationship. The argument of this model is that it can solve the problem selection bias and asymmetric trade occurring in other models. The impact of exchange rate change seems to be lower in model without correcting the selection bias and asymmetric trade than in model with those problems. Finally, the result of paper pointed out that exchange rate volatility coefficient in model is statistically significant

4 Analytical specifications

The study will apply the gravity model considered the powerful one in analyzing trade policies in order to estimate the coefficients between trade flow and FTA (Anderson & vanWincoop, 2003; Baier & Bergstrand, 2007; Silva & Tenreyro, 2006; Baier & Bergstrand, 2009; Zarzoso, 2013; Head & Mayer. 2013). The functional form is as follow:

$$\log(X_{vjt}) = \beta_0 + \beta_1 \log(GDP_{vjt}) + \beta_2 \log(DIST_{vt}) + \beta_3 FTA_{vjt} + \beta_4 \log(REER_{vjt}) + \beta_5 ERV_{jt} + \beta_6 REV_{vt} + u_{vjt}$$

Where LnX_{vjt} is natural logarithm of trade flow between Vietnam and country j in year t; $Log(GDP_{vjt})$ is natural logarithm of product of Vietnam and partner GDP share to world GDP in year t; $Log(DIST_{vt})$ is the natural logarithm of distance between Vietnam and country j; FTA_{vjt} is the dummy variable take value of 1 if Vietnam and country j is in the same FTA in year t; $REER_{vjt}$ is the real effective exchange rate in year t of Vietnam and country j; ERV_{vt}, ERV_{jt} is the real effective exchange rate volatility of Vietnam and country j in year t, respectively.

However, there are nearly 50 percent values of total trade in data equal to zero, so they will be ignored from the model. However, the omitted variable may create sample selection bias, thus the study will apply PPML model, Sample Selection Model and Fixed-Effect model with adding one in trade value as following table:

Table 1

Estimation models

Model	Model Specification	Estimation Method
Log linear Functional form		
4.9	$\log(X^*_{vjt} + t) = \beta_0 + \beta_1 \log(GDP_{vjt}) + \beta_2 \log\left(DIST_{vt}\right) + \beta_3 FTA_{vjt} + \beta_4 \log(REER_{vjt}) + \beta_5 ERV_{jt} + \beta_6 REV_{vt} + u_{vjt}$	Fixed Effect Model;
4.11	$\log(X_{vjt}) = \beta_0 + \beta_1 \log(GDP_{vjt}) + \beta_2 \log(DIST_{vt}) + \beta_3 FTA_{vjt} + \beta_4 \log(REER_{vjt}) + \beta_5 ERV_{jt} + \beta_6 REV_{vt} + u_{vjt}$	Sample selection model.
Multiplicative Functional Form		
4.5	$X_{ijt} = e^{(\beta_0 + \beta_1 \log(GDP_{vjt}) + \beta_2 \log(DIST_{vt}) + \beta_3 FTA_{vjt} + \beta_4 \log(REER_{vjt}) + \beta_5 ERVVN_{vt} +}$	Poisson Pseudo Maximum Likelihood

5 Data

The study uses panel data set of 185 countries including Vietnam from 1990 to 2012 at the country level. The export value is collected from database of International Direction of Trade Statistics. GDP data is in real values, based year in 2005, and provided by World Bank Indicator. The data on distance come from CEPII database. Real effective exchange rate is compiled from Bruegel database. The volatility of real effective exchange rate is calculated by the author. (See Appendix A1, A2 for details)

6 Empirical results and discussion

6.1 Fixed Effect Model

Table 6-1 shows the results of log-form gravity model using fixed effect in panel data. The heteroscedasticity is claimed to be a problem in the model, so regressions use white heteroscedasticity consistent covariance matrix by the robust option in STATA after all regressions to cope with the problem; hence, the standard error is now robust standard error. All models in the table use time fixed effect and country-paired fixed effect, so log of distance is omitted from model due to time-invariant value. However, it is expected that the fixed-effect techniques will control the time-invariant unobserved factors, country-pair unobserved factors; yet, the time-varying unobserved factors cannot be controlled completely from the model.

In Table 6-1, column (1A) is the estimation results from model (4.9) whose explanatory variables do not include Vietnam REER and Partner REER. As can be seen from the result, three independent variables' coefficients are statistical significance at 1% (FTA, Dummy variable for Asian Crisis, and Global Crisis) and FTA's coefficient is statistically significant at 10%; log of world share GDP's coefficient does not have statistical meaning while log of distance is omitted in FEM due to time-invariant value. For controlling factors, dummy variable for Asian Financial crisis 1997's coefficient is significantly positive; so, it seems unreasonable because Asian Financial Crisis 1997 affect South East Asian countries seriously. This problem put the question on the reliability of FEM in model (1A), so this will be compared with the results from Poisson Pseudo Maximum Likelihood model and sample selection model. While the coefficient for Global Crisis in 2008 is statistical significance, namely -1.040, this means the Global Crisis 2008 affected the export between Vietnam and other countries. The result is consistent with Levchenko, Lewis and Tesar (2010). The variable of interest FTA's coefficient is 1.367 which is consistent with the expectation that FTA will increase the export between Vietnam and its trading members. In details, on average, if Vietnam and trading partner is in the FTA, the total export will be merely 3.9 times ($e^{1.367}$) higher than the trade value between Vietnam and non-FTA trading partner, other factors are the same.

Relating to column (2A), after adding exchange rate volatility variables, the results do not change in term of coefficient's sign; the differences are the variable Log of World Share GDP is statistically-significant negative at 10%. FTA's coefficient is statistical significance at 1% in this column, and value is 3.517 which is higher than the one in column (1A), *ceteris paribus*. This indicates that if two countries are in FTA, the export value is average 33.68 times higher export value between Vietnam and non-FTA countries, *ceteris paribus.*

In conclusion, the results from FEM regressions with dependent variable are export plus one in Table 6-1 accepts the hypothesis that FTA will increase the trade flow between Vietnam and FTA-member trading countries. The coefficient in model (2A) is considerably higher than FTA's coefficient in model (1A); the results will be compared with estimation result of sample selection model and PPML model.

6.2 Sample Selection Model

Table 6-2 presents the regression results of Heckman sample selection model adjusted by Semykina and Wooldridge (2010) in panel data (column 1B, 2B, 3B and 4B). Column (1B) and (2B) are the models excluding the Real Effective Exchange Rate volatility (ERV), yet model in (2B) includes the interaction variables between inverse Mill ratio and time dummy variables. While column (3B) and (4B) are the models including Real Effective Exchange Rate volatility (ERV), yet model in (4B) accounts for the interaction variables between Inverse Mill Ratio and time dummy variables. The Wald test after each regression rejects the hypothesis that estimated coefficients of Mill ratio and interaction variables equal to zero in four models. Therefore, sample selection bias is a problem in model, and sample selection model is required to be applied (see Appendix 3 for details)

In general, four regressions are consistent in term of the sign of independent variable's impact on total export, yet the sample selection models with ERV provide higher-value results than those without ERV. As can be seen from the table, FTA impacts positively on the trade outflow of Vietnam. The level of improvement in trade between Vietnam and FTA members are about 3.55 times in column (1B), 3.84 times in column (2B), 6.16 times in column (3B), and 6.57 times in column (4B), *ceteris paribus*; all estimated coefficients are statistical significance at 1%. As a result, sample selection model does not reject the study' hypothesis. Relating to controlling variables, distance appears to have negative relationship with total bilateral trade. This is reasonable because the distance implies the variable trade cost. GDP of two countries effects positively on the trade outflow of Vietnam. Furthermore, estimated coefficients of Asian financial crisis 1997-1998 are negative and statistically significant in all four models. For the Crisis 2008, the sign of estimated coefficient in four models are negative, although it is only statistically significant for (1B) and (2B). In general, the crisis provoked unexpected consequences on the export between Vietnam and trading partners, in average and other conditions unchanged.

6.3 Multiplicative-Form Gravity Model

Table 6-3 provides the regression results for model with Possion Pseudo Maximum Likelihood estimation method. The dependent variable is export between Vietnam and trading partner (X_{vjt}). The column (1C) and (2C) contain the explanatory variables without real effective exchange rate volatility (ERV), and with ERV, respectively. In column (1C), FTA is not statistical significance, yet its sign is positive which is consistent with the hypothesis. FTA's coefficient value in column (2C) is 0.660, yet it is not statistically significant. Therefore, the PPML model may not accept the hypothesis of the study that FTA impact positively on the export of Vietnam. Relating to controlling variables, log of distance can be obtained from model (4.9) to interpret the effect of distance on trade flow. Its coefficient is negative and statistically significance at 1 percent in both regression (1C) and (2C). The results in model (1C) and (2C) are -0.77 and -0.69, respectively; the coefficients do not vary greatly after adding the ERV into model (2C). For interpreting, if the distance between Vietnam and trading partner increase 1 percent, the total trade value may decrease around 0.77 percent in column (1C) and 0.69 percent in column (2C). The World share GDP of two countries provide consistent result with Anderson & van Wincoop (2003) and Baier & Bergstrand (2007); the GDP of two countries relative to the world is greater, the more total trade value of country pair. The model can prove the statistically significant effect of crisis on trade outflow of Vietnam. In details, the sign is negative for Asian Financial Crisis 1997 and Global Crisis 2008 in both column (1C) and (2C). The impact of ERV on trade flow is ambiguous. Trading agents can be risk-averse so they will try to avoid doing business in countries with high fluctuation in exchange rate while others can be risk-loving agents to ready to trade with such countries (McKenzie, 2002). Therefore, the study does not analysis the results of real effective exchange rate and exchange rate volatility variables; and, they are used only for controlling the impact of FTA on trade value.

Note: Number in bracket is robust standard error;

, **, and * are statistical significance at 10%, 5%, and 1% respectively.*

In PPML estimators, the FTA has positive relationship with the export of Vietnam, and is consistent with those in FEM and sample selection model. However, the value of FTA's coefficient is lower than coefficients and statistically insignificant in other two methods. PPML can perform efficiently in the case of heteroscedasticity in data, yet it is claimed to be poorly estimating in the case of frequent zero-value in trade (Martin & Pham, 2008). This can be applied to the study' data where the zero value is account for nearly 50% in total observations. One indicator used to evaluate the bias in model is GDP's coefficient. Theoretically, the coefficient of GDP converge to unity (Anderson & van Wincoop, 2003); and Martin and Pham (2008) stated that if GDP's coefficient is lower greatly than one, model may be underestimated or downward biased. Looking at the coefficient of log World Share GDP in PPML model, it is significant lower than one, so it may indicate that FTA coefficient in model is downward bias. Applying to FEM models, the log World Share GDP's coefficient is considerably greater than one, so the FTA is upward biased. That may be one reason for the high value of FTA coefficients in FEM in compare to those in sample selection model and PPML model. Turning to the sample selection model, the value of log of World Share GDP's coefficient is nearly equal to one. This may subjectively assert that sample selection model is better than other model (Linder & Groots, 2006; Helpman, Melitz, and Rubinstein, 2008). Furthermore, sample selection models solve the problem of zero value trade in data. The model judges zero-trade value as non-random value and come from the decision of other factor such exporter and importer while PPML and FEM do not judge zero-trade in such way.

7 Conclusion

Empirical results from three above estimation models prove the positive relationship between FTA and Vietnam's export consistently. After joining the FTA, the trade between Vietnam and its FTA-member partner from 3.9 times to 33 times in FEM, 3.5 times to 6.5 times in sample selection model. In the descriptive statistics in Chapter 4, the impact of FTA is clearly observed in case of AFTA and ACFTA. Because the FTA is signed in 1995 and 2002, respectively, FTA impact can be seen obviously. Other FTAs is signed from 2009, so FTA's results cannot be observed in reported period. However, the results from descriptive statistics are consistent with empirical results because they do not reject the hypothesis that FTA impact positively on trade flow of goods. The reason for why FTA improves the trade flow between member countries can be attribute to the elimination in the tariffs and other trade-facilitate conditions. In details, FTA members have to follow the schedule in reducing import and export tariff which is accord by all members which is discussed in chapter 3. The tax reduction will help to reduce the trade cost substantially. The other condition is the integration in transit infrastructure and other custom obligation. One more reason for the positive impact on trade of FTA can be attributed to the "natural FTA" (Krugman, 1995). Natural FTA is terminology for the FTA between countries have advantage on geography (neighboring country, short distance), culture. The author stated that if natural FTA is established, it will impact positively on trade flow and welfare of members. Turning to Vietnam FTAs, most of them are with ASEAN countries, which can become the "natural FTA".

Study results prove the important role of free trade agreement on the trade outflow of Vietnam. Although the level of improvement in trade flow does not strongly confirm in the study due to its limitations, the positive effect of free trade agreement is clearly shown from the regression results based on previous empirical papers. The government may consider the free trade agreement as a policy for trade openness and export development. However, the study does not applied to sub sectors in the economy, so it should be a noticeable to deep analysis in the impact of FTA in specific sector which the policy aims for. The other implication come from the study results is the impact of the controlling variable. The distance variable indicates that Vietnam is less likely to trade with countries are in greater distance than the shorter ones. The trade will increase when the GDP of two countries are higher in relative to world GDP. The controlling variables help the government to decide in choosing trading partners.

8 Limitation and Further Research

Firstly, gravity model is "work horse" tool in estimating ex-post relationship between trade policy and trade flow, yet in order to estimate the ex-ante effect of FTA on trade flow of goods, the Computable General Equilibrium (CGE) is a recommended model (Hertel et al, 2007). CGE can help to anticipate the effect of FTA on Vietnam trade flow when the tax elimination fully in force in 2020-2027. Other limitation of gravity model is its functional form. The log- linear form and multiplicative form take account for non-negative observation. Thus, in the model, dependent variables are total bilateral trade, export value, or import value. Trade balance which is also important trade indicator cannot be included in the model due to its negative value. The time period in data does not capture the full impact of FTA on trade flow because the available of data is constrained at the time this study is done.

The study analyzes the aggregate data on trade flow, yet the disaggregate data also need to be taken account for because the effect of FTA will be difference depend on sectors in the industries. Trade flow is one of the points of view in judging the foreign trade policy. Other aspects are the welfare change (McCaig, 2011), the investment (Lakatos & Walmsley, 2012; Anderson, 2010) the labor wage (Fukase, 2013). Those aspects are beyond the copes of this study, and they can be a topic for future evaluation.

Appendix 3. Endogenous testing for FTA

FTA is argued to suffer the problem of endogeneity in the gravity model, yet the study does not agree with that belief for the case of Vietnam. It is the reason that FTA is tested whether it is endogenous variable or not by using the command ivreg2 and ivendog in STATA 13.0. The result is as follow

Table 5

Testing results for Interaction Terms in Sample Selection Model

H_0: Restricted model nested in non-restricted model	**Model: 1B and 2B**	**Model: 3B and 4B**
Chi-square	2.16	1.22
P-value	0.021	0.24
Accepted or Not Accepted H_0	**Not Accepted**	**Accepted**

Source: Constructed by the Author

The test accepts the null Hypothesis that FTA is exogenous.

Appendix 4. Testings in Sample Selection Model

1. Testing Results for Collinearity Problem in sample selection model

The study applies the command collin in STATA 13.0 to detect multi-collinearity problem in data. The testing will report the VIF (Variance Inflation Factor) and Condition Number. After testing, the mean VIF is 1.86 which is lower 10 and the condition number 4.5918, so the multi-collinearity is not a problem in the study. Relating to the reliability of four models, all models in the table do not contain excluded restriction variable in selection equation, so the models are argued to be vulnerable if there are the collinearity between inverse Mill's ratio and other regressors. As mentioned in Chapter 3, the collinearity is checked by calculating formula proposed by Madden (2008). The result is illustrated by following table.

Table 6

Testing Results for Collinearity Problem in sample selection model

Mean VIF	**Condition number**
2.03	4.80

Source: Constructed by the Author

The condition number is less than 20 which is the threshold for concerning collinearity problem in Sample selection (Leung &Yu, 2000), so the inverse Mill's ratio does not encounter the collinearity problem with other regressors.

2. Testing results for Interaction Terms in Sample Selection Model

Turning to test for choosing between model with interaction terms and without interaction terms, the study considers the model without interaction terms as restricted models, and model with interaction terms as non-restricted models. Thus, there are two pair of model for judgment (1B and 2B; 3B and 4B). The Wald-test will be applied for testing. The results are indicated in following table

Table 8

Testing results for Interaction Terms in Sample Selection Model

H_0: Restricted model nested in non-restricted model	**Model: 1B and 2B**	**Model: 3B and 4B**
Chi-square	2.16	1.22
P-value	0.021	0.24
Accepted or Not Accepted H_0	**Not Accepted**	**Accepted**

Source: Constructed by the Author

Between model in 1B and 2B, Wald test rejected the Null Hypothesis, so adding interaction terms in model 2B is worthy, and more preferable than in restricted model 1B. Between model in 3B and 4B, Wald test accepted the Null Hypothesis, so it does not required to add interaction term in model 4B, or restricted model is still reliable.

Appendix 5: Exchange Rate Calculation

There are two type of exchange rate applied in the study for analyzing the relationship between exchange rate and trade: real effective exchange rate (REER) and exchange rate volatility (ERV)

Real Effective Exchange Rate index (REERvjt, REERjt)

The study will use real effective exchange rate index (REER) as a proxy for controlling the impact of exchange rate on trade flow between Vietnam and her partner. REER is obtained from Nominal Effective Exchange Rate (NEER) deflated by the relative price between calculating country and its trading partners. It is consider as the measurement of the change of domestic currency in response to bundle of trading partners.

Based on Darva (2012), REER calculated as following formula

$$REER_t^d = NEER_t^d \frac{CPI_t^d}{CPI_t^f} \tag{3.9}$$

Where $REER_t^d$ is the real effective exchange rate of domestic country in year t

$NEER_t^d$ is the nominal real effective exchange rate of domestic country in year t, calculated as $NEER_t^d = \prod_{i=1}^{n} S(i)_t^{w(i)}$, $S(i)_t$ is the nominal bilateral exchange rate between domestic country and its trading partner i with the weighted w^i, n is the total trading partners.

CPI_t^d is the consumer price index of domestic country in year t

CPI_t^f is the consumer price index of trading partners weighted geometrically, calculated as $CPI_t^f = \prod_{i=1}^{n} CPI(i)_t^{w(i)}$, $CPI(i)_t$ is the consumer price index of partner i in year t

Exchange Rate Volatility

Besides of REER index, the exchange rate volatility (ERV) also impacts on the trade of country (Bahmani-Oskooee & Hegerty, 2009; McKenzie, 2002). The reason is that the uncertainty in exchange rate will distort the behavior of risk-aversion exporters. Exporters may not enter the market whose exchange rate is not stable because of the risk in future payments.

The study will use the ERV as a proxy for controlling the effect of currency-related risk on export and import value. From McKenzie (2002), and Tenreyro (2007), the ERV will be calculated by the standard deviation of percentage change in monthly real effective exchange rate, formulated as

$$ERV_{it} = \sqrt{Var(\ln REER_{i,tm} - \ln REER_{i,t(m-1)})_{\{m=1\to 12\}}} \quad (4.9)$$

where ERV_{it} is the exchange rate volatility of country i in year t

$REER_{i,tm}$ is the real effective exchange rate of month m in year t of country i.

Relating to use nominal effective exchange rate or real effective exchange rate, McKenzie (2002) pointed out that there is no different in estimation results in applying REER or NEER. Therefore, the study can use the real effective exchange rate because there is available and consistent with the REER index variable used in study

There are arguments in the effect of ERV on trade flow. Bahmani-Oskooee & Hegerty (2009) find out the negative relationship between ERV and trade flow of Mexico and United States of America; Bahmani-Oskooee and Xu (2013) analyzed the short run and long run impact of ERV on trade between Hong Kong and United States of America, the results are negative. However, Tenreyro (2007) applied instrument variable in observation the ERV and trade flow changes from 1970 to 1997. The authors did not found significant result in the relationship. McKenzie (2002) mentioned that the relationship of ERV and international trade is in arguments, and may depend on specific data and measurement of ERV.

Determinants of Accessibility to Microcredit in Terms of the Formal and Informal Sectors

Microcredit is an emerging concept helping the poor out of poverty situation. This paper attempts to investigate the determinants affecting the probability of participation in different types of credit sectors in terms of formal sector and informal sector. Using a sample size of 1,522 households participate in credit market from The Vietnam Access to Resources Household Survey (VARHS) 2012; bivariate probit model is employed to explore the determinants of household credit demand due to the binary nature of the dependent variables. Various explanatory variables include age, gender, marital_stt, edu, hhsize, income, savingamount, landsize, agriculture_act, network and location that influence probability of accessibility to different sectors of credit. Furthermore, relationship between dependent variables is accounted in this research. Results reveal that factors affecting formal credit participation are different from factors affecting informal credit participation. Additionally, the result indicates that there is negative correlation across two sectors of credit.

INTRODUCTION

There are about 1.22 billion people (21 percent of population) in the world living on less than $1.25 a day in 2010 (World Bank). Focusing towards poverty reduction and finding ways to improve living condition have taken a lot of attention of public policies in the world. The rate of poverty in Vietnam decreases remarkably in recent years. According to annual report shown by GSO, the poverty rate declined from 15.5 percent in 2006, to 13.4 percent in 2008, to 10.7 percent in 2010. In a report of GSO in 2010, it also revealed that poverty level in rural area (13.2 percent) is much higher compared to that in urban area (5.1 percent). How to distribute the benefits of economics growth, especially to rural area is one of the challenges remained. Therefore, rural economy deserves more attention and support to reduce inequality between rural and urban area. Providing a channel to ease the credit constraints for the poor rural household is the primary object in poverty alleviation strategy of developing countries, including Vietnam.

Despite the importance of credit to the poor, the poor family that lacks ability to access to adequate financial service leads to the fact that they do not have prospects for increasing their productivity and living standard. Robinson (2001) and Gonzalez Vega (2003) indicated that most of microfinance institutions have been not sustainable in developing countries. Credit subsidized interest rate provided by "Agricultural development banks" which established by commercial banks to extend credit to rural household not considered creditworthy. However, majority of these credit programs have failed to reach their targets both to be sustainable credit providers and serve the poor (Adams, Graham, and von Pischke 1984; Adams and Vogel 1986; Braverman and Guasch 1986).

Risk management and transaction costs associated with Asymmetric information are the most problematic features facing by lenders and borrowers (Pham & Lensinnk, 2007). It is also well know that different forms of credit market serve different group of borrowers, it is difficult for large number of poor households to access to credit sources. Households often face limited access to credit because of rationing of credit demand that leads to the poor and low income households are generally excluded from the formal credit sector (Stiglitz & Weiss, 1981). In fact that formal provider, semi-formal provider and informal provider exist side by side in Vietnamese financial market. To deal the level of information asymmetry between borrowers and different lenders; many government microcredit programs are accompanied by the local Peoples Committees in terms of lending process to assist microcredit market operation.

In respect of this, narrowing gaps in term of whom it serves and the service it provides, improving the efficiency and effectiveness of microfinance system is the main challenge of policy makers as well as program organizers.

With data collected from The Vietnam Access to Resources Household Survey 2012 (VARHS), econometrics techniques are employed in this research to explore the factors that affect access to credit in terms of formal credit and informal credit.

LITERATURE REVIEW

This section presents the overview of theory and discusses previous studies relate to the research topic.

Concept of credit

There are several and various definitions regarding the word credit as follows:

Credits are referred as loans that permit consuming in the present, in exchange for an agreement to make repayment at sometimes in the future (Pischie et al., 1983).

Obtaining credit was considered as the process of controlling over the use of money, goods and services based upon a promise to repay at a future day (Adegeye & Dittoh, 1985).

Ololade & Ologunju (2013) defined credit as a mean for temporary transfer of assets to individuals or organizations that has not them from individuals or organizations that has. This process requires evidences of debt obligation in return for a loan, in the case of transaction between friends or relative that based on good relationship excluded.

Microcredit that is a component of microfinance provides small loan to the poor for self –employment. That generates income, helping them care for themselves and their family (The Microcredit Summit, 1997).

To raise income level and improve living standard of semi-urban and urban areas are considered as targets of microcredit by providing of thrift, credit, other financial services and products of every small amount to the rural household (Reserve Bank of India- Master Circular, 2011).

Theory of demand for credit

According to life circle model (Franco Modigliani, 1966), individuals cannot maintain consumption at an acceptable level when the size of family changed withuncertainties of future. To maximize time life utility, income should be reallocated inter-temporally (Morduch, 1995a). Consumers can afford their purchases by using saving from past or present income or by accessing to credit funds which help borrowers to make inter-temporal choice. By borrowing money, borrowers have additional spending power in the present and duty to pay loan and interest rate in the future in exchange (Soman & cheema, 2002).

The inter-temporal model of life circle hypothesis and permanent hypothesis that explain the consumption behavior of individuals were also discussed by Modigliani in1986. It is assumed that borrower have opportunity to borrow in perfect market in Modigliani's model.

In model of Chen and Chiivakul (2008), current household‘s consumption level not only depends on the current income but also depends on household's life time characteristics (behaviors of household on participation in credit market). Additionally, it is argued that current consumption depends on expected consumption in the future period (consumers firstly estimate their ability to afford consumption in long run) which depends on their saving or demand for loan (Hall, 1978).

Moreover, in Cobb Douglas function: $Y = AL^{\alpha}K^{\beta}$, capital is viewed as a production input factor, accessible and affordable inputs; profit from production depends on labor (L) and capital (K) with given technology (Zellne at al., 1966). Cobb Douglas showed how two factors (Capital and Labor) effect on production function and how income distribution is effected by production output (Felipe and Adams, 2005). This capital can be provided by a variety of credit sources at different interest rates (cost of capital).

Determinants of participation in microcredit programs

When income and wealth to increase purchase are insufficient, households borrow money as a way to finance their consumption (Kirchler et al., 2008). There are two stages in process of getting loan. First, the households who demand credit apply for a certain amount of loan for a type of credit sector which they want to borrow from. Second, the providers choose which applicants are met requirements for loan based on household's information and availabilities of the lenders.

However, in this analysis, I focus on demand side's characteristics to consider the probability of access to credit. The determinants of microcredit participation include age, gender, marital_stt, edu, hhsize, income, savingamount, landsize, agriculture_act, network and location.

Age

According to the life circle hypothesis, the age is negative relationship with the decision to get loan. It is also confirmed in research of M. Ajugam and C. Ramasamy (2007). Similarly, Okurut (2006) and Mohamed (2003) pointed out that the possibility to access to credit resources decrease when they get older. Younger persons more likely to borrow than the elderly because of elements of personal risk level (Fabbri and Padula, 2004; Zeller, 1994; Magri, 2002; Abdul- Muhmin, 2008; Del- Rio and

Young, 2005); additionally, the young tend to spend more on a variety of activities while the old maybe less (Mpuga, 2008).

In contrast, some studies showed accessibility to credit positively related to age. For example, Tinh (2010) demonstrated that age of household head has a significant positive relationship with getting a loan. It was also proven in research in 2010 of Tang et al.

Gender of household's head

Banerjee et al. (2010) Bruno and Cre1pon et al. (2011) prove that there are a majority proportion of male borrowers from the microcredit programmes. Moreover, Nwaru (2011) and Bendig et al (2009) also proven that demanding in loan negatively related with being female.

However, contrary to mentioned studies, Owuor George (2009) stated that being a female headed household increases probability of joining financial activities.

Marital status

A vast of previous studies showed that married individuals are likely to get loans than unmarried individuals because of the level of needs (Kamleitneir and Kirchler, 2007; Bridges et al., 2004; Chen and Jensen, 1985; Duca and Rosenthal, 1994; Magri, 2002). Similarly, in a research by Kenya National Fin Access (2009) indicated that the probability of credit program participation is the highest with married persons. It is explained that there is difficult to access to credit for single household due to lack of social network (Ferede, 2012).

Level of household head's education

Education was an important factor that influences the probability of accessibility of microcredit programmes (Tang et al., 2010). Quach (2005) demonstrated that education level had a positive relationship with demanding in loan. Moreover, education level was founded as a determinant that fosters the accessibility to microcredit programme thanks to their awareness of financial market system (Yehuala, 2008; Okunade; 2007; Vaessen, 2001; and Okunade, 2007).

On the other hand, Khandker (2001) and Khandker (2005) demonstrated that higher education level of household head would less likely to borrow from microcredit program. Similar to Khandker's finding, Cuong H. Nguyen's research (2007) also proves that household head with higher education has lower chance of accessibility to credit sector in Vietnam which composed of high proportion of borrowers with education level at primary and lower secondary school.

It is interesting that the impact of this variable on various source of credits are different. Bendig et al. (2009) stated that better educated individuala tend to access to formal financial sector. Moreover, there was an inverse relationship between education and informal loan.

Household size

The ideas of relationship between household size and accessibility of credit are different from studies to studies.

Schreiner & Nagarajan (1998), Vaessen (2001), Ho (2004) and Quach (2005) indicates that the number of members in a family were significantly positive relationship with household borrowing. It is explained that more loans are demanded by large-size household or that more credits are allocated to household with more members. That idea was the same in research in the case of Nguyen (2007) and Tinh Doan (2010).

In contrast, Bendig at al. (2009) argued that household size has negative impact on probability to credit in a research of demand for financial service. This is due to the assumption that there are more dependent members including children and elderly people who would consume a large share of income in their family and had higher risk of default (Tang et al., 2010).

However, household size did not effect on getting loan in Greece (Mitrakos and Simiyiannis, 2009).

Household's income

Income is the most common measurement used to define the poor (The World Bank); hence, household with high income is not considered as the poor whereas the primary target of microcredit is to provide credit to the poor who will provided credit to increase income (World Bank, 2010). Therefore, applicants with higher income have lower chance to get loan. This idea was proven in the research by Pham & Lensink (2007) and Li et al. (2011) that household's income negative correlation with probability of participation in credit program including microcredit. It is also explained that marginal utility of consumption of poor household is high, leading to more demand for credit of the poor (Ferede, 2012).

In contrast, many researches argued that high-income household more likely access to loan than low-income household (Crrok, 2001; Lin and Yang, 2005; Jappelli and Pistaferri, 2007). The reason for that is due to assumption that high-income households hold mortgage (Ambrose et al., 2004).

Saving amount

Saving amount is identified as collateral to reduce adverse selection and moral hazard arising from lending process between lenders and borrowers. Compared to others, saving amount is more liquidity. Therefore, applicants with bigger saving amount have more opportunities for accessing credit sector. It means that relationship between household saving and possibility to lend credit is positive.

However, total saving is considered as a determinant of household's demand for credit; hence, saving amount is negatively related to probability to approach credit sector (Tang et al., 2010). It is explained that households with larger saving amount tend to borrow less because they have money for affording their spending at acceptant level, they are non-poor.

Land size

For household's characteristics, Phan (2012) found that land ownership had negatively significant relationship with demand for credit. It was similar to finding by Phan (2012). Quach (2005) also pointed that household which own more land tended to borrow less than those with smaller land size. The reason is that household with more land is considered as non-poor household who less demand for loan; therefore, there is a little of credit is allocated to them. Moreover, Khandker (2001) and Khandker (2005) proved that there was an inverse relationship between land own and probability of accessibility to microcredit sectors. It is also appropriate in the case of Vietnam (Cuong H. Nguyen, 2007 and Duong Pham, 2002).

In contrast, finding by Okurut (2006) revealed that land endowment has a positive correlation with household's probability to borrow credit. Land title may be considered as collateral for household's borrowing, so it is easier for household with bigger land size to get loan from formal sector (Sai et al, 2010). This result is in the line with the finding by Vu (2002) and Zeller (2001) that Land is the most important variable to measure the household's ability to get credit, especially credit from formal sector. Additionally, some empirical research states that households with large own land scale which is the basic source of livelihood of the farmer demands for more credit in order to run production activities (Mohamed, 2003; Ravi, 2003 and Davis et al., 1998; Svay et al, 2006).

Social network

Relationship between probability of accessibility to credit and social capital has been a controversial issue. A vast of literature has revealed that social capital play a crucial role in credit accessibility, particularly in developing countries (Okten and Osili, 2004; Fafchamps, 2000). Social network is considered as social collateral in order to obtain credit and there is a strong positive relationship between social collateral and credit borrowing shown (Karlan et al, 2009). Bui (2010) also indicated that social capital also play an important factor on credit ration. This result is consistent with the finding by Grootaert (1999) that social capital has positively influence for accessing to credit. Additionally, borrowers rely on social network to lower uncertain information lead to a better flow of information between lenders and borrowers, so demand for credit increase (Thierry, 2000). Considering the role of social network on credit obtaining, it is expected that social capital is a determinant of credit transaction.

Different from previous result, some indicates that social network does not guarantee poor households participate in rural credit (World Bank, 2000).

The objective of this research is to find out the effect of social network not only on overall credit but also on types of credit, informal sector and formal sector.

Location

The main objective of rural credit is to help the rural poor household out of poverty situation, so it is assumed that households in rural area have higher probability to get credit compared to that located in urban area.

However, Consultative Grove to Assist the Poor (CGAP) demonstrated that the probability of accessibility to credit source in rural area is probably significant lower than in urban area. Microfinance for rural areas is not sustainably provide financial services for rural populations; only densely populated areas benefit from a widespread microfinance services. Therefore, households in remote area have less chance to access to credit services. This might be due to opportunity costs of time spending, transaction costs to travel to financial institutions and deficiencies in communication with lenders because of long distance (Zeller & Sharma, 2000). This negative relationship between location and demand for credit supported the result of research by Balogun and Yusuf (2011).

In this research, I examine how location variable does affect the possibility to approach credit source of household.

Rural activities

One target of microcredit is to help the poor on rural farming activities. Therefore, it is assumed that households have more probability of accessibility to rural credit if the households take part in rural activities.

OVERVIEW OF MICROFINANCE SYSTEM

Like other countries, credit system of Vietnam comes from three main sectors including formal, semi-formal and informal sector (Meyer and Nagarajan, 1992). The coexistence of formal sector, informal sector and semi-formal financial sector not only provide greater credit source for the poor but also create greater competition among different credit suppliers in rural credit market. There are different in term of interest rate and lending practices between formal sector, semi-formal sector and informal sector (Pham and Lensink, 2007) .

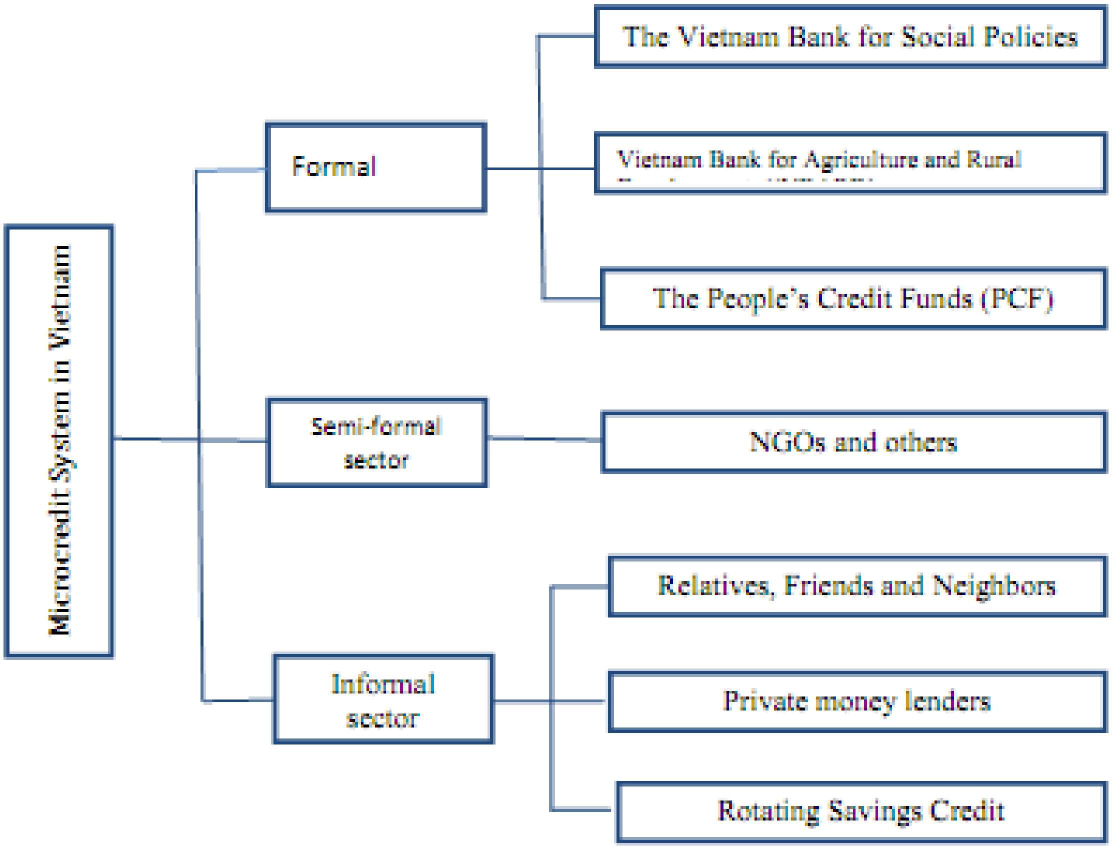

Figure 3.1 Microfinance Systems in Vietnam

The formal credit market

According to World Bank (2002), the formal sector is composed of Vietnam Bank for Social Policy (VBSP), Vietnam Bank for Agriculture and Rural Development (VBARD) that are state owned organizations, and the People Credit Funds (PCF). It was also reported by World Bank (2002) that lending by formal sector is accounted for 73.5% of total lending. Formal sector aims at covering the overall rural credit market. The main strength of this form is that it has a wide network with good connection to Local People Committee which plays an important role in financial system of Vietnam. However, its operation falls in short of achieving the defined objectives (Phan, 2012).

The Vietnam Bank for Social Policies (VBSP)

The Vietnam Bank for the Poor (VBP) was organized in 1995, and it was official renamed to The Vietnam Bank for Social Policies (VBSP) under Premier's Decision No.131/2002QD-TTg date October 4th, 2002 and the government's Decree No. 78/NP-CP dated October 4^{th}, 2002 for the poor. VBSP in the second largest state-owned Vietnam bank established is for the poor and other policy beneficiaries. It operates as an efficient tool helping Vietnam government to fight against poverty by providing low interest rate with formal collateral and accessible financial services to the poor households to reduce the gap that has emerged and to alleviate poverty (Izumida, 2003). VBSP functions under State Bank of Vietnam's supervision and granted by Vietnamese Government. In theory, serving the low income households to obtain credit is the target of VBSP; but in practice, it failed to provide service to the poor. In 2001, only half of VBSP clients served was listed as poor households.

The most quickly method is applied to delivery loans to the poor via four mass organizations namely: War veteran Union of Vietnam, Framer Union of Vietnam, Youth Union of Vietnam and Women of Vietnam. Their responsibilities are establishing saving and credit group; certifying poor households and supervising

The semi-formal credit market

Semi-formal credit sector contains Women's Union, Farmer's Association, Youth Union….or non-governmental organizations (NGOs) financial program are funded by international and national donor (Phan, 2012). Although semi-formal credit funds do not have nationwide network, they have a variety advantages as compared with formal lenders that serve the poor as targeted customers by providing subsidized credit. Additionally, semi-formal such as NGOs are recognized as the best channel providing credit, especially in group lending and social intermediation to help the poor thanks to experiences taken from abroad (Dao,2002; McCarty,2001). Moreover, semi-formal sector is considered as an important channel of many international programs for combat poverty (World Bank, 2000, p.110).

The informal credit market

Informal financial system consists of relatives, friends, neighbor, unregistered private money lenders, traders and rotating savings and credit associations (ROSCAs) (Quach, 2005).

Table 1 below summarizes the main differences between informal credit sector and formal credit sector.

Table 1 Comparison between formal and informal lenders

	Formal sector	**Informal sector**
Clients Targets	Poor household	Poor households
Administrative procedure	Complex procedure	Simple procedure
Collateral	Collaterals such as land use certificate, saving account and so on are required	Basing on trust and personal relationship between borrowers and lenders
Interest rate	Low	High
Loan size	Large	Small
Repayment rate	Low	High

The estimations of unconditional and conditional for rural credit resources are calculated from Table 2 are presented in Table 3.

Table 3 Conditional and Unconditional Credit Participation Probabilities

	Formal	Semi-formal	Informal
Prob(*)	67.61	8.55	46.39
Prob(*|F=1)	100.00	4.87	27.30
Prob(*|SF=1)	38.48	100.00	29.24
Prob(*|IF=1)	39.79	5.39	100.00
Prob(*|F=1,SF=1)	100.00	100.00	51.98
Prob(*|SF=1,IF=1)	68.40	100.00	100.00
Prob(*|F=1,IF=1)	100.00	9.26	100.00

Source: Author's calculation

The marginal probability of semi-formal sector is the lowest among three sectors with 8.55 percent of the sample. On the other hand, the marginal probability of formal sector is the highest among all type of combinaton with 67.61percent and that of observing informal sector is 46.39 percent. The probability of combination which contains three sectors at one is at the rate of 1.17 percent only.

Additionally, the likely correlations across the threes sector are also shown. For example, whereas 67.61 percent of sample takes part in formal credit, the probability of a household will be a lender from formal resource within the semi-formal participation and informal participation are lower at 38.48 percent and 39.79 percent respectively. Similarly, the percentage of a household participating in semi-formal credit sector or informal credit sector will be lower if they are a participant of any other credit sector. This mean that the probability of any sector participation decreased if there an existence of others. In other words, there is a relationship between different choices for credit participation.

All variables in this are defined in the Table 4.

Table 4 Definition of Variables

Variables	Type	Explanation
Age	Continuous	Age measures the age of household' head and it is performed over 18 years old
Gender	Binary	Gender is sex of household head. This is dummy variable which takes a value one if the household head is female and zero if the household head is male
marital_stt	Binary	Marital status is divided into two categories including married if the household head is married and single otherwise. Marital status would be coded as 1 for married, and 0 for single.
Edu	Continuous	Edu is education level of household head. It is measured by number of schooling year of household head attending.
Hhsize	Continuous	Household size is considered as the number of member in family.
Income	Continuous	Income is the total income of household (1,000,000 VND).
Savingamount	Continuous	It is measured in 1,000,000 VND.
Landsize	Continuous	Landsize is is the size of land owning by household. It is measured in 1,000 m^2.
agriculture_act	Binary	1- Household takes part in agricultural activities 0- Otherwise
Network	Binary	Network variable is zero-one dummy variable; with the value of 1 if the household is member of any Association/ Union/Cooperative/Group/Political Party, 0 otherwise.
Location	Binary	1- household is located in rural area 0- other wise

Summary statistics for all explanatory variables are given in the Table 5.

Table 5 Summary statistics

Variables	Mean	Std. Dev.	Min	Max
Age	47.13	12.38	18	93
Gender	0.84	0.37	0	1
Marital_stt	0.86	0.35	0	1
Edu	8.34	3.23	1	13
Hhsize	5.75	3.42	1	25
Income	88.23	157.53	2.01	4,500.00
Savingamount	22.42	58.27	0	820
Landsize	10.99	16.3	0.04	181.2

Data Analysis Method

It is easy to see that household participating in semi-formal credit sector accounting for only about 10 percent of the total number of household in sample; so the effect of lending from semi-formal credit sector on lending from other sectors is small. Therefore, this research investigates the determinants of accessibility to formal and informal sector as well as the relationship between two types of credit sectors namely formal sector and informal sector only.

There may be a relationship between household's choices for different credit sectors and use of any credit form is not exclusive; hence, there are possible that households use more than one credit sectors. Therefore, equations of probit for sectors participation estimated separately that seems an inefficient approach since that method ignores the relationship between error terms.

Both multivariate probit regression model and multinominal logit regression model can estimate the influence of independent observations on different categories of dependent observations with unordered multiple choices (Gbetibouo,2009). However, it seems that the former is preferred to the latter because it stimulates the effect of a set of explanatory variables on different choices as well as the relationship between these decisions at the same time.

In this case, there are two dependent variables including formal sector participation and informal sector participation; it is assumed that two dependent observations are correlated in bivariate probit model. I develop two binary variables denoting two types of credit provider including formal lender (F), and informal lender (IF) to test which factors impact on decision of access to each of credit sector.

There are two equations for this estimation and each equation is a binary choice model; for simplicity, same explanatory variables are employed in estimation which is given as below:

$$F^{*} = \beta_F X' + \varepsilon_F$$

$$IF^{*} = \beta_{IF} X' + \varepsilon_{IF}$$

In which:

X' presents for explanatory variables including age, gender, marital_stt, edu, hhsize, income, savingamount, landsize, agriculture_act, network and location.

F^{*}, IF^{*} are latent variables for the participation in formal credit sector and informal credit sector

F and IF which received value of 1 if these respective latent variable are greater than 0 and zero otherwise

$F = 1$ if $F^* > 0$ and 0 otherwise

$IF = 1$ if $IF^* > 0$ and 0 otherwise

$\varepsilon_{F,}\ \varepsilon_{IF}$ are error terms which follow multivariate normal distribution with a mean of zero and covariance equal to 1 because magnitude of the variance for the error term can't be identified for each probit estimation (Greene, 2003).

In which:

$$E(\varepsilon_F) = E(\varepsilon_{IF}) = 0$$

$$Var(\varepsilon_F) = Var(\varepsilon_{IF}) = 1$$

$$Cov(\varepsilon_{F,}\ \varepsilon_{IF}) = \rho = \rho_{F,IF} = \rho_{IF,F}$$

$$\begin{pmatrix} \varepsilon_F \\ \varepsilon_{IF} \end{pmatrix} \sim N\left[\begin{pmatrix} 0 \\ 0 \end{pmatrix} \quad \begin{pmatrix} 1 & \rho \\ \rho & 1 \end{pmatrix}\right]$$

There are four possible outcomes in bivariate probit model:

$$P_{11} = \Pr[F=1, IF=1] = \int_{-\infty}^{\beta_F X'} \int_{-\infty}^{\beta_{IF} X'} \phi_2\ (\beta_F X', \beta_{IF} X', \rho) d(\beta_F X') d(\beta_{IF} X')$$

$$P_{10} = \Pr[F=1, IF=1] = \int_{-\infty}^{\beta_F X'} \int_{\beta_{IF} X'}^{\infty} \phi_2\ (\beta_F X', \beta_{IF} X', \rho) d(\beta_F X') d(\beta_{IF} X')$$

$$P_{01} = \Pr[F=1, IF=1] = \int_{\beta_F X'}^{\infty} \int_{-\infty}^{\beta_{IF} X'} \phi_2\ (\beta_F X', \beta_{IF} X', \rho) d(\beta_F X') d(\beta_{IF} X')$$

$$P_{00} = \Pr[F=1, IF=1] = \int_{\beta_F X'}^{\infty} \int_{\beta_{IF} X'}^{\infty} \phi_2\ (\beta_F X', \beta_{IF} X', \rho) d(\beta_F X') d(\beta_{IF} X')$$

$$(\beta_F X', \beta_{IF} X', \rho) = \frac{\exp[-0.5[(\beta FX')2 + ((\beta IFX')2 + \rho(\beta FX')(\beta IFX')]]/(1-\rho 2)}{2\pi\sqrt{(1-\rho 2)}}$$

RESULTS AND DISCUSSION

In this section, bivariate probit model is used to examine which observables affect credit sector in terms of formal sector and informal sector.

Additionally, cross-sector correlatios between formal credit participation and informal credit participation in the sample is examined also.

Estimation of determinants of microcredit participation

The model is estimated by carring out in Stata presented in Table 6.

****significant at 1 percent, **significant at 5 percent, * significant at 10 percent*

The result shows that among eleven explanatory variables including age, gender, marital_stt, edu, hhsize, income, savingamount, landsize, agriculture_act, network and location are considered for research model, the probability of household's participation in formal credit is affected by seven variables namely age, edu, hhsize, income, savingamount, landsize and location. However, the determinants of accessibility to informal credit sector are different from that of formal credit sector. Estimation result indicates seven variables (age, gender, marital_stt, hhsize, income, savingamount, network and location) are statistically significant determinants of participation in informal credit source.

The relationship between age and the probability of formal credit source obtaining is statistically significant at 5% significant level. The probability is higher for the older and that rate declines with age decrease. Different from formal lenders, informal lenders prefer offering loan for the younger to the elderly, is consistent with some studies that assert that accessibility to rural credit negatively related to age (M. Ajugam and C. Ramasamy, 2007; Okurut, 2006; Mohamed, 2003 Zeller, 1994; Magri; 2002). It is explained that young person does not have accumulated asset, which is required by formal sector for their credit borrowing so they tend to borrow money from informal source such as from their friends, from their relatives and so on while the elderly have asset accumulation for collateral requirement from formal lenders. It is possible that the younger have stable income that leads to reduce risk to the informal lenders. Additionally, informal lenders refer to give opportunity for young family member who is the most productive generation in a family in their carrier.

It is possible that gender is not seen as a good proxy that influence on the probability of formal credit borrowing. Because implement of government policy that will reduce gender inequality in rural credit market, so there is no difference in the right of applicant in terms of gender for the purpose of economic empowerment and economic development. However, there is gender discrimination existence in the lending credit from informal lender with estimated coefficient for household head gender is negative and statistically significant at 10% level. In the line with literature review, more male-headed household is served by informal sector compared to female-headed household. This phenomenon is consistent with the finding by Wabei (2012) that female usually lack of collateral relative to their male counterpart.

The result from estimation shows that there is a positive relation between marital status and the chance for credit rationing from informal sector. It demonstrates that single household head have lower probability to access to informal credit sector, it is explained by Ferede (2012) that single persons are lack of social network. This phenomenon was also indicated by many researchers such as Kirchler Kamleitneir and Kirchler (2007); Bridges et al. (2004); Magri (2002).

According to this estimation, education has no effect on the probability of informal credit obtaining. In contrast to the result from the informal sector, educational level plays a critical role in determining demand for formal credit sector at 1% significant level. Positive sign of estimated education coefficient means the higher educational qualification, the higher probability of accessibility to formal sector for applicants. That is in line with the literature, demand for credit will be low if borrowers have fewer years of schooling (Khandker, 2001; Cuong H. Nguyen, 2007). Additionally, high education correlates high income with productive jobs; so the formal lenders prefer to higher educated borrowers because of their lower default risk of lending.

Besides, this research shows that the larger family has positive effect on the probability of accessibility to formal credit borrowing while that has significantly negative influence on informal credit sector participation at 1% significant level. It is explained that formal sector is partially control by government with the policy that concerns on large families with more children and elderly people because family with more dependents will be more vulnerable to economic shock. On the other hand, informal lenders do not require any document as collateral, lenders and borrowers in this sector treat each other by informal law. So the informal lenders have to consider if borrowers have repayment ability at the maturity date; if a family has many dependent family members the risk default will be high for informal lenders, so they are more willing to lend to families which do not have many children and the elderly who their age is out of labor force.

There is a strong relationship between household's income and credit allocation in both formal and informal sector. However, the sign of household's income coefficient of formal credit source is different from that of informal credit source. According to this research estimation, it points that income is an important factor that has a positive impact on household's demand for informal credit at 5% significant level. It implies that more income household get, more opportunity to borrow money from informal credit sector; this result is consistent with researches by Crrok (2001), Lin and Yang (2005), Jappelli and Pistaferri (2007), Ambrose et (2004) which states that high-income households more likely access to loan than low-income household. Different from the result from informal credit sector, it reveals that there is a negative relationship between income and credit constrain for formal sector. The result show that household would like to borrow more when their income is low because more low income, more marginal utility of consumption. As literature involved in rural credit, primary target of microfinance is that provides capital for the poor to help them in living improvement (World Bank, 2010), so the chance for credit obtaining is lower with high income applicant. This research result is in line with the finding by Pham & Lensink (2007); Li et al. (2011) and Ferede (2012).

The estimation results that saving amount plays an important factors of credit participation in both formal and informal sector at 1 percent of significance. The negative coefficient of savingamount variable in informal sector implying that household with large saving amount is not considered as a poor house. Different from that, there is a positive relationship between savingamount variable and formal credit participation. As mentioned by many researches, formal credit requires collateral for credit lending, so borrowers have bigger saving amount will have higher chance for borrow money from formal credit source. The sign of coefficient of savingamount variable in this research is consistent with literature review.

Result shown in Table 6 indicates that relationship between rural credit participation and land size is statistically significant at 1 percent level. It is explained that land size is consider as collateral for credit borrowing, so it is easy for households with bigger land size to access to credit market, especially formal market which ask household to submit collateral to reduce risk; this result is consistent with finding by Vu (2002) and Zeller (2001). According to Mohamed (2003), Ravi (2003) and others, households own large land scale need more credit for agricultural production. However, household borrowing from informal sector is significantly negative related to land size at the 1% level of significance. There is an assumption that household with large land size is not consider as the poor (Quach, 2005).

Network does not effect on formal credit sector. However, social capital plays as an important factor of participation in informal credit sector at the 5% level of significance. The positive coefficient of social network proves that household which is a member of any organization will have more probability to borrow money from informal sector. This possibly demonstrates that household's network is considered as social collateral that plays crucial role in lending from informal sector because this transaction bases more on trust and personal relationship. This result is consistent with findings of Okten and Osili (2004); Fafchamps (2000); Karlan (2009); Bui (2010) and Grootaert (1999).

Consistently with primary target of rural credit that is to help rural households, this estimation shows that probability of households located in rural areas is higher than that of households located in urban area. It demonstrates that the sign of coefficient of location variable is statically positive at 1 percent of significance in estimation of determinants of accessibility to formal credit. However, estimated result shows that more households in urban areas participate in informal credit sector. As known, standard of living in urban areas in higher than that is rural areas; so urban families have more free money for lending to help the poor.

The Likelihood-ratio (χ^2= 490.84) test suggests that two error terms are significant correlation (reject null hypothesis of zero correlation). Additionally, rho (ρ) is presented for estimated correlation receive the value of -0.81 is far away from zero and estimation shows that Prob > chi2 = 0.0000 implying that there is a relationship between two dependent variables. That leads to conclusion that bivariate probit model estimation is superior to those of unvariate probit model. Specifically, negative value of rho in estimated result indicates that the choice of rural credit sources is negatively correlation and it is also affected by unobserved variables.

There are many marginal effects can be evaluated for bivariate probit model. For example, marginal effects are calculated for different outcomes such as Pr(formal=1, informal=1), Pr(formal = 1, informal = 0), Pr(formal = 0, informal = 1) or Pr(formal=0,informal=0), or or for the unconditional probabilities such as Pr(formal = 1) and Pr(informal = 1), or for the conditional probabilities such as Pr(formal=1|informal=1) and Pr(informal=1|formal=1).

Marginal effects for continuous variable are computed differently from that for binary variables. For dummy variables, marginal effect relates to discrete change in the probability of participation in a particular sector in response to an increase of explanatory variable from zero to one; holding all other variables at their means. Whereas, for continuous variables, marginal effect relates to instantaneous rate of chance measuring the absolute change of probability of participation in a particular sector in response to one unit increase of dependent variables.

Since there is a correlation of error terms of two functions, so conditional marginal effects and marginal effects are different even at the same referent points. Because this research accounts for the relationship between two types of credit sector, conditional marginal effects make more sense than others. Therefore, in this section, I present results of conditional marginal effects only.

Estimation of conditional marginal effects

Marginal effects for conditional probability of formal participation sector with given informal sector participation, Pr(formal=1|informal=1) are as Table 7.

Table 7 Marginal effects for conditional probability of formal sector participation

Variables	dy/dx	Std. Err.	P>|z|	X
Age	0.00016	0.001	0.905	47.133
Gender	0.009	0.056	0.87	0.839
Marital_stt	0.182	0.055	0.001	0.855
Edu	0.017	0.005	0	8.34
Hhsize	-0.007	0.005	0.161	5.755
Income	-0.0002	0	0.052	88.226
Savingamount	0.001	0	0.099	22.418
Landsize	0.003	0.001	0.006	10.992
Agriculture_act	0.003	0.035	0.42	0.671
Network	0.003	0.033	0.486	0.561
Location	0.316	0.027	0	0.794

Source: Author's calculation

The predicted probability that a household participates in formal sector is 40.18 percent at the reference points, given that household participates in informal sector already: Pr(formal=1|informal=1) = 0.40, as calculated in Table 3.

Command predict(pcond1) is employed to compute conditional marginal effects for each independent variable on formal sector participation with given informal participation sector.

The estimation result presents when combining direct and indirect effects, for an additional year of education level of household head, the probability of accessibility to formal credit sector will increase by 1.7 percent; all other variables are hold constant at their reference points.

In term of marital_stt, the opportunity to get credit from formal source for married household head is 18.2 percent higher compared to that for unmarried household head.

Similarly, the location of household, which participates in informal credit sector, plays an important role in credit lending from formal sector. The result shown suggests that the predicted probability of lending credit from formal sector is expected to increase by 31.6 percent for household located in rural area, ceteris paribus.

Besides, dy/dx for income variable is -0.0002. This means that after controlling for other variables at their means, the probability of accessibility to formal credit will be reduced 0.02 percent when household's income increases by 1.000.000 VND, given that household participates in informal sector already.

Saving amount is considered as formal collateral for credit borrowing. Therefore, it has positively correlated to formal credit obtaining. Particularly, given household participates in informal credit sector, the probability of accessibility to formal credit sector increases in 0.1 percent if saving amount of household increasing 1.000.000 VND.

Additionally, the predicted probability of accessibility to formal sector of a household which participates in informal sector already will be increased by 0.3 percent when the land owned by that household increase by 1000m^2, holding other variables at their reference points.

Similarly, marginal effects for conditional probability of informal participation sector with given formal participation sector, Pr(informal=1|formal=1) are shown as Table 8.

Table 8 Marginal effects for conditional probability of informal sector Participation

Variables	dy/dx	Std. Err.	P>|z|	X
Age	-0.004	0.001	0	47.133
Gender	-0.074	0.051	0.142	0.839
Marital_stt	0.187	0.034	0	0.855
Edu	0.009	0.004	0.019	8.34
Hhsize	-0.02	0.004	0	5.755
Income	0	0	0.265	88.226
Savingamount	0	0	0.155	22.418
Landsize	0.001	0.001	0.497	10.992
Agriculture_act	0.01	0.027	0.713	0.671
Network	0.057	0.026	0.027	0.561
Location	0.061	0.029	0.038	0.794

Source: Author's calculation

The predicted probability that a household participates in informal sector is 27 percent at the reference points, given that household participates in formal sector already: Pr(informal=1|formal=1) = 0.27 as calculated in Table 3.

Command predict(pcond2) is employed to compute conditional marginal effects for each independent variable on informal sector participation with given formal participation sector.

Accordingly, household head's age has negative effect on informal credit participation, given that household participates in formal sector already; in particular, holding others variables constant, one age addition leads a decrease of 0.4 percent in probability of informal credit accessibility.

Similarly to Pr(formal=1|informal=1), Pr(informal=1|formal=1) has been affected by marital status of household head. Given household participates in formal credit sector, the possibility for that household approaches informal providers is 18.7 percent higher for married household, ceteris paribus.

Consistently with finding by Yehuala (2008); Okunade (2007); Vaessen (2001) and Okunade (2007), estimation result shows that one year increase in education level will produce a 0.9 percent increase in the probability of participation in informal credit source, holding other variables at constant.

Besides, the value of dy/dx for household size variable is -0.02 explaining that, controlling other variable at their reference, the percentage of probability for informal participation goes down by 0.2 for every additional the number of member in household which participates in formal credit sector already.

Additionally, social network and location is positively related to household borrowing from informal credit sector. According estimated result, the percentage of accessibility to informal credit sector for household participating in formal credit sector will increase by 5.7 percent and 6.1 percent respectively if the value of independent variable changes from zero to one.

CONCLUSION

This section presents findings of this research, policy recommendations as well as limitations of the research.

Research Findings

This research employs bivariate probit model to exam the factors influencing household accessibility to formal credit sector and informal credit sector as well as relationship between two of them is investigated. The results show that the determinants of the use of formal credit sector are different from the determinants of the use of informal credit sector. Furthermore, the probability of formal sector participation will be decreased if there is an existence of informal credit sector participation and vice versa.

Bases on estimated results, seven determinants namely age, edu, hhsize, income, savingamount, landsize and location affect the formal credit participation. The estimation indicates that formal lender tend to provide credit to household who are better off with collateral requirement such as land size or saving amount.

Policy implications

Based on the research results, in order to improve the smooth of microfinance system operation; some policies are suggested

As research result indicated, education level is statistically significant factor of formal credit sector; complicated process leads to imperfects in choosing credit source of poor household that has low level of education. Therefore, administrative process for lending should be more simplifier.

Secondly, criteria for lending assessment process should reflect the primary target of microfinance system, do not depend on the confidence the lender has.

Thirdly, developing an appropriate management system to manage informal credi source is to promote the positive role of this sector in poverty reduction in rura areas.

Limitations

The number of households that participate in semi-formal credit in sample collecte is small, so this research cannot examine the relationship between the choice o semi-formal credit sector and that of formal credit sector as well as that of informa credit sector.

Moreover, determinants of credit participation come from demand sid characteristics and supply side characteristic (Vaessen, 2002; Duong Pham, 2002) However, in this research, I focus on demand side presented by characteristics o household only.

The Product and Timing Effects of eWOM in Viral Marketing

Tong Tony Bao

To be effective in viral marketing campaigns, firms must first select proper disseminators, and use them as opinion leaders to communicate the information with followers via mass media in the online space. In this paper, we study major characteristics of opinion leaders and find that their online word-of-mouth (eWOM) increase product sales. Our findings provide firms managerial insights about product aspects of eWOM, and how firms should arrange the timing of eWOM for successful viral marketing campaign.

It has been noted that consumers have shown a tendency of using online word of mouth (eWOM) in finalizing their buying decisions (Guernsey 2000). Studies have revealed that consumers tend to consult with eWOM more than advertising because they trust their peers more than firms that sell products (Piller 1999). Thus, firms that receive favorable eWOM will likely enjoy a better chance for sales increase (Chevalier and Mayzlin 2006, Chung 2011). eWOM is an important source of information for consumers to make purchase decisions. Given the user-generated nature of eWOM, how can firms better utilize such eWOM to their advantage? As a hybrid between traditional advertising and consumer word of mouth, eWOM can be initiated by firms as a campaign and implemented by consumers for marketing communications (Godes and Mayzlin 2009). For an eWOM marketing campaign to be successful, it is critical to consider the behavioral characteristics of target consumers and the seeding strategy for selecting opinion leaders (Hinz et al. 2011). The purpose of this study is to identify eWOM opinion leaders and to examine the impacts of such opinion leaders' eWOM on a firm's product sales.

Literature Review

Word of mouth (WOM) has long been used to promote products or to criticize a competitor (Jacobson 1948, Katz and Lazarsfeld 1955). Its impact on sales and diffusion of new products was first reported to be positive in Arndt's study (1967). In recent years, the development of social network, and social media has further helped the spread of WOM via internet. eWOM has thus been suggested as "free sales assistant" of online sellers (Chen and Xie 2008). However, it is critical for firms to identify proper opinion leaders for seeding eWOM in order to generate favorable buzz effectively towards their products. Based on the nature of eWOM, we review the literature of opinion leader and WOM related to viral marketing and propose hypotheses for studying the relationships between opinion leaders' eWOM and sales.

Viral Marketing via Opinion Leaders

In a viral marketing campaign, firms select a small number of consumers as opinion leaders to disseminate information (Hinz et al. 2011). To be effective in such campaign, firms must first identify key opinion leaders, and then let key opinion leaders to communicate the information as disseminators with followers via mass media (Iyengar et al. 2011). Key opinion leaders are consumers who provide information and leadership to others in making their consumption decisions (Childers 1986). Given the opinion leaders' behavioral tendency and ability to influence purchase decisions of followers, a firm can benefit from effective use of such opinion leaders in order to assist potential customers for shaping their buying decisions in favor of the firm's products. A theoretical basis for viral marketing is to follow a two-step process that involves target opinion leaders (Lazarsfield et al. 1944). For example, by using the fashion-related magazines as a mass media, firms can benefit from the use of target opinion leaders in women's clothing fashion who tend to read such magazines (Summers 1970). However, how could firms identify proper opinion leaders for effective viral marketing?

Rogers and Cartano (1962) summarizes three methods of identifying opinion leaders: (1) self-designation, i.e. asking consumers to identify whether and to which extent they are opinion leaders; (2) sociometric method, i.e., using social network to compute network centrality and other network structure related measures; (3) key informant method, i.e., asking consumers whom they listen to. The self-designation method seems to be the most popular method in marketing literature due to the survey proposed by King and Summers (1970), while the key informant method is also used in recent studies (e.g., Nair et al. 2010). The main findings are that, self-designated and peer-nominated opinion leaders influence the choices of their followers. The sociometric method has been widely used by network analysis researchers, and has obtained increasing recognition among marketeers (Iyengar et al. 2011, Hinz et al. 2011). Previous studies reveal that both hub which is connected with many people and bridge which connects two clusters are influential (Hinz et al. 2011). However, large cascade of influences may not be driven by opinion leaders but by a large number of easily influenced people (Watts and Dodds 2007). In addition to the above-mentioned methods, other methods are also used to identify opinion leaders. For example, Aral and Walker (2012) use demographics to identify opinion leaders, and Godes and Mayzlin (2009) examine whether loyalty can be a moderating factor for self-designated opinion leaders. (2012).

In this study, we empirically study the appropriateness of opinion leaders identified from a dataset of Amazon reviews for the benefit of using its product sales rank and user rating information. The dataset is described in the following section. In order to classify key eWOM opinion leaders, we consider three attributes of Amazon website reviewers in the dataset. The first attribute is how many reviews a consumer posts on the website. By counting the number of reviews a consumer writes, we identify communicative reviewers as opinion leaders. According to an early study (Lazarsfeld et al. 1944), communicative opinion leaders tend to be someone who is most concerned and most articulate about the products. Consumers write their opinions for a number of reasons. Based on their expertise and/or usage experience, opinion leaders have a tendency of helping other consumers or the firm (Sundaram, Mitra, & Webste 1998). Posting reviews give them a chance to articulate their opinions and thus reduce the emotional tension if they feel strongly about a product (Dichter 1966).

The second attribute of opinion leaders is how much buzz a consumer’s review generates from peers. We identify buzz-generating consumers as opinion leaders. Previous study demonstrates that opinion leaders are progressive attention-seekers (Summers 1970). Opinion leaders fulfill their self-enhancement motivation via buzz creation (Engel, Blackwell, and Miniard 1993). The reviews written by buzz-generating opinion leaders can generate buzz among followers for them to increase product/brand awareness. And such awareness was found to be good for sales, whether the buzz is positive or negative (Berger et al. 2010). As such, buzz-generating opinion leaders could help firms to increase sales through the buzz they created.

The third attribute of opinion leaders is how trustworthy product reviews are considered by the other consumers. In the offline world, WOM is spread through consumers who know each other, that is, “whom he knows” for an opinion leader (Katz 1957). But this is not the case in an online setting where eWOM is disseminated freely among strangers. It remains a question why consumers trust eWOM from strangers? Obtaining target consumers' trust is a major challenge for firms operating on the Internet (Resnick et al. 2000). Consumers tend to rely on information sources with good reputation. Structural, lexical, sementical aspects of eWOM have been found to be related to trustworthiness of eWOM (Chen et al. 2008, Cao et al. 2011). We identify the most trustworthy buzz-creating opinion leaders as the consumers who generate the most helpful reviews.

Having identified communicative, buzz-generating, and trustworthy opinion leaders, we study the relationships between sales and eWOM of these opinion leaders. We discuss two streams of research on eWOM that have been found in the literature, namely, product effects and timing effects.

Product Effect of eWOM on Sales

There are three product aspects of eWOM, namely, product awareness/popularity, customer satisfaction and horizontal product differentiation. We first examine the product awareness/popularity of eWOM. Product awareness is the first phase in consumer's buying decision. Without product awareness, consumers will not have the interest and desire to consider a particular product that leads to a buying decision. The amount of eWOM influences consumers in two ways. It has been noted that the amount of eWOM increases exposure to a product and therefore increases consumer's awareness of the existence of a product (Liu 2006). In addition, large amount of eWOM suggests popularity of a product (Chen et al. 2004, Zhu and Zhang 2010). Previous studies reveal that volume of eWOM drives sales (Chevalier and Mayzline 2006, Liu 2006, Dellarocas et al. 2007 and Duan et al. 2008). We thus propose:

H1a: *Product Popularity and Awareness* is positively associated with Sales.

Consumers communicate their satisfaction using online user rating, (Chen and Xie 2008, Sun 2012). The persuasiveness of user review depends on consumption goal of a consumer. Positive review is more persuasive than negative review for products used for promotional consumption goal, while the opposite holds for products used for prevention consumption goal (Zhang et al. 2010). It has been found that consumer satisfaction can influence future sales (Kopalle and Lehmann 2006, Yi 1989). In his study, Liu (2006) indicates that positive rating can enhance consumer's attitude while negative rating reduces attitude. Although most existing literature finds that product satisfaction drives sales (Chevalier and Mayzline 2006, Dellarocas et al. 2007, Moe 2009, Chintagunta et al. 2010), negative review can also drive sales due to its ability to increase consumer awareness (Berger 2011). Therefore, we propose:

H1b: *Product Satisfaction* is positively associated with Sales.

Consumers perceive vertical differentiation in the same way. In contrast, consumers have different rankings of a group of products which are horizontally differentiated (Hotelling 1929). For example, fuel efficiency in mile per gallon (mpg) is vertical differentiation. But features of comfort vs. sportiness are examples of horizontal product differentiation. The same product can satisfy some consumers and receive high ratings while disappoint other consumers and receive low ratings at the same time. And a high variance indicates that a product is well differentiated horizontally, satisfying more consumers in different target segments, and therefore drives sales (Godes and Mayzlin 2004, Clemons et al. 2006, Sun 2012). We thus propose:

H1c: *Horizontal Product Differentiation* is positively associated with Sales.

Timing Effect of eWOM on Sales

It has been noted that eWOM marketing campaign tends to last a short period of time (Godes and Mayzlin 2009). The timing of launching eWOM is thus critical for generating desired effect of a firm's marketing campaign. Researchers have found that eWOM at the early stage of product luanch increases product sales (Liu 2006, Li and Hitt 2008). However, eWOM has diminishing effects over time (Cao et al. 2011). It is then a challenge for firms to decide how to arrange the timing of eWOM marketing campaign. Two hypotheses (H3a and H3b) are developed accordingly to test the relationships between the first arrival and time span of eWOM and sales. Finally, similar to advertising intensity, we hypothesize (H3c) that the intensity of eWOM also has an impact on sales (Strong 1977, Naik et al. 1998, Appleton-Knapp et al. 2005). We use standard deviation of opinion leaders' eWOM as a proxy for eWOM intensity.

H2a: Early arrival of top eWOM is positively associated with sales.

H2b: Time span of top eWOM is positively associated with sales.

H2c: Standard deviation of top eWOM is negatively associated with sales.

Data and Model

Data and Opinion Leaders

Online user review has been used as a proxy for overall eWOM (Zhu and Zhang 2009). In this paper, we use an Amazon user review dataset to identify opinion leaders and study eWOM dissemination. The dataset contains a sample of 350122 book, music, video and DVD titles which, as experience goods, have qualities difficult to ascertain before consumption, and therefore user reviews are helpful for consumers (Nelson 1970, Park and Lee 2009). A user review on Amazon has both a star rating and a text review. For each title, we collect three statistics of star rating, i.e., average rating, number of reviews, and variance of all star ratings for the title. On average, a title receives 13.98 reviews with an average rating of 4.33 and variance of 0.68. Amazon puts a title into relevant product categories. Amazon product category has a tree structure. For example, Jane Austen's Sense and Sensibility belongs to the category: /Books/Literature & Fiction/World Literature/ British/19th Century. The category at the top level of the tree is book, and the deeper the tree is, the finer the category is. The category count for a title ranges from 1 to 116 with an average of 4.88. Our approach to identify opinion leaders is based on the fact that Amazon allows consumers to display their names for their user reviews. We identify 1479053 unique consumers who write 86% of the user reviews in the dataset. The remaining 14% of the user reviews have no unique identifications. On average, a unique consumer writes 4.37 reviews. The most prolific consumer writes 8659 reviews. Amazon provides a mechanism for consumers to respond to a user review, that is, consumers can vote whether a user review is helpful or not. The number of vote (either helpful or not) that a user review receives is a proxy for buzz. And the number of helpful votes is a proxy for how trustworthy a user review is. On average, a consumer receives 26.43 votes, and 12.83 helpful votes.

Some researchers treat all reviewers as opinion leaders (Cui et al. 2010). But we are interested in examining a much smaller set of reviewers because it is costly for a firm to recruit all available reviewers. The theoretical basis for considering a subset of reviewers is that opinion leadership is not a dichotomy: consumers are not clearly divided into two groups of opinion leader and followers. Instead, opinion leaders also listen to followers, and opinion leadership varies in a continuous fashion (Rogers 1962). As discussed in Introduction, we identify communicative opinion leaders as the top 21458 reviewers in terms of the number of user reviews written (1.5% of the total unique consumers in the dataset). We identify buzz-generating opinion leaders as the top 21458 reviewers in terms of number of votes, and identify trustworthy opinion leaders as the top 21458 reviewers in terms of the number of helpful votes. It is worth noting that the three types of opinion leaders are not mutually exclusively. The total size of the three sets is 21458×3=64371, but the total distinct number of the opinion leaders in the three sets is 34340. 12109 consumers are both communicative and buzz-generating opinion leaders. 11819 consumers are both communicative and trustworthy opinion leaders. And, 16989 consumers are both buzz-generating and trustworthy opinion leaders. 10886 consumers belong to all three sets. The overlapping of different types of opinion leaders is consistent with extant literature (Iyengar et al. 2011).

Opinion Leader's eWOM

We discuss how to operationalize the hypothesis for communicative opinion leaders (the same operationalization applies to buzz-generating and trustworthy opinion leaders). Since we are interested in the impact of opinion leaders on sales, the unit of analysis is a title. Following extant literature, we use log transformation of sales rank as a proxy to sales (Chevalier and Mayzlin 2006). To test product effects of eWOM (H1a-c), we collect star ratings from communicative opinion leaders for each title. Then we compute the three statistics for each title, i.e., number of ratings (volume), average rating (valence), and standard deviation (SD). We operationalize product popularity/awareness, product satisfaction, and horizontal differentiation by volume, valence, SD (summary statistics of the variables for communicative opinion leaders are reported in Table 1). A title receives between 1 and 1000 reviews from communicative opinion leaders, and the average rating is 4.24, and the standard deviation is 0.40.

Table 1: Summary Statistics

Variable	Mean	Std. Dev.
Log sales rank (*Sales*)	11.57	1.60
Category count ($Count_{cat}$)	5.34	4.95
Volume of reviews (*Volumn*)	6.02	17.57
Average rating (*Valence*)	4.24	0.86
Std. dev. of rating (*SD*)	0.40	0.50
Arrival time of first review ($Time_1$)	454.70	562.48
Average arrival time of reviews ($Time_{ave}$)	758.80	634.58
Std. dev. of arrival time of reviews ($Time_{SD}$)	239.20	264.82
Average knowledge of opinion leader (*Know*)	3710.00	4793.44
Average distinct knowledge of opinion leader ($Know_d$)	2874.00	4453.40

To study timing effects of eWOM, we need a measure of when user reviews arrive. Since we do not have information on when a title is launched on Amazon, we use the date of the first user review as a proxy for the launch date. The *arrival time* of a user review is the days elapsed from the launch date. We collect arrival time of the first review written by a communicative opinion leader. We also collect the arrival time of all reviews by communicative opinion leaders, and use them to find the average and standard deviation of arrival time.

We add two control variables for each title. The first is the number of categories a title belongs to as *category count*. As shown in Table 1, a title belongs to 5.34 categories. The highest number is 116. As described in Data section, Amazon's category has a tree structure. We use the top level of category as a control variable and refer to it as *group*. A group can be book, music, video, and DVD (Table 2).

Table 2: Summary Statistics for Product Group

	Book	Music	Video	DVD
Number	129615	46913	10725	12000

We specify the following model to empirically test our hypothesis.

$$sales = \beta_0 + \beta_1 group + \beta_2 count_{cat} + \beta_3 valence^j + \beta_4 volume^j + \beta_5 SD^j + \beta_6 time_1^j + \beta_7 time_{ave}^j + \beta_8 time_{SD}^j + \varepsilon.$$

$Sales$ = logarithm of sales rank

J = types of opinion leaders, i.e., communicative, buzz-generating, and trustworthy

$Group$ = top level of category tree, i.e. book, music, DVD, and video

$Count_{cat}$ = number of categories to which a title belongs

$Valence^j$ = average review by type j opinion leader

$Volume^j$ = number of reviews by type j opinion leader

SD^j = standard deviation of reviews by type j opinion leader

$Time_1^j$ = arrival time of first review by type j opinion leader

$Time_{ave}^j$ = average arrival time of reviews by type j opinion leader

$Time_{SD}^j$ = standard deviation of arrival time of reviews by type j opinion leader

Results and Discussions

We first test our model specifications with two alternative models where timing effects and knowledge effects are omitted. We conduct regression analysis on 90% of the total sample, and then use the estimated parameters to conduct a prediction exercise on the remaining 10% hold-out sample. Comparison of in-sample fit and prediction error on hold-out sample suggests that our model fit the sample the best (Table 3). Next we report estimation results on communicative opinion leaders. Similar results hold for buzz-generating and trustworthy opinion leaders (we omit detailed reporting due to space limit).

Table 3: Model Validation

	In sample (AIC**)	Hold-out sample (RMSE***)
Model 1*	580977.700	3.086
Model 2	570920.200	3.054

*Model 1: product effects only; model 2: product and timing effects.
**Akaike's Information Criterion (AIC) is defined as $AIC = -2 \times \log(l) + 2 \times p$
where l is likelihood and p is number of parameters.
***RMSE = Root Mean Square Error.

The intercept estimates in Table 4 is interpreted as the intercept for book group since group is a factor variable. The music group has a significant estimate of -1.304 where the minus sign implies that, as a group, music titles have higher sales than book titles because a lower sales rank means higher sales. Comparing estimates on music, video, and DVD, we find that video has the highest sales, DVD the second highest, music the third highest, and book the lowest. The estimate on category count is -0.011 and significant. It implies that sales increase in category count. An explanation is that category count is a proxy for content diversity of a title. The more diversified a content is, the more market segments a title appeals to, and thus the more consumers it is able to attract.

Table 4: Estimates of eWOM

	Model 1 (product effects)	Model 2 (product and timing effects
Intercept	13.472*	13.460*

Std. dev. of arrival time of reviews ($Time_{SD}$)		2.900e-04*
		(2.956e-05)
Average arrival time of reviews ($Time_{ave}$)		-1.007e-03*
		(2.094e-05)
Arrival time of first review ($Time_1$)		7.471e-04*
		(2.177e-05)

Product Effects

The estimate for volume is -0.011 and significant. It implies that high product popularity/awareness increases sales (H1a). The estimate for average rating is -0.163 and significant. It implies that high product satisfaction increases sales (H1b). The estimate for standard deviation is -0.216 and significant. It implies that high horizontal differentiation increases sales (H1c). Although the extant literature has demonstrated the three product effects, researchers have not found evidence that all three product effects are significant in one empirical setting. Explanations for the inconsistency are: (1) empirical issues including collinearity and functional form (Godes and Mayzline 2004), market aggregation and time series (Chintagunta et al. 2010), (2) specific roles of a measure including volume increasing awareness (Liu 2006) and variance signaling hyper-differentiation (Clemons et al. 2006), and (3) variance and volume both depends on quality (Moe 2009). Consumer satisfaction, consumer awareness/popularity, and horizontal differentiation are all costly to accomplish. The extent literature seems to suggest that marketers only need to focus on two of three product effects. But our result is the first evidence to support the importance of improving all three product effects at the same time. We also compare the three types of opinion leaders in terms of eWOM. We find that communicative opinion leader's eWOM is the strongest on the dimension of consumer satisfaction. Buzz-generating opinion leader's eWOM is the strongest on the dimension of horizontal differentiation. Trustworthy opinion leader's eWOM is the strongest on the dimension of product awareness/popularity.

Timing effects of eWOM from Opinion leaders

The estimate of arrival time of the first review by communicative opinion leader is 6.363e-04 and significant. It implies that a short arrival time of the first communicative opinion leader's eWOM increases sales (H2a). But the estimate of average arrival time of all communicative opinion leaders is -9.032e-04 and significant. It implies that a long average arrival time of all communicative opinion leaders' eWOM increases sales (H2b). In addition, the estimate of standard deviation of all communicative opinion leaders is 2.335e-04 and significant. It implies that a small standard deviation of all communicative opinion leaders' eWOM increases sales (H2c).

Although early researchers have found evidence that opinion leaders and early purchasers can overlap, opinion leaders are not necessarily early purchasers (Arndt 1967, Baumgarten 1975). Recent studies in eWOM context have found that eWOM has more impact at the early stage of the product life cycle (Liu 2006, Li and Hitt 2008). So an implication is that firms should have eWOM marketing at the early stage of product launch. Our finding implies that opinion leader's eWOM has effects on sales at both early and later stage of product life cycle. In addition a given eWOM has diminishing effects over time (Cao et al. 2011). So to arrange the timing of eWOM, firms should start eWOM of opinion leader as early as possible. But firms should also spread eWOM from opinion leaders over time. As a consequence, the average time will increase. The finding that small standard deviation of arrival time increases sales suggests that eWOM of opinion leaders should be close to one another. Such implication is consistent with the findings that advertising messages need to be grouped together to increase intensity in advertisement scheduling literature (Naik et al. 1998, Appleton-Knapp et al. 2005). Among the three types of opinion leaders, communicative opinion leaders has the largest marginal effects in first eWOM arrival time, average arrival time, and standard deviation of arrival time.

Conclusion

In summary, our findings provide the following insights to help firms create communication campaigns in the US. Despite being a small fraction of target consumers, communicative, buzz-generating, and trustworthy opinion leaders drive sales through disseminating eWOM. Firms should start the eWOM campaign as early as possible in order to obtain early mover advantage. But firms should not arrange all opinion leaders to write reviews at the early stage of the product adoption process. Instead, firms should have eWOM from opinion leaders over a long period of time. And eWOM intensity needs to be strong. This paper has the following limitations that we hope to address in the future research. First, we do not consider mediation factors such as willingness to buy and online-store image/product image. Second, the extant literature has identified opinion leaders based on network structure (Hinz et al. 2012). Our dataset does not have information to study the network-related properties of opinion leaders identified in our paper.

Open University of Ho Chi Minh City, Vietnam
duc.vo@erawa.com.au

This study was conducted to estimate the equity beta, a key input of the Sharpe-Lintner capital asset pricing model, which then can be used to determine an expected return on equity. The motivation of this study is to provide the Vietnamese Government with an additional piece of evidence in relation to the determination of the sale prices of the government owned assets during the process of privatization and equalization.

Using a sample of 19 listed companies operating in the Utilities Industry in the Ho Chi Minh City Stock Exchange for the period of more than 7 years (from 2007 to 2013 inclusive), a new approach (a Quantile Regression approach); together with the other two traditional approaches (the OLS and the LAD), have been used to estimate the equity beta for these listed firms in this study. Estimates of beta were conducted at the individual firms' level and at the portfolios' level. At the portfolios' level, two different types of portfolios are formed: (i) the equally-weighted portfolio; and (ii) the value-weighted portfolio.

Under all approaches, estimates of beta indicate that the appropriate value of the equity beta for companies operating in the Utilities Industry in Vietnam is 0.8 – which is still below the market beta of the entire market. This finding provides an evidence to confirm that a level of risk faced by a company in the Utilities Industry is below the average of the level of risk for the entire market.

Keywords: Equity beta; Sharpe Lintner CAPM; Quantile regression; Ho Chi Minh City Stock Exchange.

1. Introduction

Vietnam is going to be the next young Tiger in the Asian region for the next decade or so. In achieving this dream, privatization and/or equitization of the government-owned businesses, particular in the capital intensive Utilities Industry including energy, water, electricity, and public transport, is considered unavoidable to ensure that scarce resources are best utilized. The presence of the government ownership in these state-owned companies is very significant. This presence will limit the government's ability to meet its other socio-economical objectives and/or to under-invest in these public utilities companies. However, selling these assets to the private sector requires an appropriate pricing to ensure that these assets will raise fair amount of money for the public. In a financial term, the government is required to determine its appropriate expected return on equity for being present in these public utilities businesses in any offer of selling their assets. This expected return on equity can be used to confirm whether or not current government owned businesses in the same or similar industry are efficient in running their businesses and/or to determine a fair price of the assets (the companies) should the Government decide to privatize and/or equitize these assets.

Estimating a return on equity is an extremely complicated task and there is no consensus so far among academics and practitioners. One of the important elements to evaluate the efficiency of enterprises and to provide evidence whether or not the government should privatize a particular enterprise within the public utilities industry is the expected return which is generated by the company in the future.

Among all approaches, the first ever capital asset pricing model (CAPM), Sharpe-Lintner CAPM, introduced by Sharpe (1964) and Lintner (1965), has still been widely used by policymakers including regulators from countries around the world. In particular, according to Mckenzie and Partington (2014), regulators in Australia, Germany, New Zealand, USA, Canada and UK are currently using this CAPM to estimate an expected return adopted in their regulatory decisions (see Appendix 1 for details).

A key component of this CAPM is the equity beta. In order to estimate the equity beta, most of the previous empirical studies have adopted the standard Ordinary Least Square (OLS) and Least Absolute Deviation (LAD) to estimate the beta coefficient in the CAPM model. It has been argued for a long time that estimating beta suffers instability of the estimates. In addition, extreme outliers in the sample have been considered as a key issue for any empirical estimate of beta. In this context, this paper argues that Quantile Regression approach may be useful in minimizing the effects of outliers in the sample. This paper aims to provide the estimation of betas for individual company as well as the portfolio in the Utilities Industry in Vietnam using a new approach, the Quantile Regression approach.

The structure of the paper is as follows. Following this Introduction, Section 2 presents a brief summary of literature relating to the CAPM and empirical studies on beta estimation. Data description is presented in Section 3. Section 4 presents results and discussions. This paper is concluded by some main conclusions and policy implications in Section 5.

2. Literature review

2.1. The Capital Asset Pricing Model

The Capital Asset Pricing Model (CAPM), introduced by Sharpe (1964) and Lintner (1965) describes the relationship between the expected return and risk. In this model, the expected return of a security (an asset) is given by the following equation:

$$E(r_i) = r_f + \beta_i\left[E(r_m - r_f)\right]$$

Where $E(r_i)$ is the expected return of security i, r_f is the risk free rate, r_m is the expected return of the market portfolio, $\beta_i = \frac{Cov[r_i, r_m]}{Var[r_m]}$ is the beta coefficient of security i. Moreover, β_i is defined as the profitability volatility measurement, and therefore it is considered as security's risk measurement.

The CAPM indicates that the expected return of security is positively correlated with its Beta coefficient. Assuming that the capital market is efficient and unsystematic risk can be reduced completely through diversification, the return of a security is only affected by its systematic risk. The higher the Beta coefficient is, the riskier the security is. Therefore, investors tend to require a higher return to compensate the higher risk (or high Beta).

2.2. Current approaches to estimate equity beta

The systematic risk, which cannot be managed through portfolio diversification, can be obtained from the following regression:

$$r_{i,t} = \alpha_i + \beta_i r_{mt} + \varepsilon_{i,t} \qquad (1)$$

In which, the residual is $\varepsilon_{i,t} = r_{i,t} - \alpha_i - \beta_i r_{mt}$

In 2009, Associate Professor Henry from the University of Melbourne, Australia established his work in estimating equity beta for the Australian Utilities regulation as an advice to the Australian Competition and Consumer Commission (Henry, 2009). Five years later, Henry and Street (2014) updated the estimates. In these two studies, the OLS and LAD approaches were utilized.

Vo, Mero, and Gellard (2014) re-examined the estimates of beta in the Australian regulatory context. In their study, a data set is updated in comparison with Henry's study in 2009. In addition, another key contribution from Vo et al. (2014) study is that two new approaches were added in their study: (i) the Maximum Likelihood robust theory (MM) and (ii) the Theil Sen methodology. For each of these new approaches, the authors argued that among the robust regression estimators currently available, the MM regression has the highest breakdown point (50 percent) and high statistical efficiency (95 percent) while the Theil Sen estimator is proposed by Fabozzi (2013) in response to the OLS estimator being acutely sensitive to outliers.

We acknowledge that the two new approaches adopted inVo et al. (2014) study were a choice of different, arguably more advanced, econometric techniques. However, for the purpose of this paper, these two new approaches are not considered. Instead, we consider that it is even more appropriate to introduce a new approach, a Quantile Regression, which is best known for its capacity to limit the effects of outliers on the estimates. In addition, other two traditional approaches, the OLS and the LAD, are also in use in this study.

2.2.1. Ordinary Least Squares

The OLS method estimates the α_i and β_i in the equation (1) by minimizing the sum of squared residuals:

$$\sum_{t=1}^{T} \varepsilon_{i,t}^2 = \sum_{t=1}^{T} (r_{i,t} - \hat{r}_{i,t})^2 = \sum_{t=1}^{T} (r_{i,t} - \hat{\alpha}_i - \hat{\beta} r_{m,t})^2$$

The β coefficient from OLS indicates the average relationship between the regressor and the outcome variable based on the conditional mean function.

2.2.2. Least Absolute Deviations

In the LAD approach, the absolute value of residuals is minimized to achieve the estimates from equation (1) as follows:

$$\sum_{t=1}^{T}|\varepsilon_{i,t}| = \sum_{t=1}^{T}|r_{i,t} - \hat{r}_{i,t}| = \sum_{t=1}^{T}|r_{i,t} - \hat{\alpha}_i - \hat{\beta} r_{m,t}|$$

Since the sum of the absolute value of residuals is minimized rather than minimizing the sum of squares, the estimators obtained from the LAD method may alleviate the effect of outliers.

3. Methodology and data

3.1. Data

The listed companies belonging to the Utilities Industry in Vietnam are examined in this paper. There are currently 19 companies listed in the Utilities Industry in Ho Chi Minh Stock Exchange. Daily closing stock price of an individual company is collected from its starting day until 31/12/2013. The sample of companies (see Appendix 2 for more details) and time period are presented in Table 1 below:

Table 1. Listed utilities companies in the sample

Name of company	Code	From	To
An Pha Petrol Joint Stock Company	ASP	15/02/2008	31/12/2013
BaRia Thermal Power Joint Stock Company	BTP	25/11/2009	31/12/2013
Cholon Water Supply Joint Stock Company	CLW	11/01/2011	31/12/2013
CNG Viet Nam Joint Stock Company	CNG	23/11/2011	31/12/2013
Hydro Power Joint Stock Company – Power No.3	DRL	23/11/2011	31/12/2013
PetroVietnam Gas Corporation	GAS	11/04/2012	31/12/2013
Khanh Hoa Power Joint Stock Company	KHP	02/01/2008	31/12/2013
MTGas Joint Stock Company	MTG	15/01/2009	31/12/2013
Petrolimex Gas Corporation - JSC	PGC	02/01/2007	31/12/2013
PetroVietNam Low Pressure Gas Distribution JSC	PGD	26/11/2009	31/12/2013
Pha Lai Thermal Power Joint Stock Company	PPC	26/01/2007	31/12/2013

Vinh Son - Song Hinh Hydropower JSC	VSH	02/01/2007	31/12/2013

The market return volatility is measured by the Vietnam Stock Index, the VN Index, in the relevant period.

3.2. *Methodology*

3.2.1. *Return and return period*

Equation 1 can be run using the raw return of stocks or the excess return which is the difference between the raw return of stock and the risk free rate of return. It is argued that the raw return of stock is applied widely in the empirical studies. On the other hand, the excess return is also considered. Suppose the risk free rate does not fluctuate significantly, the excess return may be obtained by transforming the data $R_{i,t} = r_{i,t} - r_{f,t}, R_{m,t} = r_{m,t} - r_{f,t}$ and equity beta is estimated from:

$$R_{i,t} = \beta_i R_{m,t} + \varepsilon_{i,t} \tag{2a}$$

Or

$$r_{i,t} - r_{f,t} = \beta_i (r_{m,t} - r_{f,t}) + \varepsilon_{i,t} \tag{2b}$$

Subtracting $r_{f,t}$ from both sides of (2b) and rearranging yields (3):

$$r_{i,t} = (1 - \beta_i) r_{f,t} + \beta_i r_{m,t} + \varepsilon_{i,t} \tag{3}$$

In the circumstances when the variance of risk free rate is low as the intercept term, $(1 - \beta_i) E(r_{f,t}) = \mu$, the Beta yielded from equation (3) should be consistent with those estimated from equation (1) (Henry & Street, 2014). Furthermore, no assumptions about possible variations in chosen risk free rate is required when the raw returns instead of the excess returns are used. For these reasons, this paper employs the raw returns for its simplicity.

The return period of stock or market is calculated at different frequency such as daily, weekly, monthly, etc. Henry and Street (2014) argued that weekly frequency of return should be used to avoid both the noisy nature in daily data and unreliable estimators from monthly data due to too few observations. Therefore, data on the weekly return of stocks are used in this paper.

There are two different ways in which a weekly return of a stock can be calculated. *First*, the weekly stock return is measured by the difference between *a closing price* on Fridays and *an opening price* on Monday from a same week. Since stock trading does not happen on Saturdays and Sundays, the closing price of Friday of the week before is used instead of an opening price on Monday. This weekly return represents the change in stock price during a particular week.

Second, alternatively, the weekly return can be estimated using the average daily return within a week. This means that the weekly return indicates the average change of the five trading days of a stock during a week. This paper adopts the former weekly return and uses the latter weekly return as an alternative to check the robustness of the estimates. In general, the stock return in period t can be calculated as follows:

$$r_{i,t} = \frac{Stockprice_{i,t} - Stockprice_{i,t-1}}{Stockprice_{i,t-1}}$$

Similarly, the weekly market return is computed using the VNI Index.

3.2.2. A new approach – Quantile Regression

In relation to a validity of a Quantile Regression approach, it has been argued that:

> *"On the average" has never been a satisfactory statement with which to conclude a study on heterogeneous populations. Characterization of the conditional mean constitutes only a limited aspect of possibly more extensive changes involving the entire distribution".*

Buchinsky (1994)

When all of the OLS assumptions are satisfied, the β coefficient estimated from (1) is the best linear unbiased estimator. It indicates the average relationship between the regressor and the outcome variable based on the conditional mean function. Indeed, using OLS method leads to some attractive statistical properties of estimators which are straightforward to interpret and easy to calculate (Hao & Naiman, 2007).

However, OLS estimator has some limitations as follows:

(1) The strict assumptions cannot always be met in reality. In particular, the homoscedasticity assumption is likely to fail in estimating the return on equity. Also, the heavy-tailed distributions commonly occur in reality.

(2) The conditional mean attracts the researchers' attention into the central location and steers them away the whole distribution' properties as well as the noncentral locations. Koenker and Bassett Jr (1978) indicated that when the exogenous variables affect the dependent variable at different parameters in the distribution from the mean, the analysis would be seriously weakened.

(3) The effect of existing outliers tends to be magnified due to square effect in the optimization function. Therefore, the validity of OLS estimators is concerned in the outlying conditions.

There are some possible approaches to deal with above problems. This paper applies the most common method, the Quantile Regression. With the Quantile Regression (QR) proposed by Koenker and Bassett Jr (1978), the estimator can be found with following minimization function:

$$\beta_{QR} = \arg\min \left[\sum_{Y_i \geq \beta X_i} \tau(Y_i - \beta X_i) + \sum_{Y_i < \beta X_i} (1-\tau)(Y_i - \beta X_i) \right] \forall \tau \in (0,1)$$

The QR method, considered as an ordered statistics-based estimation, might estimate coefficient vector which is not sensitive to the influences of outliers since the minimization function is a weighted sum of absolute deviations. Moreover, it loosens some of OLS assumptions such as normality, homoscedasticity, etc. (Johnston & DiNardo, 1997). Estimating simultaneously many different percentiles could provide a complete view of the relationship and extend the analysis to noncentral locations, which are the main interests of recent social science researches. For instance, studies in gender inequality and income gaps pay attentions in the poor (lower tail) and the rich (upper tail). Researchers in education may have intrinsic interests and need to fully understand in pre-established achievement levels.

The interpretations for the OLS and QR coefficients have different meanings. While the OLS estimators suggest the **average** marginal effect of regressor on dependent variable, the QR estimators examine the **marginal** effect under each conditional percentile. By using the QR, it is possible to investigate the relationship between returns and Beta at the lower and upper tail observations relative to the mean. Indeed, the LAD is a special case of QR at 0.5 percentile. In this paper, equity Beta is estimated at 0.05, 0.2, 0.4, 0.6, 0.8 and 0.95 percentile to investigate the consistency of the relationship. We agree that this choice is arbitrary but believe that a full coverage of percentiles will provide a more comprehensive result of the estimates.

With the above mentioned advantages compared with the OLS estimations, the QR method is applied widely recently in various areas of research after the approach was first introduced by Koenker and Bassett Jr (1978). Buchinsky (1998a) and Buchinsky (2002) applied this QR approach to analyze the female wage distribution in the US in relation to demographic characteristics. Then, Buchinsky (1998b) developed guidelines for empirical research using QR.

Taylor (1999) found some good achievement by practicing QR in estimating the distribution of daily Value at Risk. Yu, Lu, and Stander (2003) concluded that researchers in survival analysis, pharmaceutical and many other scientific areas of research have also applied QR in their studies. Recently, various papers used QR as a new approach to their empirical studies (Atella, Pace, & Vuri, 2008; Hung, Shang, & Wang, 2010; Ramdani & Witteloostuijn, 2010)

3.2.3. *Portfolio construction*

After estimating Beta for individual companies, some portfolios are constructed in order to provide a general view for those who are interested in more than 1 stock in the Utilities Industry. There are 2 set of portfolios used in this paper: (i) an equally-weighted portfolio and (ii) a value-weighted portfolio with the company's market capitalization being used as a weight. Furthermore, because companies in the sample were listed at different points in time, portfolios are updated every 6 months. For example, starting in January 2007, all companies listed within a period from January 2007 and June 2007 were used to form a portfolio. As a result, 14 portfolios are formed in this paper including 7 equally-weighted and 7 value-weighted portfolios (see Appendix 3 for the details of the companies in each portfolio).

The first portfolio, P1, includes PGC, PPC, SFC, SJD and VSH with the available data from 26th Jan 2007. The second portfolio adding ASP and KHP into P1 starts on the 15th Feb 2008. P3 adds MTG and TMP to P2. It is estimated from the 18th June 2009. Adding TBC, TIC, BTP and PGD to the current P3 yields P4 with the sample period starting from 26th Nov 2009. The fifth portfolio is considered from 11th Nov 2010 by including SBA and TDW to P4 and so on for the sixth and seventh portfolios.

3.2.4. *De-levered/Re-levered estimates of β*

Estimating beta for a particular company will implicitly assume the gearing level of a company in the estimation. As such, the estimates of equity beta for a particular company may not reflect an overall level of risk faced by the utilities industry in the context of the Vietnamese economy. The Vietnamese Government (as a seller) and investors may need to know the overall level of risk faced by the entire industry for their investment decisions. Following the practice adopted in Henry and Street (2014) and Vo et al. (2014) studies, all equity betas are de-levered using the relevant company's gearing ratio (for a particular company) or a portfolio's average gearing ratio (for a portfolio's estimates) over the examined period and re-levered using the average leverage ratio for the whole industry. Supposing that the debt β equals to zero, the de-levering/re-levering equation is:

$$\beta_A = \beta_E \frac{E}{V}$$

In which β_A and β_E are the asset β and equity β; E/V is the ratio between the market value of equity and the company's total asset. The gearing ratio is usually defined as the proportion of the book value of debt in the value of the company which is measured by its total asset. Considering $\bar{G}$ as the gearing ratio, $\overline{D}$ as the book value of debt and E is the market value of equity, then:

$$\bar{G} = \frac{\overline{D}}{\overline{D} + E}$$

Currently, for 19 companies in the Utilities industry in Vietnam, the average leverage ratio is approximately 42 percent. For the raw beta estimation, the following re-levering factor should be applied:

$$\omega = \frac{1 - \bar{G}}{1 - 0.42}$$

Assume that $\bar{G}$ is independent of $\hat{\beta}$ and ω is constant, the re-levered β, $\hat{\beta}_r$ has a mean of $\omega\hat{\beta}$.

4. Result and discussion

4.1. Individual companies' Beta estimates

The stock return used in the CAPM regression in this paper is the raw returns of the stocks. The weekly frequency is chosen to take advantage of avoiding the noisy in daily data and obtaining the statistical accuracy from many observations. VNI Index is considered as market index. The weekly return is measured by the change of return within a week, from last week Friday (closing price) and this week Friday (closing price). Table 2 reports the equity Beta estimated from OLS, LAD, and different quantiles for individual companies.

Table 2. Estimates of equity beta for individual companies, using the weekly return from Friday-to-Friday week closing prices

Source: Authors' analysis

Most Beta OLS estimates are statistically significant and lower than 1 – the market beta. When the market return changes by 1 percent, these stock returns would change in the same direction with a magnitude of less than 1 percent. However, the Quantile Regression results are mixed for some companies in the sample. Some key conclusions have been achieved as below.

- *First*, at various percentiles, the beta estimates are lower than 1 (the market beta)and these estimates are relatively stable in relation to the OLS method for the following companies BTP, CNG, GAS, PGD, SBA, SFC, SJD, TBC, TIC, and TMP. Although some estimates are not significant at τ = 0.95 (e.g. BTP, CNG, SBA, TIC and TMP). These outcomes point out that there is no biased tendency due to the heavy-tailed distribution in these companies.

- *Second*, for ASP, CLW, DRL, KHP, MTG and VSH, the beta estimates are interesting to note. While the OLS method and most percentiles under the QR method show that the equity betas are lower than 1, the 0.95 percentile regression indicates the estimates of greater than 1. This suggests at 95% percentile, these stock returns tend to fluctuate more than the fluctuation of the market returns. In other words, it presents evidence to confirm the existence of the upper tail observations and these presences make the OLS estimates biased. Especially, there is not only the upper tail but also the lower tail observations in the case of DRL. In particular, at τ = 0.05, Beta is 1.337, higher than the OLS Beta (0.764); at τ = 0.95, the Beta is even much higher (2.202).
- *Third*, there are two companies with Beta estimates higher than 1 at most estimations (i.e. PGC and PPC). While the Betas of PGC are stable and consistently higher than 1 with the average is 1.168, the PPC's Betas seem to be affected by the lower tail outliers. At 0.05 and 0.20 percentile, PPC's Betas are lower than 1 (0.752 and 0.869, respectively).
- *Last*, beta estimates for TDW are not statistically significant by all methods.

Table 2 presents beta estimates of individual companies in the sample when the alternative measurement of weekly return is used. The estimates are relatively similar and unchanged in comparison with outcomes presented in Table 3 when weekly return is measured as change in closing prices from last Friday to this Friday.

Table 3. Estimates of equity beta for individual companies, using the average of the daily returns within a week as weekly return

4.2. Beta estimates of various portfolios

Two set of portfolios including (i) an equally-weighted portfolio and a value-weighted portfolio are formed in order to provide a deeper analysis for more than 1 stock and to test the robustness of beta estimates for individual companies. Given the choice of the approach in which the weekly returns are measured does not affect beta estimates for individual companies, the Friday-to-Friday approach is used to construct the portfolios. Then the OLS, LAD and QR at different percentile approaches are all adopted. Table 3reports the equity Beta estimates for each portfolio:

Table 4. Estimates of portfolios equity beta

Equally-weight portfolios

Source: Authors' analysis

For the equally-weight portfolio, the estimates of Beta using the OLS, LAD and QR at all percentile except 95%fall within a range of 0.482 to 0.976. Moving from P1 to P6 by adding more companies to the portfolios will decrease the estimates of beta. However, Beta estimates of P7 increases compared to the decreasing trend from P1 to P6. This change may be due to a limited data available for P7 On the other hand, at 95% percentile regression, the estimates of

Beta fluctuate significantly across different portfolios. The estimates of Beta for P3 are 1.040, which is higher than the beta for the entire market. This higher-than-expected coefficient, in particular, and the fluctuation, in general, may be explained by the existence of heavy tail observations or outliers in the additional companies being added into P7.

For the value-weighted portfolio, the results are mixed. At 95% percentile regression, the estimates of Beta of P1, P2 and P3 are higher than 1. Moreover, Beta estimations of P1 and P2 are higher than 1 at some percentiles. Other estimates of Beta face a declining trend from P2 to P6 and increase in P7. Again, these changes could be a result of less and less available data in the sample under P7.

4.3. De-levered/Re-levered estimates of β

The weekly returns measured by the change of stock prices from closing price of last Friday and this Friday are also adopted in this analysis. The results of de-levered and re-levered Beta estimates of individual companies and portfolios are shown in Table 5 and Table 6.

Table 5. De-levered/Re-levered estimates of β for weekly frequency: Individual companies

	Gearing (%)	ω	OLS	LAD	τ=0.05	τ=0.20	τ=0.80	τ=0.95

Source: Authors' analysis

The de-levered/re-levered estimates of individual companies' equity β for the OLS estimates are from 0.446 to 1.263 while the corresponding de-levered LAD β estimates range from 0.351 to 1.279. The existence of outliers still affect seriously on the outcomes. For instance, at 95% percentile, the equity β of CLW, DRL, MTG, PGC, TBC and VSH are much higher than those obtained from OLS and LAD. Besides, the effect of lower tail observations can be seen at the 5% percentile regression for DRL.

Similarly, the de-levered estimates are applied for portfolio betas. Both the equally-weighted portfolios and the value-weighted portfolios results are quite stable with a magnitude of lower than 1 for all estimates except at the 95% percentile regression for P1.

Table 6. De-levered/Re-levered estimates of β for weekly frequency: Portfolios

	Gearing (%)	ω	OLS	LAD	τ = 0.05	τ = 0.20	τ = 0.80	τ = 0.95
Equally-weighted portfolios								
P1	45.31	0.943	0.858	0.873	0.713	0.825	0.920	0.852

5. Conclusion

The Vietnamese Government's effort to a process of privatization and equitization of key government owned assets has attracted attention from both Vietnamese and international investors. This process is considered unavoidable to pave a way for the national economy to fully integrate with the world economy. Privatization and/or equitization require a sale of government owned assets to the private investors. A question is how the government can determine a reasonable price for these assets to ensure that the Vietnamese people will get the fair share.

In response to this complicated question, this study is conducted to estimate a key input, the equity beta, adopted in the Sharpe Lintner CAPM, which then can be used to determine a rate of return on equity for the owner of the assets (the Government). This expected return on equity can be used to confirm whether or not current government owned businesses in the same or similar industry are efficient in running their businesses and/or to determine a fair price of the assets (the companies) should the Government decide to privatize and/or equitize these assets.

Using a sample of 19 listed companies operating in the Utilities Industry in the Ho Chi Minh City Stock Exchange for the period of more than 7 years (from 2007 to 2013 inclusive), a new approach (a Quantile Regression approach); together with the other two traditional approaches (the OLS and the LAD), have been used to estimate the equity beta for these listed firms in this study. Estimates of beta were conducted at the individual firms' level and at the portfolios' level. At the portfolios' level, two different types of portfolios are formed: (i) the equally-weighted portfolio; and (ii) the value-weighted portfolio.

Under all approaches, estimates of beta indicate that the appropriate value of the equity beta for companies operating in the Utilities Industry in Vietnam is 0.8 – which is still below the market beta of the entire market. This finding provides an evidence to conform that a level of risk faced by a company in the Utilities Industry is below the average of the level of risk for the entire market.

While it is well beyond the scope of this paper, an indicative quick estimate of an expected return on equity for utilities in Vietnam is approximately 12.4 per cent – an estimate using the Sharpe Lintner CAPM with equity beta of 0.8, the risk free rate of 6 per cent and the market risk premium of 8 per cent. It is obvious to note that these estimates require an update to reflect the prevailing market conditions for funds at different point in time. An estimate of 12.4 per cent in this paper can be used to set a benchmark and to compare with the realized return on equity of the Government owned businesses to confirm whether these companies are operating efficiently and/or to determine a fair price for the government owned assets to be sold to the private sector.

Profitability of Momentum Strategies: The Role of Consistent Winners and Losers

Momentum profits, resulting from buying winners and selling losers, are robust and persistent in the stock market; however, less than 60% of winner and loser stocks remain in winner and loser groups in the subsequent formation month. This study applies duration analysis to test the consistency of momentum effect and demonstrates that consistent winners and losers experience higher subsequent momentum profits than inconsistent winners and losers. Consistent with the information asymmetry hypothesis and the heterogeneous beliefs hypothesis, the momentum consistency is associated to size, idiosyncratic risk, institutional ownership, and trading volume. In addition, an asymmetric effect is observed that the post-formation return contributes to the winner consistency more, while the formation period return can explain the loser consistency more. The duration analysis also shows that the trading volume reflects effects of both heterogeneous beliefs among investors and the momentum lifecycle. The consistent momentum strategy may offer an enhanced performance despite controlling for factors associated to market risk, size, book-to-market ratio, momentum effect, and liquidity risk.

Keywords: Consistent winners; Consistent losers; Duration; Censored life regression; Trading volume; Heterogeneous beliefs; Momentum lifecycle; Consistent momentum strategy.

1. Introduction

Return continuations of individual stocks and equity indices in the intermediate term have been documented in the literature (e.g., see Jegadeesh and Titman, 1993; Chan, Jegadeesh, and Lakonishok, 1996, Rouwenhorst, 1998; Moskowitz and Granblatt, 1999; and Griffin, Ji, and Martin, 2003). The momentum strategy proposed by Jegadeesh and Titman (1993), taking a long position in the top decile and a short position in the bottom decile of companies raked by prior stock returns, becomes a benchmark for academics analyzing return continuation of equity and also a suggestive strategy for practitioners. Grinblatt, Titman, and Wermers (1995), Chen, Jegadeesh, and Wemers (2000), Chan, Chen, and Lakonishok (2002), and Jin and Scherbina (2011) show that mutual fund managers tend to utilize momentum strategies to enhance performances of their portfolios. However, we find a large variation in post-formation performance for momentum stocks, indicating momentum profits may be just average numbers and only contributed by certain winner and loser stocks. Given the limited number of stocks an investor or a fund manager can trade (see Sapp and Yan, 2008), buying a portion of winner stocks and selling a portion of loser stocks may not yield a positive return, and even face a potential lose.[1]

Studies demonstrate that a further sample-grouping can reduce number of securities in winners and losers portfolios, and yield more promising momentum profits. For example, Jegadeesh and Titman (1993) and Zhang (2006) find momentum strategy is more profitable in small stocks. Hong, Lim, and Stein (2000), Zhang (2006), Avramov, Chordia, Jostova, and Philipov (2007), Arena, Haggard, and Yan (2008), and Stambaugh, Yu, and Yuan (2012) show that momentum effect exists in stocks with lower analyst forecast coverage and credit rating, and higher analyst forecast dispersion, idiosyncratic volatility, and investor sentiment. Chen, Chen, Hsin, and Lee (2014) show that momentum profits can be enhanced by incorporating earnings and revenue information. However, back to the observation of large variation in post-formation performance for momentum stocks, the turnover of winner and loser stocks and the distribution of their post-formation returns are less well understood. Only a few studies conduct examinations on the return predictability of winners and losers in terms of the persistency of previous stock returns. For example, Watkins (2003) and Grinblatt and Moskowitz (2004) show that stocks with consecutive positive returns during the formation period will strongly outperform stocks with consecutive negative returns in the same horizon. Watkins (2006) finds short-term reversals for stocks with consistent positive or consistent negative previous weekly returns. However, the definition for winner and loser stocks by Watkins (2003), Grinblatt and Moskowitz (2004), and Watkins (2006) are quite different from Jegadeesh and Titman's (1993) winners and losers, and they only examine how the return components during the formation period can affect post-formation returns of stocks rather than investigate post-formation turnover rates and the distribution of post-formation returns for winner and loser stocks.

We therefore begin this study by investigating the distribution of post-formation returns and the turnover rates for stocks in winner and loser portfolios. A duration analysis provides us an avenue to tackle such tasks. We here define the duration of a winner (loser) stock as the

[1] Sapp and Yan (2008) show that an equity mutual fund holds only 90.85 stocks in average and 228.83 stocks in the top quintile.

number of month for which a winner (loser) stock can stay in the top (bottom) decile portfolio. Consistent winners (losers) are, therefore, winner (loser) stocks with duration greater than one, and inconsistent winners (losers) are winner (loser) stocks with zero duration. We find that at least one-quarter winner (loser) stocks experience negative (positive) post-formation returns and may make the momentum strategy face a potential lose if an investor coincidently longs for such winner stocks and shorts for such loser stocks. We also find that, in terms of 6-month formation period, more than 40% of winner and loser stocks are inconsistent winners and losers. The large dispersion of post-formation performance and high turnover rates for winner and loser stocks inspire us to further explore the difference of post-formation performance for consistent winners (losers) and inconsistent winners (losers). We subsequently separate winner (loser) stocks into two subsamples, consistent winners (losers) and inconsistent winners (losers), and examine their post-formation returns. Empirical results show that, in terms of post-formation performance, consistent winners experience a larger price appreciation than inconsistent winners, while consistent losers may lose more than inconsistent losers. Such different post-formation performance can last for more than six months.

Given the fact that consistent winners (losers) and inconsistent winners (losers) have significantly different post-formation performance. We are interested in finding determinants of consistent winners and losers. O'Hara (2003), Sadka (2006), and Chen and Zhao (2012) show that the greater information asymmetry will make investors react a firm's good news or bad news in a more conservative way, leading a delayed price adjustment. Allen, Morris, and Shin (2006), Hong and Stein (2007), Banerjee, Kaniel, and Dremer (2009), Verardo (2009) and Makarov and Rytchkov (2012) argue that higher heterogeneity among investors implies a stronger momentum effect. Instead of examining the magnitude of the delayed reaction by the literature, this study investigates the persistency of price adjustment induced by information asymmetry. Consistent with information asymmetry hypothesis and heterogeneous beliefs hypothesis, we find that winner and loser stocks with higher level of information asymmetry and higher degree of heterogeneous beliefs tend to be winners and losers in the next formation period. Moreover, in addition to the formation period returns, the post-formation returns also significantly contribute to the consistency for winner and loser stocks, indicating that consistent winners and losers do not only depend on their extreme returns during the formation period.

We further investigate how long the consistent winners and losers can sustain in winner and loser portfolios and try to find characteristics affecting winner and loser durations. Among consistent winners (losers) based on prior 6-month stock returns, 18.6% (19.0%) of those stocks have only a 1-month duration, 10.8% (10.9%) of those stocks have a 2-month duration, and around 97% of consistent winners and losers have a duration of less than 6 months. Consistent winners and losers with relative small size, low book-to-market ratio, high idiosyncratic volatility, and small institutional ownership will have longer duration as winners (losers). That is, investors tend to underreact stocks with greater information asymmetry, leading a momentum effect. In addition, the positive association between the duration and the trading volume indicates that the duration of momentum stocks will be longer if momentum stocks have higher degree of heterogeneous beliefs among investors. We also find that, in terms of duration of consistency, the formation period return plays a relatively important role for consistent losers, while the post-formation return is more important for consistent winners.

Besides exploring the consistency and future returns for winner and loser stocks, the duration analysis for the consistency also provides us an opportunity to reconcile the role of trading volume under heterogeneous beliefs hypothesis and momentum lifecycle hypothesis. Hong and Stein (2007) and Verardo (2009) argue that investors with different opinions on the liquidation value for a stock will trade in opposite directions and lead a higher trading volume, and therefore the trading volume can be a measure of the disagreement among investors. Verardo (2009) empirically show that higher heterogeneity among investors (higher trading volume) will lead a stronger momentum effect. In contrast, Lee and Swaminathan (2000) propose a momentum lifecycle hypothesis and demonstrate that low-volume winners and high volume losers do not attract investors' notice and have more persistent momentum effect, while high-volume winners and low-volume losers have caught the eye of investors and have relatively short-lived momentum effect. However, Lee and Swaminathan (2000) do not test the momentum lifecycle hypothesis at the individual firm level nor directly examine the persistency for winners and losers in different periods of favoritism. We therefore apply a censored life regression to test the persistency for winner and loser stocks and to decompose the effect on trading volume into the effect of heterogeneous beliefs and the effect of momentum lifecycle. Results show that the trading volume reflects effects of both heterogeneous beliefs and momentum lifecycle, while the effect of momentum lifecycle cannot dominate the effect of heterogeneous beliefs.

Finally, given the fact that consistent winners and losers have stronger and more persistent momentum effect, we conduct a consistent momentum strategy by buying consistent winners and selling consistent losers. A consistent momentum strategy is found to yield monthly returns as high as 1.25%, which amounts to an annual return of 15%. Such a consistent momentum strategy outperforms original momentum strategy by almost 20 basis points in monthly return (more than 20% improvement). The superior profits for consistent momentum strategy remain robust after adjusting for capital asset pricing model, the Fama-French three-factor model, Carhart's (1997) momentum factor, and Pastor and Stambaugh's (2003) liquidity factor.

Overall, this study contributes to finance literature in several ways. First, this study provides an evidence of implementation cost for the momentum strategy. Knez and Ready (1996), Shleifer and Vishny (1997), Grundy and Martin (2001), Korajczyk and Sadka (2004) argue that the trading cost may deterring investors from applying momentum strategy, while the effect of trading costs cannot fully explain momentum profits. This study demonstrates a large dispersion of post-formation returns and a high turnover rate for winner and loser portfolios, indicating that not all of winner and loser stocks follow the mid-term return continuation. The momentum strategy contains an implementation risk that investors would face a potential loss if they cannot long for all of winner stocks and short for all of loser stocks. Such implementation risk, one of indirect implementation cost for the momentum strategy, is new to literature and may present a venue to track the sources of the momentum effect. Second, this study confirms the role of information asymmetry and heterogeneous beliefs in the momentum consistency. Literature demonstrate that, in terms of momentum profits, the momentum effect is stronger among stocks with more serious information asymmetry and larger difference of opinions among investors. However, those studies either keep silent or indirectly show that information asymmetry and heterogeneous beliefs can enhance the consistency of momentum effect. This study fills in the gap providing a direct test on the consistency of momentum effect, and shows that information asymmetry and heterogeneous beliefs do enhance the persistency of momentum effect. Third, this study reconciles the role of trading volume under heterogeneous beliefs hypothesis proposed and momentum lifecycle hypothesis by decomposing the effect of trading volume. To the best of our knowledge, this study is the first to offer evidence that the trading volume reflects effects of both heterogeneous beliefs and momentum life cycle, while the effect of momentum life cycle cannot dominate the effect of heterogeneous beliefs. Last, this study finds a consistent momentum strategy may offer monthly return as high as 1.25%, which outperforms Jegadeesh and Titman's (1993) momentum strategy by 19 basis points. Aside from academic interest, we believe that our findings can serve as a useful guide for asset managers seeking profitable investment strategies.

The paper is organized as follows. In Section 2, we describe the methodologies and the data used in this study. In Section 3, we discuss how consistent winners and losers affect momentum profits and the determinants of consistent winners and losers. In Section 4, we discuss the role of trading volume under the information asymmetry hypothesis and the heterogeneous beliefs hypothesis. In Section 5, we test the profitability of consistent momentum strategies. Section 5 concludes.

2. Methodology and data description

2.1. *Durations for winners and losers*

We first construct winner and loser portfolio according to the approach suggested by Jegadeesh and Titman (1993). At the end of each month, we identify our sample as those stocks which have complete data available for their past *J*-month returns (J = 3, 6, 9, and 12) and subsequent 24-month returns. We rank those sample stocks into deciles based on their prior *J*-month returns, and group the stocks into 10 equally weighted portfolios. Sample stocks in the top decile portfolio are called "winners," and those in the bottom decile are called "losers." A duration for a winner (loser) stock is defined as the number of month which a winner (loser) stock is continuously ranked in the top (bottom) decile portfolio in the following months. The durations for winner stocks and for loser stocks can, therefore, be expressed as

$$Duration_{i,t}^{W} = \sum_{k=t+1}^{t+24} I_{i,k} \ , \tag{1}$$

where $I_{i,k}$ is one if stock *i* is in the winner portfolio from *t* to *k*, and zero otherwise; and

$$Duration_{i,t}^{L} = \sum_{k=t+1}^{t+24} I'_{i,k} \ , \tag{2}$$

where $I'_{i,k}$ is one if stock *i* is in the loser portfolio from *t* to *k*, and zero otherwise.

We further identify consistent winners as the winner stocks with duration greater than one, and consistent losers as loser stocks with duration greater than one. For example, a winner stock in month *t* has the highest ranked returns from month *t-J+1* to month *t*, while a consistent loser in month *t* are defined as a stock has the lowest ranked returns for at least two consecutive periods, from *t-J+1* to *t* and from *t-J+2* to *t+1*.

Only few studies investigate the role of return consistency. Watkins (2003) and Grinblatt and Moskowitz (2004) find stocks with consistent positive returns over a period yields higher future returns, and demonstrate that return consistency can predict future stock returns. In contrast, this study focuses on stocks in winner and loser portfolios based on their previous returns and treats a winner (loser) stock as a consistent winner (loser) if it stays in winner (loser) portfolio in the following formation months. The measure of consistency, durations for winners and losers, used in this study has two advantages. First, consistent winners (losers) defined in this study should be stocks stay in winner (loser) group for at least two consecutive months, while consistent winning (losing) stocks defined by Watkins (2003) and Grinblatt and Moskowitz (2004) are not necessary to be winners (losers) during the formation period. This study is to investigate post-formation performance of winner (loser) stocks with different consistency, and hence the consistency measure used in this study is more appropriate. Second, Watkins (2003) and Grinblatt and Moskowitz's (2004) consistency is so restrictive that, on average, only 1.32% (1.12%) of observations are consistent winning (losing) stocks, whereas this study has 60.71% (59.59%) consistent winners (losers). Hence, this study can be free from small sample size problem and provide trustworthy implications for the analyses of consistent winners and losers.

2.2. *Data*

We collect the basic firm information and the firm accounting data from COMPUSTAT, and obtain stock price, stock returns, trading volume, market capitalization, share codes, and exchange codes from Center for Research in Security Prices (CRSP). Institutional holdings are compiled quarterly from SEC 13-F filing. The sample period is from 1980 through 2011. Only common stocks (SHRCD = 10, 11) and firms traded on the NYSE, AMEX, or NASDAQ are included in our sample. We exclude closed-end funds, Real Estate Investment Trusts (REITs), American Depository Receipts (ADR), utility services, and financial institutions. We also exclude firms with stock prices below $5 on the formation date, considering that investors generally pay only limited attention to such stocks. To investigate durations for winner and loser stocks and their price performance, firms in our sample should have at least six consecutive monthly returns prior to the formation month and at least 24 consecutive monthly returns after the formation month. In addition, firms in our sample should have their corresponding size, book-to-market ratio, turnover, idiosyncratic volatility, and institutional ownership in each formation month.

To ensure that the firm accounting information is available to the public investors at the time the stock returns are recorded, we follow the approach of Fama and French (1992) and match the accounting data for all fiscal year ending in calendar year *t*-1 with the returns for July of year *t* to June of *t*+1. The market capitalization is calculated by the closing price of the last trading day of June of that year times the number of outstanding shares at the end of June of that year. Book-to-market ratio is calculated as a firm's book value of common equity for the fiscal year ending in year *t*-1 divided by its market equity at the end of December in year *t*-1. We adopt Lee and Swaminathan's (2000) method to obtain a firm's monthly turnover as the average daily ratio of the number of share traded to the number of shares outstanding.[2] Similar to Ali, Hwang, and Trombley (2003), the idosyncratic volatility is defined as the residual variance from regressing of a firm's daily excess returns on market daily excess returns over the past 12 months. Institutional ownership is the percentage of outstanding shares held by institutional investors.

2.3. *Distribution of momentum profits and turnover rates of winner and loser portfolios*

Table 1 presents the distribution of post-formation performance for winner and loser stocks. In terms of 6-month post-formation performance for winner and loser stocks on the basis of their prior 6-month returns, winner stocks experience an average 0.5% price appreciation with a standard deviation as high as 3.2%, and loser stocks suffer 1% loss with a standard deviation of 4.2%. In addition, the first quartile performance for winner stocks is -0.13%, and the bottom quartile performance for loser stock is 1.4%. Consistent with Lesmond, Schill, and Zhou (2004), the finding of large variation of post-formation performance for winner and loser indicates that not all of winner and loser stocks follow the finding of mid-term return continuity. On the contrary, at least one quarter of winner and loser stocks appear a contrarian pattern in the intermediate future after the formation month. Therefore, although a momentum strategy can statistically generate a significantly positive return, high standard deviations of the post-formation performance for winner and loser stocks may lead a potential loss if investors randomly long and short for a small portion of winner and loser stocks.

[Insert Table 1 about here]

Table 2 summarizes the average turnover rates for winners and losers portfolio based on different formation periods. In terms of six-month formation period, 60.71% of winner stocks and 59.59% loser stocks will stay in winner and loser group in the following one month. There are 0.83% (0.95%) of winner (loser) stocks will turn to be losers (winners) just one month after they are ranked as winners and losers.[3] We understand that a turnover happens when a winner (loser) stock is not ranked as the top (bottom) decile if we retire its most previous monthly return and include its most recent monthly return one month after formation date. The observation that only a change of $1/J$ formation period return will make near 40% of winner and loser stocks out of winners and losers groups confirms the

[2] Gould and Kleidon (1994) show that trading volume for NASDAQ securities may be inflated due to the double counting of dealer trades. We therefore follow Anderson and Dyl (2005) to scale down the trading volume for NASDAQ securities by 50% before 1997 and by 38% after 1997.

[3] One may argue that inconsistent winner stocks are those winner stocks with lower formation period returns, and hence are easily dropped from the winner portfolio next month. We therefore further divide sample firms into 20 groups in each formation month and investigate turnover rates for extreme winner and loser portfolios. Appendix A shows that only 56.08% of top 5% winners and 54.29% of bottom 5% losers stay in extreme portfolios, indicating that the consistency of momentum portfolios is not driven by extreme previous formation period performance.

importance of the role of the subsequent monthly returns for winner and loser stocks. It also indicates an existence of a large difference of post-formation performance between consistent winners (losers) and inconsistent winners (losers). The fact that large variation of post-formation performance and high turnovers for winner and loser stocks therefore inspires us to further explore price behaviors for consistent and inconsistent momentum portfolios.

[Insert Table 2 about here]

3. Momentum profits for consistent and inconsistent momentum portfolios

3.1. *Post-formation performance of consistent and inconsistent momentum portfolios*

We here divide winner (loser) stocks into consistent winner (loser) group and inconsistent winner (loser) group, and examine their post-formation performance. Panel A of Table 3 presents the averages of subsequent 13 monthly returns after the formation month *t* for consistent winners and inconsistent winners. The 6-month formation period winner stocks experience an average of 2.7% monthly return (R_{t+1}) one month after the formation month, while consistent winners have as high as 7.3% monthly return and inconsistent losers have a loss of 4.9%. By definition, consistent winners are those winner stocks stay in winners group in the next formation month, so it is reasonable that consistent winners have higher monthly returns one month subsequent to the formation date.[4] However, in terms of raw return and risk-adjusted return, we can find significant different post-formation performance between consistent winners and inconsistent winners up to seven months after the formation month. A strong post-formation performance for consistent winners relative to inconsistent winners can also be observed for winner portfolios with different formation periods. Similar results for loser portfolios as shown in Panel B of Table 3 that, relative to inconsistent losers, consistent losers experience large losses one month after the formation month, while the relatively bad price performance for consistent losers can last for eight months after the formation month. Figures 1 and 2 depict the average buy and hold return for consistent and inconsistent momentum portfolios in various formation periods. In addition, a large spread of holding returns between consistent and inconsistent momentum portfolios provide us an opportunity to utilize a zero-investment strategy to generate a positive return. We will discuss consistent momentum strategies in Section 5.

[Insert Table 3 about here]

[Insert Figure 1 about here]

[Insert Figure 2 about here]

Besides the finding of significantly different post-formation performance between consistent and inconsistent momentum portfolios, results from Table 3 also provide some interesting implications on the implementation of momentum strategy. As suggested by Jegadeesh and Titman (1993), momentum strategies usually skip a week between formation period and

[4] Our results are still held when we skip one week in calculating post-formation returns to avoid bid-ask bounce.

holding period to avoid short-term reversal induced by bid-ask bounce, price pressure, and lagged reaction effects documented in Jegadeesh (1990) and Lehmann (1990). However, stocks with strong short-term reversal are typically treated as inconsistent winners or losers, and may experience a weak momentum effect in the future as Table 3 shows. That is, even though skipping one week in momentum strategy can avoid a short-term reversal due to bid-ask bounce, price pressure, or lagged reaction, an investor or a fund manager may get relatively weak momentum profits if they coincidently include inconsistent winners or losers into their momentum portfolios.

3.2. *Determinants of consistent and inconsistent momentum portfolios*

Given the different post-formation performance between consistent and inconsistent momentum portfolios, we subsequently try to find determinants of the consistency. Specifically, we use a cross-sectional Probit regression to examine what factors can make a winner (loser) stock to be a consistent winner (loser) or not. The model specification is denoted as

$$\begin{aligned} P\left(Duration_{i,t}^{W} > 0\right) = a_t + b_{1,t}\ln(Size)_{i,t} + b_{2,t}BM_{i,t} + b_{3,t}Ivol_{i,t} + b_{4,t}IO_{i,t} \\ + b_{5,t}Turnover_{i,t} + b_{6,t}R_{i,t-J+1,t} + b_{7,t}R_{i,t,t+1} + \varepsilon_{i,t} \end{aligned}, \text{ and} \tag{3}$$

$$\begin{aligned} P\left(Duration_{i,t}^{L} > 0\right) = a_t + b_{1,t}\ln(Size)_{i,t} + b_{2,t}BM_{i,t} + b_{3,t}Ivol_{i,t} + b_{4,t}IO_{i,t} \\ + b_{5,t}Turnover_{i,t} + b_{6,t}R_{i,t-J+1,t} + b_{7,t}R_{i,t,t+1} + \varepsilon_{i,t} \end{aligned}, \tag{4}$$

where $Duration_{i,t}^{W}$ and $Duration_{i,t}^{L}$ are durations for a winner stock and a loser stock, and the dependent variable is one if a winner (loser) stock has a non-zero duration, and zero otherwise. Independent variables are the natural logarithm of firm size, book-to-market ratio, the monthly turnover, idiosyncratic volatility, institutional ownership, previous *j*-month return (j = 3, 6, 9, and 12), and one-month post-formation return.

Table 4 presents the time-series averages of estimates from Probit regressions. We find that both the formation-period return and the one-month return subsequent to the formation month are important in determining consistent winners and losers. The significance of post-formation performance implies that to be a consistent winner or lower stock does not solely depend on its previous higher or lower returns, but also depend on its most recent price performance. Controlling for returns before and after formation month, we also find that, among winner and loser stocks, stocks with smaller size, higher turnover, higher indiosyncratic volatility, and lower institutional ownership yield a higher probability to be consistent winners or losers. As shown in Table 3 that consistent winners and losers will have relatively pronounced momentum effect during the post-formation period. Therefore, our findings support the argument that investors will underreact new information for firms with more degree of information asymmetry and larger divergence of investors' opinions, resulting a stronger and more persistent momentum effect.

[Insert Table 4 about here]

3.3. *Durations for momentum portfolios*

We further investigate how long the consistent winners and losers can sustain in winner and loser portfolios and try to find characteristics affecting winner and loser durations. To avoid double count on firm-months in the same duration period, we restrict our sample firms to those winner and loser stocks which do not belong to winner and loser portfolio in the previous formation month. Table 5 presents distributions of duration for winner stocks and loser stocks in different formation periods. For the six-month formation period, 46.69% of winners and 47.00% of losers have zero duration, and the rest of 53.31% of winners and 53.00% of losers are consistent winners and consistent losers. Around 19% of winners and losers can only stay in momentum portfolios for consecutive two months (duration is equal to one month), around 11% of winners and losers can stay in momentum portfolios for consecutive three months (duration is equal to two month), and around 95% of winners and losers cannot sustain in momentum portfolios longer than seven months (duration is equal to six month). The average durations are 0.889 months for all winners and 1.914 months for consistent winners; while the average durations are 0.836 months for all losers and 1.855 months for consistent losers. The observation of short durations for winner and loser stocks indicate that, when an investor implements momentum strategies, including short-duration momentum stocks may result higher frequency of stock turnovers and higher transaction cost. That is, if a momentum strategy investor coincidently chooses inconsistent winners and losers into his momentum portfolio, not only the relatively poor post-formation performance, but also a higher transaction cost he will face. We are, therefore, interested in finding characteristics which affect winner and loser durations.

[Insert Table 5 about here]

3.4. *Determinants of the duration for momentum portfolios*

In this section, we attempt to examine whether information asymmetry hypothesis, heterogeneous beliefs hypothesis, or other factors can determine the duration of momentum portfolios. Atiase (1985) and Huddart and Ke (2007)suggest that a firm with small size, lower book-to-market ratio, and lower institutional ownership may suffer more serious information asymmetry problem, and lead investors react the new information of such firm more conservatively. A stronger momentum effect can therefore be found in firms with higher degree of information asymmetry (e.g. Zhang, 2006; and Chen and Zhao, 2012). In addition, Harris and Ravid (1993), Shalen (1993), Gebhardt, Lee, and Swaminathan (2001), Boehme, Danielsen, and Sorescu (2006), Hong and Stein (2007), and Verardo (2009) show that the idiosyncratic volatility and/or the trading volume can represent the degree of heterogeneous beliefs of investors on a firm. If a firms has higher trading volume or higher idiosyncratic volatility, the large divergence of investors' opinions will also lead a stronger momentum effect on the stock return of the firm (e.g. Hong and Stein, 2007; and Verardo, 2009). However, those studies only investigate the relative strength of momentum effect in terms of the magnitude of post-formation returns rather than the consistency of momentum effect. The duration analysis provides us an opportunity to examine whether factors associate to information asymmetry and heterogeneous beliefs can affect the consistency of momentum effect, more specifically, the duration for consistent winners and losers. We apply a life regression model with censored data used by Ongen and Smith (2001) and Deville and Riva (2007)to deal with the dependent variable, the duration of consistent winners and losers, censored between zero and twenty four.[5] The model specification is denoted as

$$\begin{aligned} Duration_{i,t} = {} & a_t + b_{1,t}\ln(Size)_{i,t} + b_{2,t}\ln(Size)_{i,t} * D_{i,t} + b_{3,t}BM_{i,t} + b_{4,t}BM_{i,t} * D_{i,t} + b_{5,t}Ivol_{i,t} + b_{6,t}Ivol_{i,t} * D_{i,t} \\ & + b_{7,t}IO_{i,t} + b_{8,t}IO_{i,t} * D_{i,t} + b_{9,t}Turnover_{i,t} + b_{10,t}Turnover_{i,t} * D_{i,t} \\ & + b_{11,t}\left|R_{i,t-J+1,t}\right| + b_{12,t}\left|R_{i,t-J+1,t}\right| * D_{i,t} + b_{13,t}\left|R_{i,t,t+1}\right| + b_{14,t}\left|R_{i,t,t+1}\right| * D_{i,t} + \varepsilon_{i,t} \end{aligned} \quad , (5)$$

where the dependent variable is the duration for consistent momentum stocks, and independent variables are the natural logarithm of firm size, book-to-market ratio, the monthly turnover, idiosyncratic volatility, institutional ownership, absolute value of previous J-month return (j = 3, 6, 9, and 12), absolute value of previous j-month return times winner dummy, absolute value of one-month post-formation return, and absolute value of one-month post-formation return times winner dummy. Besides investigating the effect of information asymmetry and heterogeneous beliefs on momentum consistency, we also examine the role of formation period performance and post-formation performance in determining the duration for consistent momentum stocks. Table 6 shows results of the censored life regressions. Consistent with information asymmetry hypothesis and heterogeneous beliefs hypothesis, the momentum duration is positively associated to idiosyncratic volatility and monthly trading volume, and negatively associated to size, book-to-market ratio, and institutional ownership. Specifically, if consistent winner and loser stocks have relatively higher idiosyncratic volatilities, higher trading volume, smaller size, lower book-to-market ratio, and lower institutional ownership, those stock prices are underreacted to new information due to investors' conservatism and different opinions. Hence, those consistent winner and loser stocks can sustain in winner and loser portfolios for a longer period.

[Insert Table 6 about here]

Table 6 also shows that both formation period performance and one-month post-formation return can determine the duration of consistent winners and losers. The significantly positive coefficients indicate the higher formation period returns and higher monthly return after the formation date can extend the duration of consistent winner and loser stocks. Moreover, we find a slightly negative on the interaction between winners dummy and formation period performance and a significantly positive coefficient on the interaction between winners dummy and one-month post-formation return. The asymmetry effect on the duration between consistent winners and losers indicates that, in terms of the duration of consistency, the post-formation performance plays a more important role for consistent winners than consistent losers, while the formation period performance is relatively less important for consistent winners than consistent losers.

---

[5] Estimations of ordinary least square would be biased if the dependent variable violates normality assumption. It is obvious that the dependent variable in Eq. (5), the duration of momentum portfolios, is between zero and twenty-four. We therefore adopt a censored life regression model to investigate the influence of explanatory variables on the right-censored dependent variable.

4. Heterogeneous beliefs and momentum life cycle

Besides examine the consistency of momentum effect, the duration analysis for the consistency also provide a venue to examine effects of the trading volume under heterogeneous beliefs hypothesis proposed by Hong and Stein (2007) and Verardo (2009) and under the momentum lifecycle hypothesis proposed by Lee and Swaminathan (2000). Hong and Stein (2007) demonstrate that even investors receive same information signals, their different analysis models may result in different opinions on the liquidation value for a stock. The existence of disagreement among investors for a stock may induce investors to trade with one another, leading a higher trading volume on the stock. Hong and Stein's (2007) disagreement model also shows that the momentum effect should be more pronounced in those stocks with higher trading volume. Verardo (2009) provides an empirical evidence that momentum effect is stronger for stocks with higher trading volume. In contrast, Lee and Swaminathan (2000) propose a momentum lifecycle hypothesis, in which stocks experience periods of investor neglect will have stronger and more persistent momentum effect, while stock under periods of favoritism will have relatively less momentum effect in terms of magnitude and persistency. They suggest that trading volume may provide information useful in locating the degree of favoritism for a stock. Specifically, low-volume winners and high volume losers are during the periods of neglect and have more persistent momentum effect, while high-volume winners and low volume losers are during the periods of favoritism and have relatively short-lived momentum effect. However, Lee and Swaminathan (2000) do no directly examine the persistency for winners and losers in different periods of favoritism.

The trading volume therefore may be positively associated to momentum consistency if the trading volume stand for the degree of heterogeneous beliefs among investors, while the trading volume may be positively associated to winner consistency and negatively associated to loser consistency if the trading volume represents the degree of favoritism for a stock. We here take advantage of the censored life regression to decompose the effect of trading volume into the effect of heterogeneous beliefs and the effect of momentum life cycle.

$$\begin{aligned} Duration_{i,t} &= a_t + b_{1,t}\ln(Size)_{i,t} + b_{2,t}BM_{i,t} + b_{3,t}Ivol_{i,t} + b_{4,t}IO_{i,t} + b_{5,t}Turnover_{i,t} \\ &+ b_{6,t}Turnover_{i,t} * D_{i,t} + b_{7,t}\left|R_{i,t-J+1,t}\right| + b_{8,t}\left|R_{i,t-J+1,t}\right| * D_{i,t} + b_{9,t}\left|R_{i,t,t+1}\right| + b_{10,t}\left|R_{i,t,t+1}\right| * D_{i,t} + \varepsilon_{i,t} \end{aligned}, \quad (6)$$

where the dependent variable is the duration for consistent momentum stocks, and independent variables are the natural logarithm of firm size, book-to-market ratio, the monthly turnover, the monthly turnover times winner dummy, idiosyncratic volatility, institutional ownership, absolute value of previous *j*-month return (*j* = 3, 6, 9, and 12), absolute value of previous *j*-month return times winner dummy, absolute value of one-month post-formation return, and absolute value of one-month post-formation return times winner dummy. If the trading volume represents heterogeneous beliefs among investors, higher trading volume may lead longer momentum consistency and a positive estimated coefficient on turnover can be observed. If the trading volume stands for favoritism for a stock under the momentum lifecycle hypothesis, higher trading volume will contribute a shorter momentum consistency for winner stocks than that for loser stocks. Therefore, the estimated coefficient on the interaction of turnover and winner dummy will be negative.

Table 7 shows estimation results of censored life regressions. The significantly positive coefficients for the turnover support the prediction of heterogeneous beliefs hypothesis and the loser part of momentum lifecycle hypothesis. The significantly negative coefficients for the interaction between the turnover and winner dummy confirm the effect of the winner part of momentum lifecycle hypothesis. Our results show that the trading volume reflects effects of both heterogeneous beliefs hypothesis and momentum lifecycle hypothesis. However, the magnitudes of the negative coefficients for the interaction term is smaller than those of the positive coefficients for the turnover, implying that, at least for winners, the effect of momentum lifecycle cannot dominate the effect of heterogeneous beliefs.

[Insert Table 7 about here]

5. Consistent momentum strategies

Table 3 presents a large spread of post-formation returns between consistent and inconsistent momentum portfolios. In addition, the higher degree of information asymmetry and heterogeneous beliefs among investors for consistent winner and loser stocks may make the momentum effect last longer. Our findings then suggest that a consistent momentum strategy using one more monthly return information should offer improved momentum profits. Specifically, the enhanced performance of a consistent momentum strategy can be observed by taking a long positions for consistent winners and a short position for consistent losers and holding the portfolio for subsequent six months.[6] Panel A of Table 8 provides raw and adjusted returns to consistent momentum strategy, inconsistent momentum strategy, and traditional momentum strategy suggested by Jegadeesh and Titman (1993). In terms of six-month formation period and six-month holding period, a consistent momentum strategy yields a monthly raw return as high as 1.25%, which is significantly higher than those returns earned by inconsistent momentum strategy (0.47%) and by traditional momentum strategy (1.06%). That is, investors can earn an average monthly return 1.25% by buying consistent winner stocks and selling consistent loser stocks, which outperforms the traditional momentum strategy by almost 19 basis points.

[Insert Table 8 about here]

The superior performance for consistent momentum strategy is still held after adjusting for capital asset pricing model, the Fama-French three-factor model, Carhart's (1997) momentum factor, and Pastor and Stambaugh's (2003) liquidity factor. Note that, profits from traditional momentum strategies and inconsistent momentum strategies can be explained away by Fama-French 3-factors and Carhart's momentum factor, whereas 3-month formation period and 6-month formation period consistent momentum strategies can sustain significantly positive profits after adjusting by Fama-French 3-factors and Carhart's momentum factor.

One may argue that the superior performance of consistent momentum strategies is because consistent momentum strategies include one more month information than traditional

---

6 Because we need one more monthly return to define winners (losers) as consistent winners (losers) and inconsistent winners (losers), the implementation date of the consistent momentum strategy is one month after the formation date of the traditional momentum strategy.

momentum strategies. To tackle such possible explanation, as shown in Panel B of Table 8, we further conduct a traditional momentum strategy with a 7-month formation period and obtain a monthly raw return of 1.09%. Comparing to the consistent momentum strategy, which yields 1.28%, the 7-month formation period momentum strategy still cannot perform as well as the consistent momentum strategy. We therefore conclude that the higher profitability of consistent momentum strategies is not due to the more information generated, but due to investors' conservatism toward consistent momentum stocks.

6. Conclusion

This paper conducts a comprehensive analysis on the consistency of momentum effect. We show that only 60% of winner and loser stocks can be consistent winners and losers and at least 25% of winner and loser stocks experience a contrarian effect rather than momentum effect. Such high turnover rates and large return dispersions in the post-formation period for momentum stocks not indicate that momentum strategy not only involves a higher direct implementation cost, transaction cost, but also contains an indirect implementation cost that momentum investors may face a potential loss if they cannot include all of winner stocks and loser stocks in their portfolio.

We find, in the post-formation period, consistent winner stocks outperform inconsistent winner stocks, while consistent loser stock will continuously underperform inconsistent loser stocks. The finding of a large spread of post-formation returns between consistent and inconsistent momentum portfolios confirms the importance of consistency for momentum portfolios in determining the strength of the momentum effect. In addition, this pattern also indicates a zero-investment strategy by buying consistent winners and selling inconsistent winners. An enhanced trading strategy, consistent momentum strategy, is therefore found, yielding an average monthly return of 1.25% and remaining significant after adjusting for various asset pricing factors.

Behavioral explanations to the momentum effect, including the information asymmetry hypothesis and heterogeneous beliefs hypothesis, show that investors' conservatism and divergence of their opinions to the liquidation value of a company may lead a delayed reaction to the stock price of such company. Results of the duration analysis provide a new evidence that both information asymmetry hypothesis and heterogeneous beliefs hypothesis can explain not only the magnitude of momentum profits but also the persistency of the momentum effect. We also find an asymmetric effect that the post-formation return contributes to the winner consistency more, while the formation period return can explain the loser consistency more. Moreover, the duration analysis provides us an opportunity to directly examine the momentum lifecycle hypothesis, which lower favoritism winner stocks and neglected loser stocks have more persistent momentum effect. Using the trading volume to proxy for investors' favoritism, the duration analysis supports the argument of momentum lifecycle hypothesis, while the effect of momentum lifecycle hypothesis cannot dominate the effect of information asymmetry.

As mentioned earlier, the momentum effect is robust and persistent in the stock market for more than four decades, while the consistency of winner and loser stocks is less well understood. This paper contributes to the extant finance literature in presenting new evidence on the market efficiency with respect to the momentum consistency. The further research is necessary in tracing the distribution and the consistency of post-formation performance for momentum portfolios.

Table 1. The distribution of momentum profits

This table presents distributions of various holding period returns for winner and loser stocks. At the end of each month from January 1960 to December 2011, all stocks are ranked by their prior *J*-month return (*J* = 3, 6, 9, and 12) and assigned to one of deciles. Stocks in the highest prior return decile are winners, and stocks in the lowest prior return decile are losers. *K*-month (*K* = 3, 6, 9 and 12) holding period return are equally-weighed *K*-month returns holding winner or loser group. Mean, standard deviation, minimum value, the first quartile, median, the bottom quartile, are maximum value for various holding period returns are presented.

		Winners				Losers

Table 2. Turnover rates of momentum portfolios

This table reports the average turnover rates for winner and loser stocks in the next formation month. At the end of each month, winner stocks are those stocks with top decile previous *J*-month (*J*= 3, 6, 9, and 12) returns, while loser stocks are those stocks with bottom decile previous *J*-month returns. Panel A presents average percentages of winner stocks which will be ranked and assigned to a certain decile in the next formation month. Panel B presents average percentages of loser stocks which will be ranked and assigned to a certain decile in the next formation month.

Panel A: Winner stocks										
J	P1(Losers)	P2	P3	P4	P5	P6	P7	P8	P9	P10(Winners)
3	1.784%	1.982%	2.204%	2.600%	3.154%	4.189%	6.037%	9.746%	19.257%	47.242%
6	0.832%	0.842%	0.890%	1.109%	1.432%	2.110%	3.584%	7.194%	19.697%	60.713%

12	67.968%	18.977%	4.933%	2.084%	1.291%	0.954%	0.799%	0.739%	0.711%	0.839%

Table 3. Average post-formation returns for consistent and inconsistent momentum portfolios

This table reports average monthly post-formation returns for consistent and inconsistent momentum stocks. At the end of each month, winner stocks are those stocks with top decile previous *J*-month (*J*= 3, 6, 9, and 12) returns, while loser stocks are those stocks with bottom decile previous *J*-month returns. Consistent winners (losers) are those winner (loser) stocks stay in winner (loser) group both in the formation month *t* and in the next formation month *t*+1, while inconsistent winners (losers) are those winner (loser) stocks do not stay in winner (loser) group in the next formation month *t*+1. Panel A presents the subsequent 13 monthly equally-weighted returns for winners, consistent winners, and inconsistent winners. Panel B presents the subsequent 13 monthly equally-weighted returns for losers, consistent losers, and inconsistent losers.

Table 4. Characteristics of consistent momentum portfolios

This table presents the time-series averages of estimates from Probit regression models. The cross-sectional regression is estimated for each month during the period of 1981 to 2011, with all of winner and loser stocks listed on NYSE, AMEX, or NASDAQ. Coefficients estimated from the cross-sectional regressions are then averaged over the months. The models are as follows:

$$P\left(Duration_{i,t}^{W} > 0\right) = a_t + b_{1,t}\ln(Size)_{i,t} + b_{2,t}BM_{i,t} + b_{3,t}Ivol_{i,t} + b_{4,t}IO_{i,t} + b_{5,t}Turnover_{i,t} + b_{6,t}R_{i,t-J+1,t} + b_{7,t}R_{i,t,t+1} + \varepsilon_{i,t}$$

$$P\left(Duration_{i,t}^{L} > 0\right) = a_t + b_{1,t}\ln(Size)_{i,t} + b_{2,t}BM_{i,t} + b_{3,t}Ivol_{i,t} + b_{4,t}IO_{i,t} + b_{5,t}Turnover_{i,t} + b_{6,t}R_{i,t-J+1,t} + b_{7,t}R_{i,t,t+1} + \varepsilon_{i,t}$$

The dependent variable is one if a winner (loser) stock has a non-zero duration, and zero otherwise. A duration for a winner (loser) stock is defined as the number of month which a winner (loser) stock is continuously ranked in the top (bottom) decile portfolio in the following months after the formation date. The independent variables are the natural logarithm of firm size, book-to-market ratio, the idiosyncratic volatility, institutional ownership, monthly turnover, previous J-month return (J = 3, 6, 9, and 12), and one-month post-formation return. The idiosyncratic volatility is the residual variance from regressing of a firm's daily excess returns on market daily excess returns over the past 12 months. Institutional ownership is the percentage of outstanding shares held by institutional investors. The monthly turnover is the average daily ratio of the number of share traded to the number of shares outstanding within one month. Newey-West t-statistics are shown in parentheses. *, **, and *** denote statistical significance at the 10%, 5%, and 1% respectively.

Table 5. Distribution of winner/loser durations

We report the percentage and the number of observation for each duration length. Duration is the maximum length of time that a winner (loser) being winner (loser) in the subsequent month(s). To avoid the overlapping problem when computing durations, we also report the non-overlapping durations of the whole sample for each duration length. Panel A and Panel B show winners' overlapping and non-overlapping duration distributions, and Panel C and Panel D show losers' overlapping and non-overlapping duration distributions.

Table 6. Determinants for momentum consistency

This table presents the time-series averages of estimates from censored life regression model. The cross-sectional censored life regressions are estimated for each month during the period of 1981 to 2011, with all of non-overlapped consistent winners and losers listed on NYSE, AMEX, or NASDAQ. Coefficients estimated from the cross-sectional censored life regressions are then averaged over the months. The models are as follows:

$$\begin{aligned} Duration_{i,t} = {} & a_t + b_{1,t}\ln(Size)_{i,t} + b_{2,t}\ln(Size)_{i,t} * D_{i,t} + b_{3,t}BM_{i,t} + b_{4,t}BM_{i,t} * D_{i,t} + b_{5,t}Ivol_{i,t} + b_{6,t}Ivol_{i,t} * D_{i,t} \\ & + b_{7,t}IO_{i,t} + b_{8,t}IO_{i,t} * D_{i,t} + b_{9,t}Turnover_{i,t} + b_{10,t}Turnover_{i,t} * D_{i,t} \\ & + b_{11,t}\left|R_{i,t-J+1,t}\right| + b_{12,t}\left|R_{i,t-J+1,t}\right| * D_{i,t} + b_{13,t}\left|R_{i,t,t+1}\right| + b_{14,t}\left|R_{i,t,t+1}\right| * D_{i,t} + \varepsilon_{i,t} \end{aligned}$$

The dependent variable is the duration of consistent winners or losers. A duration for a winner (loser) stock is defined as the number of month which a winner (loser) stock is continuously ranked in the top (bottom) decile portfolio in the following months after the formation date. The independent variables are the natural logarithm of firm size, book-to-market ratio, idiosyncratic volatility, institutional ownership, the monthly turnover, absolute value of previous *J*-month return (J = 3, 6, 9, and 12), absolute value of previous *J*-month return times winner dummy, absolute value of one-month post-formation return, and absolute value of one-month post-formation return times winner dummy. The idiosyncratic volatility is the residual variance from regressing of a firm's daily excess returns on market daily excess returns over the past 12 months. Institutional ownership is the percentage of outstanding shares held by institutional investors. The monthly turnover is the average daily ratio of the number of share traded to the number of shares outstanding within one month. Winner dummy is equal to one if the observation belongs to consistent winner, and zero otherwise. Newey-West t-statistics are shown in parentheses. *, **, and *** denote statistical significance at the 10%, 5%, and 1% respectively.

Table 7. Heterogeneous beliefs versus momentum lifecycle

This table presents the effects of heterogeneous beliefs hypothesis and momentum lifecycle hypothesis on the momentum consistency. Time-series averages of estimates from censored life regression model are presented. The cross-sectional censored life regressions are estimated for each month during the period of 1981 to 2011, with all of non-overlapped consistent winners and losers listed on NYSE, AMEX, or NASDAQ. Coefficients estimated from the cross-sectional censored life regressions are then averaged over the months. The models are as follows:

$$Duration_{i,t} = a_t + b_{1,t}\ln(Size)_{i,t} + b_{2,t}BM_{i,t} + b_{3,t}Ivol_{i,t} + b_{4,t}IO_{i,t} + b_{5,t}Turnover_{i,t} + b_{6,t}Turnover_{i,t} * D_{i,t}$$
$$+ b_{7,t}\left|R_{i,t-J+1,t}\right| + b_{8,t}\left|R_{i,t-J+1,t}\right| * D_{i,t} + b_{9,t}\left|R_{i,t,t+1}\right| + b_{10,t}\left|R_{i,t,t+1}\right| * D_{i,t} + \varepsilon_{i,t}$$

The dependent variable is the duration of consistent winners or losers. A duration for a winner (loser) stock is defined as the number of month which a winner (loser) stock is continuously ranked in the top (bottom) decile portfolio in the following months after the formation date. The independent variables are the natural logarithm of firm size, book-to-market ratio, idiosyncratic volatility, institutional ownership, the monthly turnover, the monthly turnover time winner dummy, absolute value of previous *J*-month return (J = 3, 6, 9, and 12), absolute value of previous *J*-month return times winner dummy, absolute value of one-month post-formation return, and absolute value of one-month post-formation return times winner dummy. The idiosyncratic volatility is the residual variance from regressing of a firm's daily excess returns on market daily excess returns over the past 12 months. Institutional ownership is the percentage of outstanding shares held by institutional investors. The monthly turnover is the average daily ratio of the number of share traded to the number of shares outstanding within one month. Winner dummy is equal to one if the observation belongs to consistent winner, and zero otherwise. Newey-West t-statistics are shown in parentheses. *, **, and *** denote statistical significance at the 10%, 5%, and 1% respectively.

Table 8. Returns to consistent momentum strategies

This table presents returns and the associated *t*-statistics from consistent momentum strategies, inconsistent momentum strategies and Jegadeesh and Titman's (1993) momentum strategies executed during the period from 1980 to 2011. At the end of each month, winner stocks are those stocks with top decile previous *J*-month (*J*= 3, 6, 9, and 12) returns, while loser stocks are those stocks with bottom decile previous *J*-month returns. Consistent winners (losers) are those winner (loser) stocks stay in winner (loser) group both in the formation month *t* and in the next formation month *t*+1, while inconsistent winners (losers) are those winner (loser) stocks do not stay in winner (loser) group in the next formation month *t*+1. For the consistent momentum strategy, the zero-investment portfolios which long for consistent winner stocks and short for consistent loser stocks are held for six subsequent months and are not rebalanced during the holding period. For the inconsistent momentum strategy, portfolios of buying inconsistent winner stocks and selling inconsistent loser stocks are held for six subsequent months and not rebalanced during the holding period. For the Jegadeesh and Titman's (1993) momentum strategy are developed by buying winner stocks and selling loser stocks and held for six subsequent months and not rebalanced during the holding period. Panel A shows the average monthly returns for consistent and inconsistent momentum strategies based on *J*-month formation period return. Panel B presents the average monthly returns between consistent (inconsistent) momentum strategies based on 6-month formation period return and Jegadeesh and Titman's (1993) momentum strategies based on 7-month formation period return. Panel C reports the average monthly return differences between consistent (inconsistent) momentum strategies and Jegadeesh and Titman's (1993) momentum strategies. Raw returns and risk-adjusted returns for various momentum strategies and the differences between momentum strategies are presented in this table. Risk-adjusted returns are intercepts of regressions of the capital asset price model (CAPM), Fama-French 3-factor model (FF-3), Fama-French three factors plus Charhart's momentum factor (FF-4), and Fama-French three factors plus Stambaugh's liquidity factor (FF-3+LIQ). The associated *t*-statistics are in parenthesis. *, **, and *** denote statistical significance at the 10%, 5%, and 1% respectively.

Figure 1. Average buy-and-hold returns to consistent and inconsistent momentum portfolios

These figures show the average buy-and-hold returns to winner (loser), consistent winner (loser), and inconsistent winner (loser) portfolios. *Winner* (*loser*) means the winner (loser) in a standard momentum strategy. At the end of each month, winner stocks are those stocks with top decile previous *J*-month (*J*= 3, 6, 9, and 12) returns, while loser stocks are those stocks with bottom decile previous *J*-month returns. Consistent winners (losers) are those winner (loser) stocks stay in winner (loser) group both in the formation month *t* and in the next formation month *t*+1, while inconsistent winners (losers) are those winner (loser) stocks do not stay in winner (loser) group in the next formation month *t*+1. The holding period is calculated from one month after defining consistent and inconsistent momentum portfolios (*t*+2) up to 12 months after defining consistent and inconsistent momentum portfolios (*t*+13).

Figure 1.a 3-month formation period

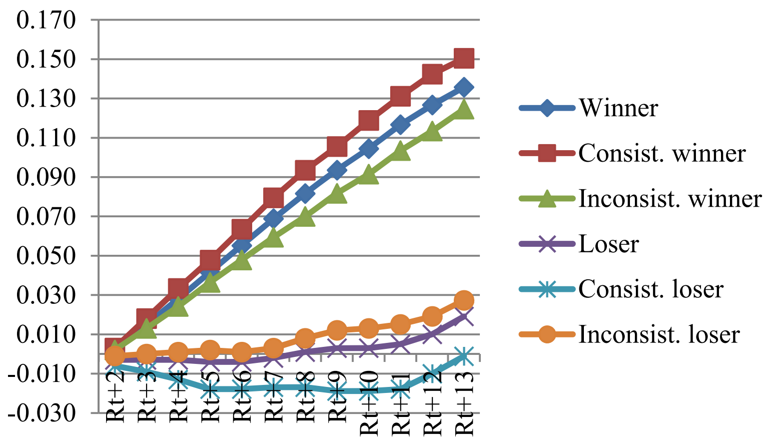

Figure 1.b 6-month formation period

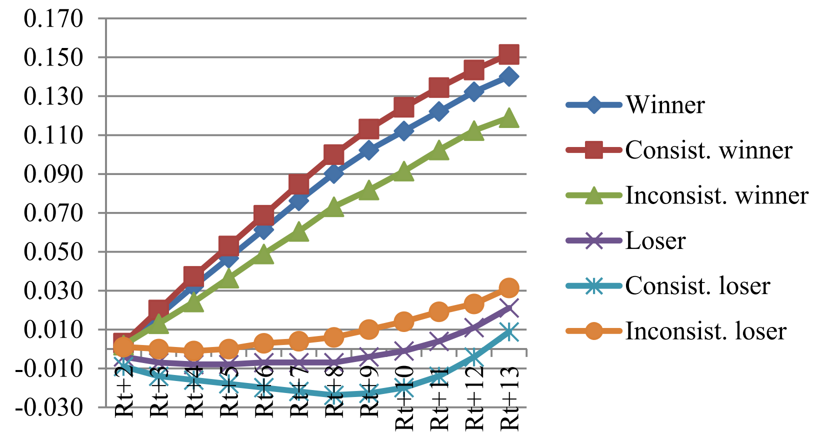

Figure 1.c 9-month formation period

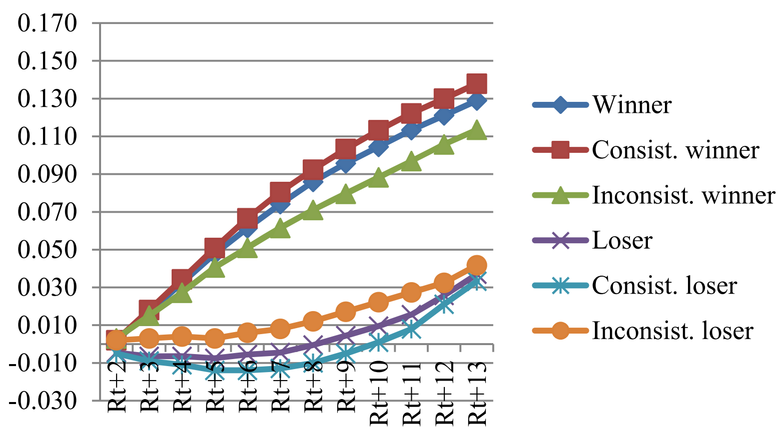

Figure 1.d 12-month formation period

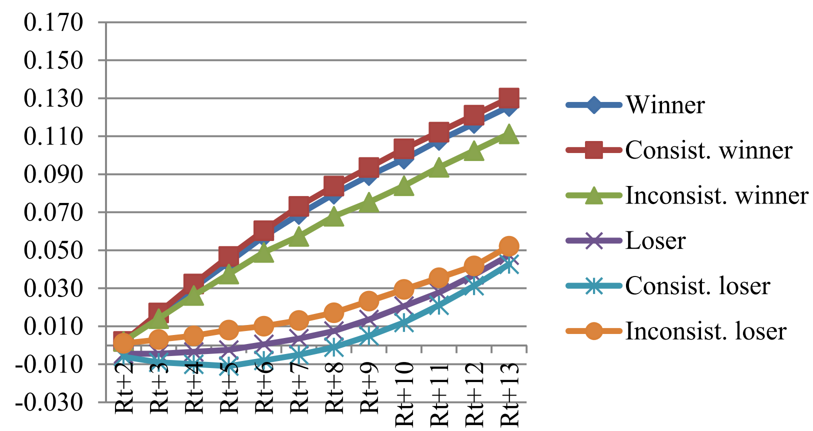

Table A1. Turnover rates of momentum portfolios: 20 groups

This table presents the average turnover rates for winner and loser stocks in the next formation month. At the end of each month, winner stocks are those stocks with top 5% previous *J*-month (*J*= 3, 6, 9, and 12) returns, while loser stocks are those stocks with bottom 5% previous *J*-month returns. Panel A presents average percentages of winner stocks which will be ranked and assigned to one of twenty groups in the next formation month. Panel B presents average percentages of loser stocks which will be ranked and assigned to one of twenty groups in the next formation month.

Sustainability of Vietnam's Current Account Deficit in the Period of 1990-2013

Tran Kim Ngoc
Faculty of Business and Administration
Saigon Technology University
Vietnam
ngoc.trankim@stu.edu.vn

This paper uses stationarity and cointegration tests and potential sustainability indicators to evaluate the sustainability of the Vietnamese current account between 1990 to 2013. The results of the stationarity test performed on Vietnam's current account balance over the period 1990–2013, reveal sustainability. Cointegration test also performed on exports and imports reflect that the two are cointegrated with the cointegrating coefficient of 0.900195 which is significantly below one, implying that the current account was not on the sustainable path indicating a weak form of sustainability. A number of leading sustainability indicators examined in the study point to weak sustainability of the Vietnam's current account deficit due to a number of factors, including sizable fiscal deficits, growing external debt, inefficient investment, growing errors and omissions, the risk of the exchange rate becoming overvalued, and inadquate foreign exchange reserves. These weaknesses have presented serious developmental challenges for Vietnam and have negatively affected the attainment of accelerated economic growth which is necessary to avoid the so-called middle income trap.

Keywords: current account; sustainability; stationarity test; Johansen cointegration test.

1. Introduction

Current account balance (CAB) is an important macroeconomic indicator in any open economy, since it is closely related to other important components of national savings and investment - the budget balance and private savings - and has important implications for overall economic growth, exchange rate movements, and competitiveness (Roubini and Wachtel, 1997).

In principle, an economy will be able to sustain deficits as long as it can raise the necessary funds by borrowing. Although such behaviour may be feasible in the short-run, the ability of the economy to service its debt by resorting to further borrowing is likely to be questioned once the deficits become persistent. Persistent deficits may have serious effects. First, they might increase domestic interest rates to attract foreign capital, and, secondly, the accumulation of external debt owing to persistent deficits will imply increasing interest payments which imposes an excess burden on future generations. Episodes of currency crisis in the 1990s have been associated with large, growing and eventually unsustainable current account imbalances. The Mexican peso crisis of 1994 and the 1997 currency turmoil in a number of Asian countries (in particular Thailand, Malaysia and the Philippines) appear to have been partly triggered by unsustainable current account imbalances.

Figure 1 shows that the current account in Vietnam has been worsened (up to 1998), improved (from 1999-2001) and again deteriorated (from 2002-2010) and once again improved. While the current account does not appear to be a source of policy concern, especially in recent four years, a sudden negative terms of trade shocks could easily produce an external crisis as the financing of future current account deficit (CAD) become constrained by the existing stock of external debt obligations.

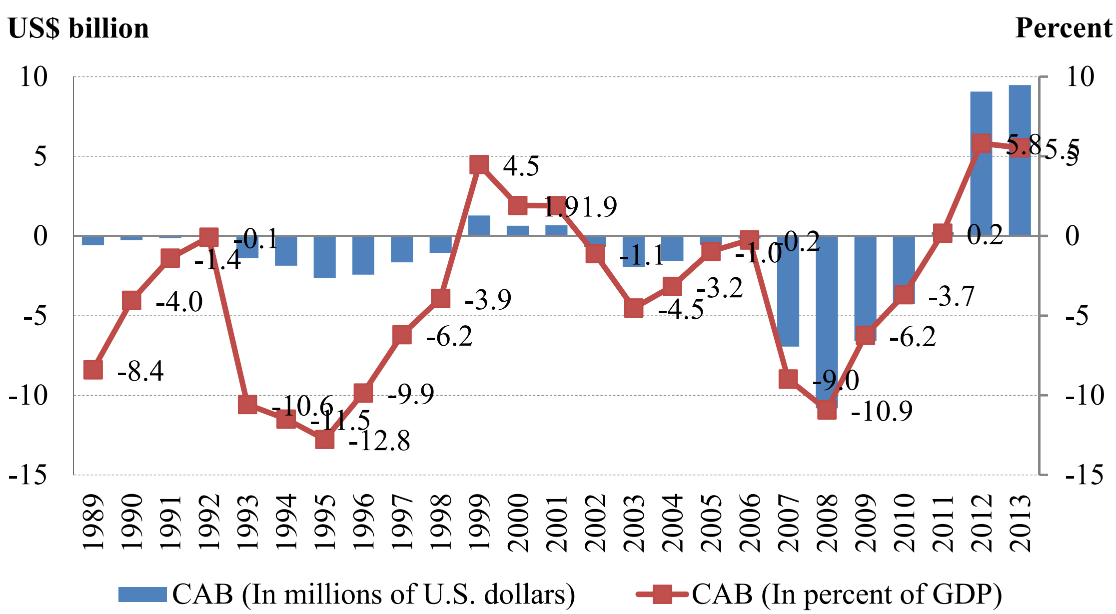

Figure 1. Current account balance in Viet Nam, 1989-2013

This paper attempts to add some insight towards understanding the current account sustainability of Vietnam. The paper is organized as follows: Section 2 presents the theoretical framework. Section 3 provides methodology and data. Section 4 presents the empirical results of examining current account sustainability. Finally, the last section summarizes the paper's main conclusions.

2. Theoretical framework

2.1 *Basics of the current account*

According to the IMF Balance of Payments Manual (1993 and 2008), the current account balance is a component of the balance of payment accounts, which systematically summarizes, transactions in goods, services, income and transfers between residents of an economy and the rest of the world in a given time period, usually a year.

(1) On one side, the current account balance is the sum of three components: the balance on goods and services, the balance on primary income (previously called factor services), and the balance on secondary income (formerly referred to as current transfers). Expressed in equation form:

$$CAB = X - M + BPI + BSI \qquad (1)$$

where

X = exports of goods and services

M = imports of goods and services

BPI = balance on primary income

BSI = balance on secondary income

(2) On the other side, the current account balance is also equal to the difference between the economy’s total savings and its total investment

$$CAB = S - I \qquad (2a)$$

$$= (S_p - I_p) + (S_g - I_g) \qquad (2b)$$

where

S = gross saving

I = gross capital formation (capital formation includes fixed capital, inventories, and valuables)

S_p and I_p = private saving and investment

S_g and I_g = government saving and investment

As equation (2b) show, the current account represents the outcome of forward-looking investment and savings decisions of economic agents. Economic theory suggests that intertemporal borrowing and lending are natural vehicles for achieving faster capital accumulation, a more efficient allocation of investment, and the smoothing of consumption.

Equation (2b) also shows that the budgetary position of the government ($S_g - I_g$) may be an important factor influencing the current account balance. In particular, a sustained current account deficit may reflect persistent government spending in excess of receipts, and such excess spending suggests that fiscal tightening is the appropriate policy action.

(3) It could be said that the current account balance is the change in the net foreign liabilities of a country and equals the sum of balances on the capital and financial accounts (with signs reversed, if necessary, depending on the presentation used) including reserve assets.

$$CAB_t = F_t - F_{t\text{-}1} \qquad (3a)$$

$$= NKF_t + RT_t \qquad (3b)$$

where

F = the stock of net foreign assets

NKF = net capital and financial account transactions excluding reserve assets

RT = net reserve asset transactions

Equation (3b) demonstrate that all economies face an *intertemporal budget constraint* (IBC) that relates current account imbalances over time. As such, a current account deficit today must be matched in present value terms by current account surpluses in the future. An incurrence of current account deficit today implies that a country becomes a net debtor, thereby tying up future foreign exchange earnings to meet its debt service and repayment obligations. Hence, a perpetual current account deficit will clearly not satisfy the IBC. Clearly, if lenders believe that a current account deficit today will continue in perpetuity, they have no prospect of repayment and will not voluntarily finance today's deficit. Therefore, persistent current account deficits are often viewed as a sign of weakness that implies a need for policy action.

2.2 *"Sustainable" current account deficit*

As current account deficits represents an increase in the net foreign liabilities of a country (see equation 3(a)), one approach to current account sustainability focuses on an economy's solvency. An economy is accepted as solvent if the present discounted value of future trade surpluses equals current external indebtedness. Ultimately, such a definition is difficult to apply since it relies on future events/policy decisions without imposing any restriction on them. A country can remain technically solvent even while running large external deficits as long as policies are adjusted as needed in the future to bring about the required surpluses that enable debt to be repaid.

Milesi-Ferretti and Razin (1996) developed another, more complete, approach to current account sustainability. In their view, CAD sustainability refers to whether the resulting path of an economy's trade balance is consistent with intertemporal solvency (i.e. an economy is capable of meeting its IBC) in the long run without a drastic change in the current government policy stance and/or in the present private sector behaviour. The sustainablity adds on to the notion of solvency the idea that policies remain constant for the indefinite future. Thus, an external position is sustainable if, under the assumption that policies do not change, the country does not violate its intertemporal solvency constraint. The problem with the sustainability concept is that what matters for the current account are people's expectations of future policies rather than the policies themselves. These expectations are notoriously difficult to observe and measure, which makes the sustainability concept difficult to apply operationally (Ostry, 1997).

2.3 *Operational criteria of current account sustainability*

While large and persistent current account deficits begin to raise doubts about long-term sustainability, there is no agreement of what constitutes a high or persistent current account deficit. Lawrence Summers, the U.S. deputy Treasury secretary, wrote in The Economist on the anniversary of the Mexican financial crisis (Dec. 23, 1995-Jan. 5, 1996, pp. 46-48) *"that close attention should be paid to any currentaccount deficit in excess of 5% of GDP, particularly if it is financed in a way that could lead to rapid reversals."* Calvo (1998, p. 27) put deficit little lower *"Prominent people and institutions regard a CAD in excess of 4 percent of GDP as "large"."* Although 1994 Mexican peso crisis and the 1997 Asian currency crisis appear to support this view, some countries with larger deficits have not experienced crises (Fry, 1997). Moreover, a clear definition of persistence is also not available. While some countries have faced a high current account deficit for over a decade without a crisis, as in the case of Australia (Milesi-Ferretti and Razin 1996a, b), other countries have suffered a crisis following only a few years of high current account deficits. Therefore, large and persistent current account imbalances do not necessarily imply unsustainability regardless of other factors. Following non-structural case study, Milesi-Ferreti and Razin (1996a, b) and Roubini and Wachtel (1997) suggest that, when performing an assessment of the current account deficit sustainability one should take into account the following factors/indicators: the cause of the current account deficit; current account structure; the structure and volume of foreign capital inflow; the level of economic growth; real exchange rate appreciation; the structure and level of external debt, the level of foreign reserves; financial system stability; openness of the economy; political and macroeconomic stability; global factors. However, the main obstacle to to assess current ccount sustainability based on indicators is *"how to "rank" these different indicators and how to translate them into an overall measure of external sustainability"* (IMF, 1998, p. 87), thereby lacking the ability to provide a quantitative analysis of sustainability.

2.4 *Intertemporal approach: Empirical studies*

A large number of empirical studies on CAD sustainability focus on the tests of the intertemporal long-run budget (solvency) constraint. This lends credence to the assertion by Baharumshah et al (2005) that *"The claims that the current account is sustainable if exports and imports are cointegrated with the cointegrating vector being (1, -1), is, by now, a widely accepted theory"*. The intertemporal solvency constraint holds if the initial foreign debt of the economy is paid off by future trade balance surpluses. This solvency constraint requires that the current account balance be stationary and, thus, the exports and imports cointegrated.

Therefore, in evaluating the sustainability of the external deficits in open economy settings, one may apply the methodology developed by Trehan and Walsh (1991). These two authors states that the sustainability refers to stationarity of the current account balance over time, whereas nonstationarity implies that the country violates its IBC.

Alternatively, Hakkio and Rush (1991) and Husted (1992) propose a model in which cointegrating (long-run equilibrium) properties of the exports and imports variables are tested. In this framework, cointegration of the exports and imports variables is a necessary condition for the country to have sustainable external deficits (ie. intertemporal external solvency). The model starts with the budget constraint of an individual who is able to borrow and lend freely to the rest of the world. Clearly, this model can be extended from an individual to a household or to a country. The current-period budget constraint of this representative household is:

$$C_0 = Y_0 + B_0 - I_0 - (1+r)B_{-1}$$

where C_0, I_0, Y_0, B_0 and r are the current consumption, investment, output, international borrowing and one-period interest rate, respectively. $(1+r)B_{-1}$ is the initial debt size. After making several assumptions, Husted (1992) derives the following testable model:

$$X_t = \alpha + \beta M_t + \varepsilon_t \qquad (4)$$

Where X is exports of goods and services, and M is imports of goods and services plus net transfer payments and net interest payments.

Under the null hypothesis, in the economy that satisfies its IBC (i.e. for a sustainable current account deficit), it is expected that $\beta = 1$ and ε_t is a stationary process.

The empirical results may allow establishing several conclusions concerning the sustainability of the intertemporal budget constraint:

- when there is no co-integration the current account is not sustainable and do not move towards external-account equilibrium.;
- when there is co-integration with $\beta = 1$, the current account is sustainable,
- when there is co-integration, with $\beta < 1$, economy's imports growing faster than economies exports, and the current account may not be sustainable.

As Hakkio and Rush (1991) demonstrate in the context of government finance also if X and M are non stationary variables in level, the condition $0 < \beta < 1$ is a sufficient condition for the budget constraint to be obeyed. However, when imports and exports are expressed as a percentage of gross domestic product or in per capita terms, it is necessary to have $\beta = 1$ in order for the trajectory of the debt-to-GDP not to diverge in an infinite horizon.

3. Methodology and data

Based on the synthesis of the literature reviewed in the foregoing, this study employs a unit root analysis of Vietnam's current account deficits over the period 1990-2013. In addition, the study seeks to reenforce the findings of the unit root tests on the current account balance with a cointegration analysis of the country's export and imports to ascertain their long-run relationship and implications for current account sustainability. As such, the model suggested in Hakkio and Rush (1991) and Husted (1992) will be used in this study. The long-run relationship between exports and imports will be determined by using the Johansen procedure.

A necessary condition for testing for a long-run relationship between two variables is that these variables are I(1), i.e., stationary in first differences. We, therefore, use the classical unit root tests, namely, the Augmented Dickey-Fuller (ADF) test (see Dickey and Fuller, 1981; Said and Dickey, 1984) and KPSS test from Kwiatkowski et al. (1992). ADF test is based on the null hypothesis that a unit root exists in the time series. The KPSS semi-parametric procedure tests for level (η_μ) or trend stationary (η_τ) against the alternative of a unit root. Further evidence regarding the nature of time series data is provided by the DF-GLS unit root test, which is more powerful than the ADF and PP tests.[1] Like in other unit root tests the null hypothesis in the DF-GLS test is that the variable under consideration is non-stationary against the alternative that it is stationary.

Once it is established that two series representing measures of exports and imports are I(1), we can proceed to test for a long-run relationship between the series. If such a relationship exists, the two series are cointegrated and the intertemporal budget constraint is satisfied. We tested cointegration using the two cointegration techniques devised by Johansen and Juselius (1990). In the Johansen and Juselius (JJ) method, two tests are used to determine the number of cointegrating vectors (r): the trace test and the maximum eigenvalue test. In the trace test, the null hypothesis is that the number of cointegrating vectors is less than or equal to r, where r is 0, 1, or 2. In each case, the null hypothesis is tested against a general alternative. In the maximum eigenvalue test, the null hypothesis $r = 0$ is tested against the alternative that $r = 1$, $r = 1$ against the alternative $r = 2$, etc.

The study also comprehensively analyse a number of factors based on the aforesaid three perspectives on the current account balance (see section on "Basics of the current account"):

(1) a domestic perspective based on national income and product accounts;
(2) an international perspective based on trade flows in goods and services; and
(3) an international perspective based on flows and holdings of financial assets.

These three perspectives are different lenses through which to analyze the current account balance. Each perspective involves a decision to focus on certain variables or economic relationships and to ignore other variables and relationships. Each perspective may be particularly useful in certain situations or time frames. All together, the three perspectives give views that are consistent and mutually reinforcing.

At the same time, the following several complementary criteria that are helpful in assessing the sustainability a path of current account imbalances (Milesi-Ferreti and Razin,

---

[1] Maddala and Kim advocate that the traditional ADF and PP tests should be discarded and KPSS should be avoided. Instead, it is better to use one of the following: DF-GLS test (Elliott, Rothenberg, Stock, 1996), Ng-Perron test (Perron and Ng, 1996), …. But the commonly used ADF, PP, and KPSS tests should be added that as yet there is no uniformly powerful test of the unit root hypothesis.

op. cit.; and Roubini and Wachtel, op. cit.) are also included in the analysis:

- the level of economic growth;
- the level of foreign reserves;
- openness of the economy;
- real exchange rate appreciation; and
- investment efficiency.

Sources and data

Almost the data are available on the IMF web site (elibrary-data.imf.org). The data on balance of payment over the period 2005-2013 were obtained from IMF Data homepage while the data for the period 1990-2004 from IMF country reports. Other data will be indicated in this paper. Exports (X), imports (I), and current account balances (CA) used in unit root/stationary tests and Johansen cointegrating test are measured in nominal terms as a percentage of nominal GDP[2], where exports include exports of goods and services, while imports includes imports of goods and services plus net transfer payments and net interest payments[3].

4. Research findings

As shown in Figure 1, Vietnam's CABs have mostly remained in negative territory for the analysis period, indicating that the deficits is a persistent feature of Vietnamese economy. It also indicates that CAB has exceeded ten times some threshold value 5 percent, this result would make one to say that the current account deficit is unsustainable.

However, in some sense, focusing on the current account balance is misguided. After all, the current account is not a fundamental economic force in itself, but only one manifestation of the general equilibrium interaction between many factors. Therefore, it is useful and common to take all three perspectives on the current account deficit (Mann, 2002).

4.1.1 *A perspective based on international trade in goods and services*

The first viewpoint on the current account is an international perspective based on the factors that underpin the flows of exports and imports of goods and services. Evidently, Vietnam's current account balance largely emanates from the merchandise trade balance. As illustrated

---

[2] Studies of several authors measure variables in real rather than nominal terms. If done so, it is more appropriate to use the merchandise export price index and merchandise import price index to derive the real exports and the real imports, respectively, instead of using the consumer price index (CPI). However, the author can't find the data of Vietnam over the analysis period. The United Nations Conference on Trade and Development (UNCTAD) has the data only from 2000. Similarly, the World Trade Organization (WTO) has the data (annual percentage changes) only from 2002. The World Economic Outlook (WEO) database contains data series on annual percentage changes of volume of exports and imports of goods and volume of exports and Imports of goods and services. The CPI can't be used as deflator for both import and export series instead since the available data for the 2000-2013 period show that the values of the export price index, import price index (from UNCTAD), and CPI are different.

[3] This is the convention in the literature. See Husted (1992).

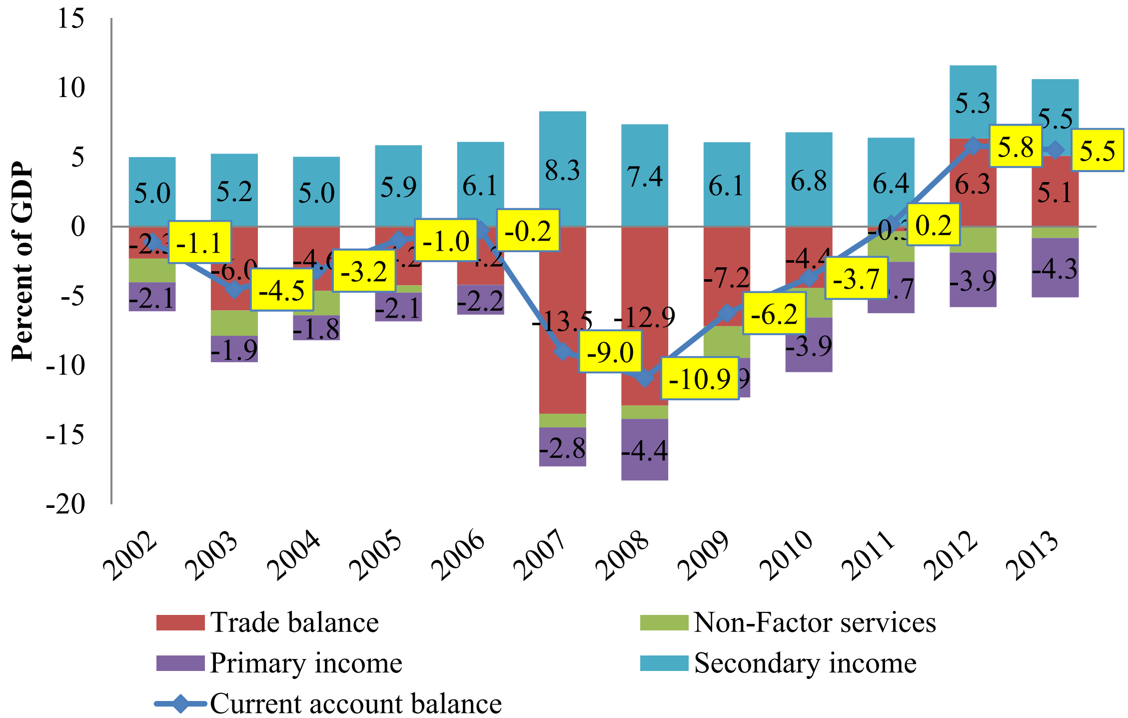

Figure 2. Vietnam: Level and composition of current account balance, 2002–2013

in Figure 2, in the period of 2002-2010, the trade account recurred to deficit levels, thereby pulling the current account deficit with it. In 2011, both the trade and the current accounts nearly balanced. In the next two years 2012 and 2013, Vietnam earmarked current account surpluses, including trade surpluses for the first time since 2002. Exports rose rapidly thanks largely to production from a large foreign-financed investment project coming on stream while imports, in line with slower demand, remained subdued.

The two components of Vietnam's current account balance, the balance on service trade and net primary income, have been consistently negative, or in deficit. Trade in services has remained a minor component of Vietnam's foreign trade: in 2013, exports (receipts) of commercial services, mainly from travel services, accounted for 7.4 percent of total exports of goods and services; and imports (payments) of commercial services, primarily from transportation and shipping of imported goods, represented about 8.8 percent of total imports of goods and services. Increased payment on investment income has led to increased net primary income payments to the rest of the world. With a growing stock of FDI, one would expect higher level of investment payments in future years.

At the same time, the country has received significant amounts of current transfers, mainly private remittances sent by "Việt kiều" and migrant workers. The surlus on current transfers has offsetted the dificits on net service and net primary income, except the year 2012.

Openness, and direction and composition of trade

A more open economy (with a higher share of exports or trade in GDP) can service it's external debt more easily, because debt service absorbs a lower fraction of total exports. Thus, the effect of a shock on imports or domestic production is lower, ceteris paribus, than for low-export countries. The cost of default is also higher for a more open economy – it has more to lose – and the domestic constituency to avoid trade disruptions will be stronger (Ostry, 1997). Nonetheless, a high degree of openness could make the country more vulnerable to external shocks, especially when the export base is thin.

The Vietnamses economy has become increasingly open since 1990. The ratio of exports to GDP increased from 30% in 1990 to 70% in 2008, slowed down somewhat in 2009 due to the global recession, and increased again to 83% in 2013.

In terms of geographical destinations, overall, Vietnam's merchandise exports have been fairly diversified. The United States domestic market was truly opened up for exports from Vietnam by the Vietnam- U.S. bilateral trade agreement, which came into effect in November 2001. Immediately in 2002, exports to the US doubled and the the U.S. became the largest single-country export market, overtaking Japan. In 2013, exports to the US accounted for about 19% of Vietnam's total exports. Other key export markets include the European Union (EU), Japan, China, ASEAN-4 (Indonesia, Malaysia, Philippines, and Thailand), and Korea. In recent years, new markets are being developed, especially in United Arab Emirates, India and other countries in the Western Hemisphere, raising expectations for potential future growth. Unlike many countries in the East Asia and Pacific (EAP) region that have been sending an increasingly larger share of their exports to China, Vietnam continues to rely on industrial countries for the majority of its exports. Overall, industrial countries account for nearly two-thirds of Vietnamese exports.

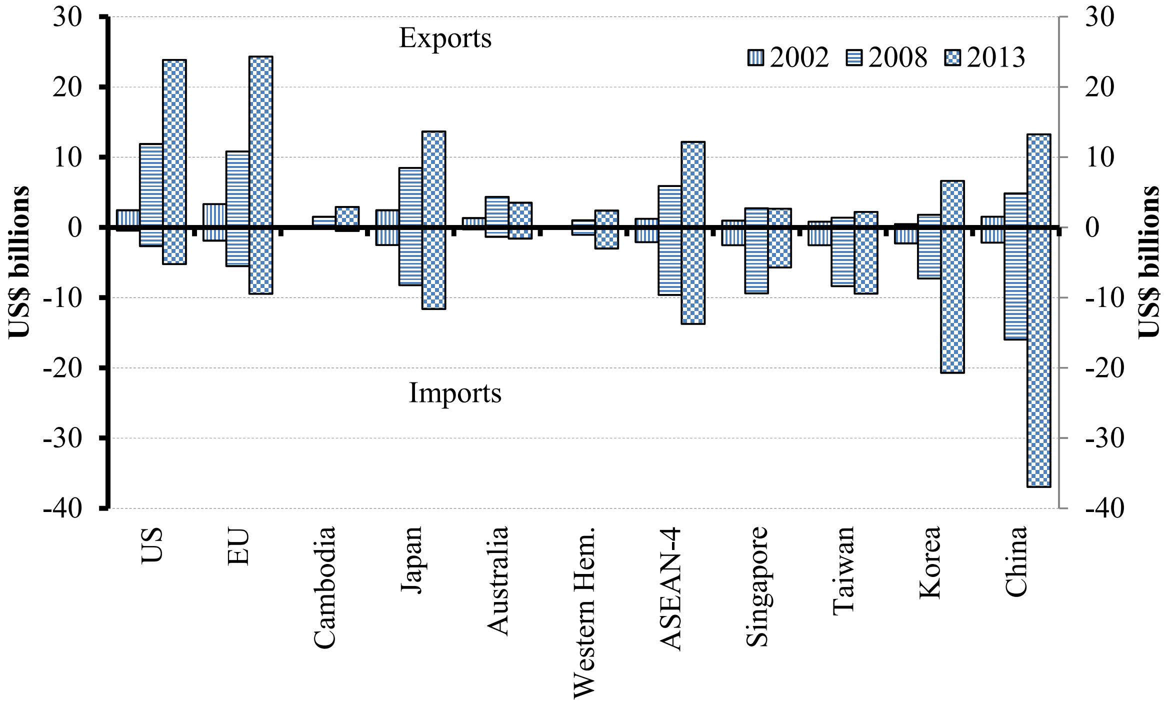
However, Vietnam's merchandise imports are quite concentrated. The top 10 partners account for above 80 percent of imports in 2013.[4] China is the largest supplier of imports to Vietnam, overtaking Japan from 2003. In 2013, imports from China accounted for nearly 29% of Vietnam's total imports value. It is followed by Korea, ASEAN-4, Japan (9%), the EU, Taiwan, Singapore, United States. So Vietnam's import sources are China and other East Asian countries.

This explains, as can be seen from Figure 3, why Vietnam continues to register trade surplus with industrial countries, while at the same time runs large trade deficit with trading partners in the region (The bilateral trade balance with China has turned from a surplus of US$135 million in 2000 to a deficit of near US$23,7 billion in 2013 - ten times Vietnam's overall trade deficit of US$2,4 billions. Vietnam has also run large and growing trade deficit with Korea, amounting to $14.07 billion in 2013.) World Bank (December 2010) comments: *"This could imply either of the two things. One, Vietnam is yet to be linked to the global production networks that end in the EAP/ASEAN region. Second, there are some global production networks, especially those involving low-cost, labor intensive products like garments and footwear, whose final stage is in Vietnam. This provides an important opportunity for Vietnam to strengthen the global supply chains ending up in its own territory as well as to use*

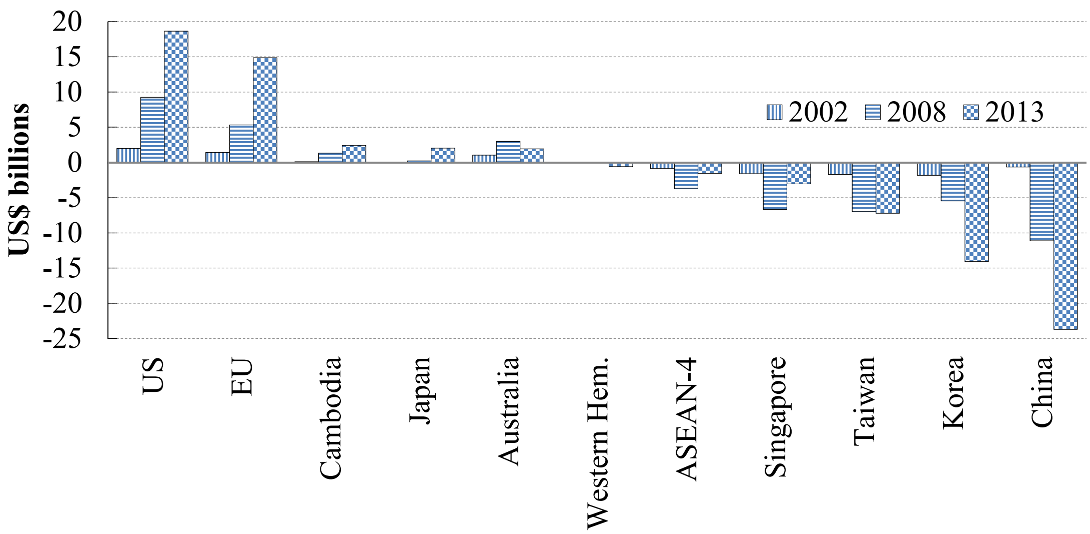
[4] Countries are ranked by descending order, including: China, Korea, Japan, Taiwan, Thailand, Singapore, United States, Malaysia, Germany, and India.

regional trade agreements such as ASEAN to become part of global production network passing through the region, including China."

Vietnam's exports are becoming more diverse, as it moves from primary products (oil, rice, coffee, rubber and coal) into labor-intensive light manufactures (garments, footwear, and furniture) and more sophisticated industrial goods (electronics, computers, and cell phones).

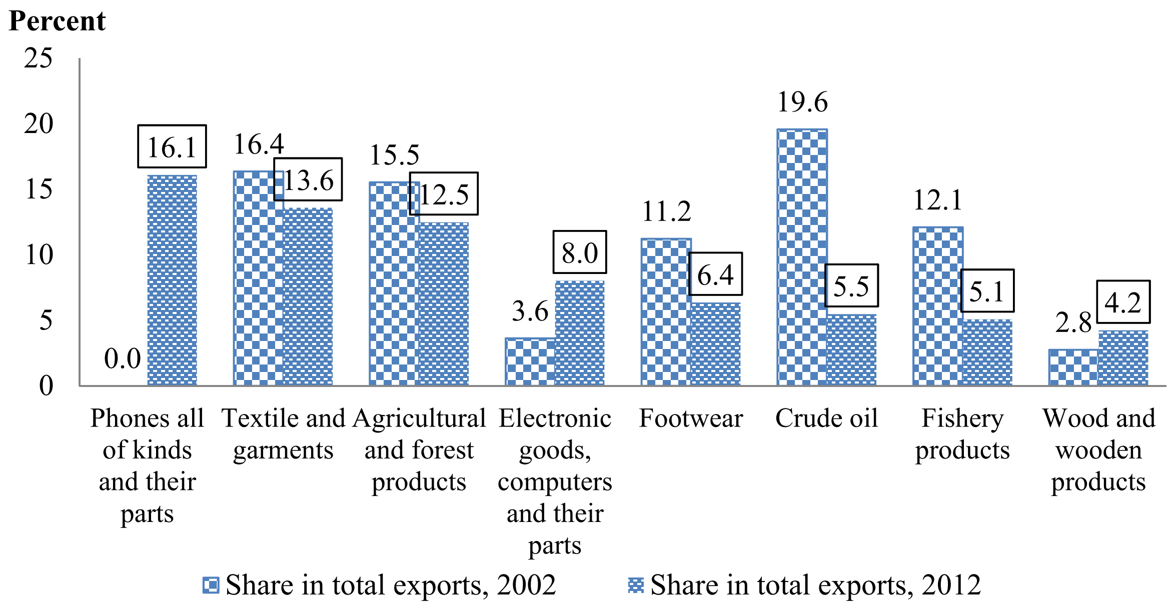


(a) Vietnam: Merchandise trade with selected partners



(b) Vietnam: Trade balance with selected partners

Figure 3. Merchandise trade and trade balance with selected partners



Source: GSO, Statistical yearbook of Vietnam (various issues) and author's calculations.

Figure 4. Vietnam: Selected export products

Vietnam's traditional exports items such as garments, footwear, and furniture continue to sustain rapid growth. More recently, exports of hi-tech and higher value-added products (e.g., cell phones and parts, computers, electronics and accessories, automobile parts) have emerged as Vietnam's largest exports. These new sectors could become the next driver for exports. In summary, the aforesaid diversification of exports increases the resilience of the Vietnamese economy to external shocks.[5]

Efforts to open up more overseas markets for Vietnamese exports. Vietnam has embarked on a process of internationalization and integration that has resulted in membership in the ASEAN Free Trade Area, AFTA, since 1996, membership in the World Trade Organization, WTO, since 2007 and a very significant diversification of external economic relations. Vietnam is now exerting efforts in Trans-Pacific Partnership (TPP)[6] negotiations and concluding Free-Trade Agreements (FTAs) with the European Union and South Korea. These agreements are expected to secure access to main export markets and spur market-based reforms.

Some schools of thought believe that TPP membership may be able to help Vietnam to expand its export market and compensate for its trade deficit with China through a surplus in trade with TPP members, especially the U.S. In a study by Peter A. Petri and Michael G. Plummer (2012), Vietnam is projected to gain the most from the TPP. Vietnam's Exports on the TPP track by 2025 would increase by $89 billion (of 2007 dollars) (37 percent over the

---

[5] Trade diversification can be achieved through either products (introduction of new product lines, a more balanced mix of existing exports or product-quality upgrading) or trading partners (Papageorgiou and Spatafora, 2012).

[6] The countries involved in the TPP talks include 12 countries in the Pacific rim: USA, Australia, Malaysia, Mexico, Brunei, Canada, Chile, Japan, New Zealand, Peru, Singapore and Vietnam.

baseline). Three factors explain this result: strong trade with the United States; high protection abroad against apparel and footware, which are Vietnam's principal exports; strong competitive positions in these and other manufacturing industries where China's competitive advantage is fading. These tree factors boost Vietnamese exports and terms of trade under the TPP.

However, the benefits would be far from certain. Take the textiles, garment and footwear industries, for example. Vietnam's competitiveness in large markets such as the U.S. should give it comparative advantages over China. Yet the TPP's rules of origin, namely the "yarn forward" rule, put the benefits in question. Vietnam's supply chain is heavily dependent on Chinese inputs, which could disqualify Vietnamese garments makers from access to zero tariffs under the TPP. Vietnam could turn to other suppliers within the TPP, but none can match China on price. Moreover, Chinese companies have recently rushed to invest in Vietnam's textile market in order to reap the benefits that the TPP is projected to provide. For the short term, at least, it will be unrealistic for Vietnam to expect an immediate decline in its trade imbalances with China.

Real exchange rate

A country's large current account deficit is likely to be less sustainable when its real exchange rate is overvalued beyond a certain threshold value, or above an historical average. A significant real appreciation of the currency (from large capital inflows or any other reasons) may lead to a loss of external competitiveness and a worsening of the trade balance, thus jeopardizing the sustainability of the current account.

According to World Bank staff estimates (Table 1), Vietnam's real effective exchange rate (REER) has exhibited appreciating trends for many years. Nevertheless, Vietnam's external competitiveness is likely to remain adequate. In its latest assessment, the IMF (2014) says that the results of CGER-type analysis[7] and broader trends in the balance of payments suggest there is no convincing evidence of misalignment. The external balance of the FDI-intensive export-oriented sector remains in significant surplus, with the recent overall current account improvement. Wages remain competitive, and foreign direct investment inflows remain robust. However, there is the risk of the exchange rate becoming overvalued if large public contingent liabilities are realized during bank restructuring.

Table 1. Vietnam: Real effective exchange rate, 2003-2013

	2003	2004	2005	2006	2007	2008	2009	2010	2011	2012	2013

[7] the Consultative Group on Exchange Rate Issues (CGER)

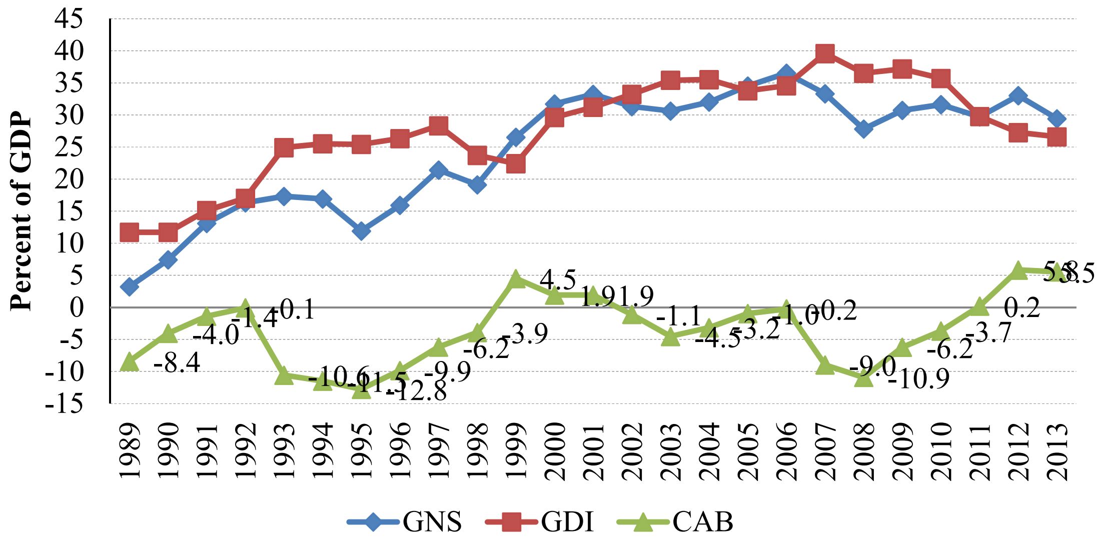

Figure 5. Vietnam's current account balance, total investment and gross national saving as percentage of GDP, 1989–2013

4.1.2 *A domestic perspective based on the national income and product accounts*

The second perspective to gain further insights into the CAB is to consider national savings and domestic investment. Milesi-Ferretti and Razin (1996a, b) argue that both the theoretical and empirical evidence suggests that, *ceteris paribus*, a current account imbalance is likely to be less sustainable if: (a) the imbalance is due to a reduction in national saving rates rather than an increase in national investment rates; (b) national savings rates are low.

Viewing from saving-investment gap, in pursuit of economic growth by relying on investment, Vietnam has maintained high investment rate. However, domestic saving is not sufficient to support the investment demand. As a result, Vietnam's economy depends on external sources to finance the saving-investment imbalnce, raising concerns about the country's external deficits and foreign currency reserves. Figure 5 shows that the gross domestic investment (GDI)/GDP ratio generally exceeds the gross national saving (GNS)/GDP ratio from 2002. As long as the saving-investment gap exists, Vietnam will continue suffering from current account deficit.

If we devide the analysis period into two sub-periods: 1990-2001 and 2002-2013, then CAB in the latter was less serious than CAB in the former (Table 2). However, a striking difference is CAB in the former turning into surpluses owing to GNS increases while GDI

Table 2. Comparison of Vietnam's current account balances in two sub-periods

Sub-period	n	average	median	max	min
1990-2001	12	-4.3	-4.0	4.5	-12.8
2002-2013	12	-2.4	-2.1	5.8	-10.9

almost constant. In the latter period, CAB turning into surpluses owing to GDI decreases while GNS almost constant. Total investment in 2013 was 26.6 percent of GDP, significantly lower than the investment rate of 35,7% in 2010.

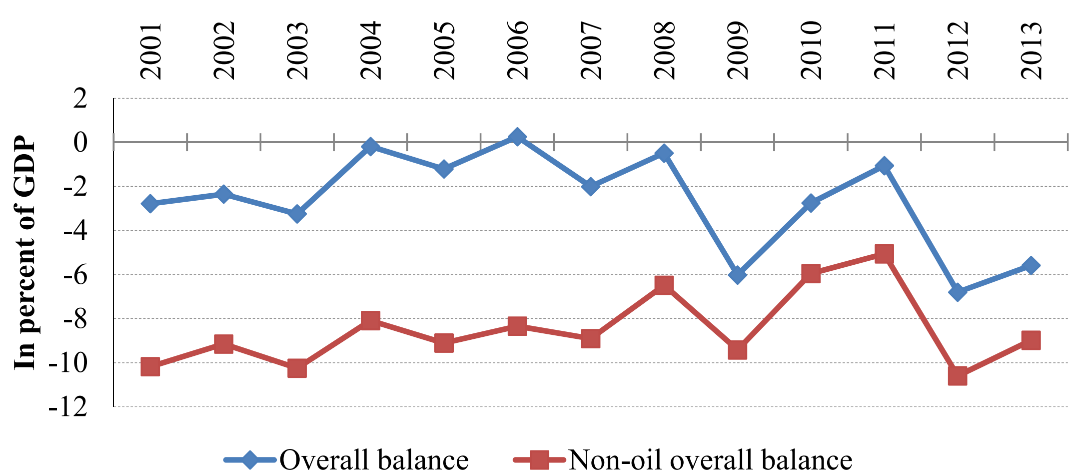
Budget deficits

The current account balance is closely related to the fiscal balance and private savings. Hence, judgement about sustainability will also be affected by the fiscal policies underlying external deficits. In this regard, Vietnam's budget deficits have been sizable recently – 5.6 per cent of GDP in 2013 (Figure 6). The government has received substantial tax and royalty revenue from the oil and gas sector – the share of revenue from crude oil exports in total revenue and grants declined from 17,1% in 2012, to 14,6% in 2013. Hence, that may make the state budget unsustainable in case a fall in global oil prices will reduce the amount of tax collected. In addition, as shown in Figure 7, budget expenditure of Vietnam in the period 2006-2013, on average, is higher 1.2 times than those of China and Thailand; 1.5 times than those of Philippines and Indonesia and equals that of Malaysia. Therefore, it seems that large and persistent budget deficits have largely driven by high budget expenditure, but not by low budget revenue.

Efficiency of the economy

In addition to the level of savings and investment, the *allocation* and *efficiency* of investment is also clearly important for assessing current account sustainability.

Total factor productivity (TFP), which is GDP per unit of combined inputs, is a crucial



Source: General Statistics Office (GSO), various issues

Figure 6. Vietnam's overall budget balance and non-oil budget balance as percentage of GDP, 2001–2013

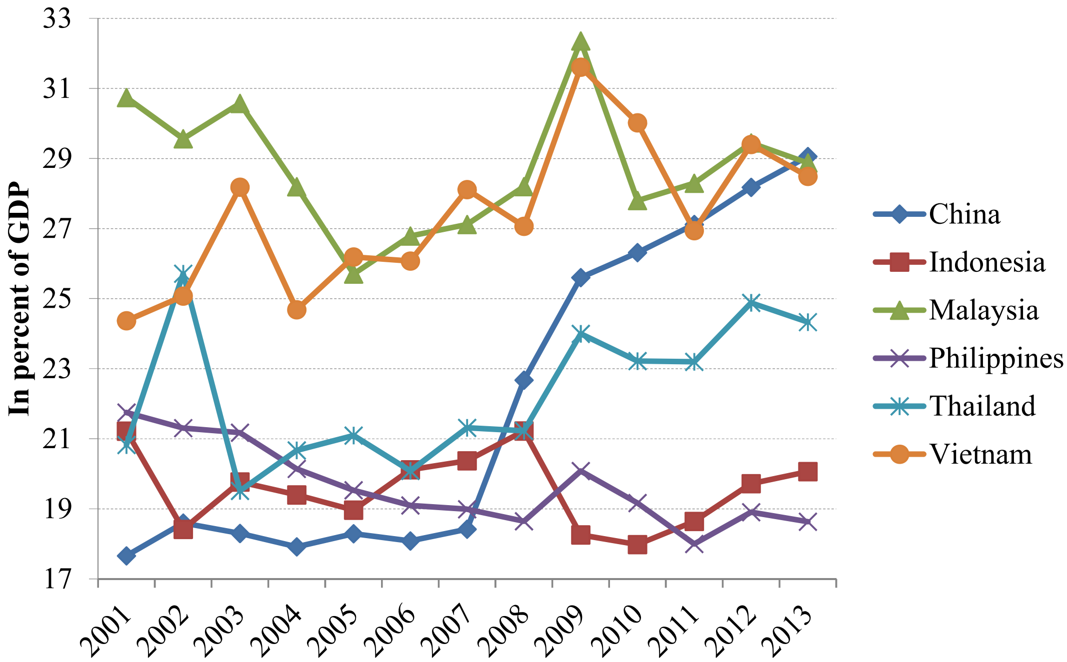


Figure 7. Vietnam's budget expenditure as percentage of GDP in comparison with those of some Asian countries, 2001–2013

measure of a country's production efficiency and thus an important indicator for policymakers. According to figures compiled by Asian Productivity Organization (APO), over the period 1990–2012, Vietnam's TFP growth was at 2.5% on average per year, in third place of the 18 Asian countries compared (Figure 8(a)) but the trend had declined. In terms of its contribution to vietnam's economic growth, TFP accounted for 44% in 1985-2000 and down to 21% in 2000-2012 – tied with singapore for second place in reverse order [Figure 9(b)]. As shown in Figure 8(c), in the last seven year (2006-12), almost entire growth came from factor accumulation and not productivity.

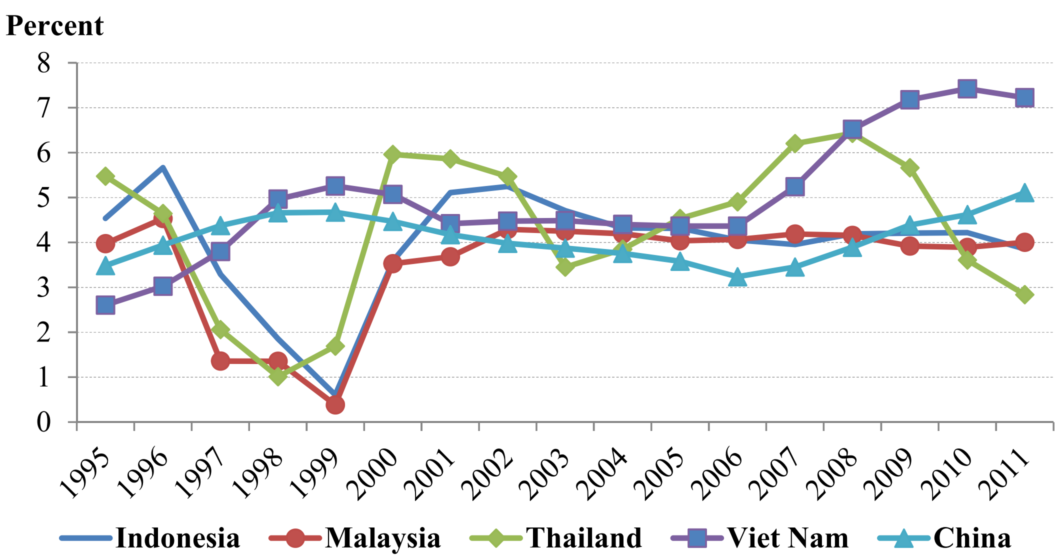
Figure 8. Efficiency of the Vietnamese economy



Source: OECD Development Centre`s calculation

Figure 9. ICOR in emerging Asia, 1995-2011

Incremental capital-output ratios (ICORs) provide another indication of comparative productivity among the countries and their trends over time.[8] The higher the ICOR, the more additional capital it takes to produce a unit of GDP. Generally, ICOR tends to be comparatively low in early stages of develoment, when the aggregate capital stock is low and higher at later stages, when the capital stock is higher and additional investment produces less of an increase in output.

The OECD (2013), based on World Bank, reported the relatively high and rising ICOR for Vietnam (Figure 9). However, based on IMF, figures were somewhat lower and declined since 2010 – the ICOR of Vietnam climbed to 6.88 in 2009 and then down to 4.91 in 2013.

Moreover, the efficiency of foreign invested enterprises (FIEs) is constrained by insufficient infrastructure and the shortage of skilled labor. Relatively low levels of labor skills limit FDI within low value-added industries and make technology transfer via labor movement difficult. As a result, the technology spillovers from FIEs to domestic firms are limited.

Public investment, channeled largely through weak state-owned enterprises (SOEs), has led to inefficient public investments and a high level of indebtedness in the state sector. SOEs themselves are not only inefficient but also distort the allocation of resources. Therefore, local firms in the private sector are placed at a disadvantage in terms of access to capital and land for investment.

GDP growth

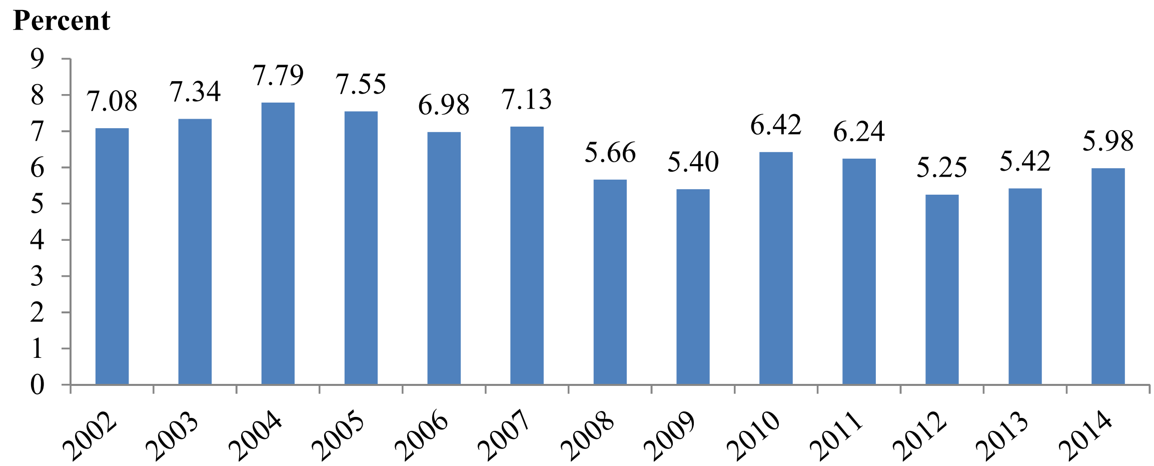
The historical experience suggests that a large CAD is likely to be sustainable when current and expected economic growth is high. For a given ratio of CAD to GDP, higher growth rates will lead to a smaller increase in the foreign debt to GDP ratio, and enhance the country's ability to service its external debt. Higher GDP growth tends to lead to higher investment rates driven by expectations of increased profitability. At the same time, high growth might lead to temporary lower private savings rates resulted from higher expected future income. If this is the case, CADs driven by a temporary fall in private savings and an increase in domestic investment should not be a concern.

The Vietnamese economy has experienced a downturn in growth since 2008. In the past five years, the annual growth averaged about 5.86 per cent and remains below potential (IMF, 2014a[9]; World Bank, 2014a, b). Moreover, the quality, and hence sustainability, of growth remain a source of concern, given the resource-intensive pattern of growth, high levels of pollution, low domestic value-added in exports, and the declining contribution of productivity to growth. In the longer-term, World Bank assesses: *"growth potential remains hampered by a web of structural problems in state-owned enterprises and the banking sector, policy weaknesses that continue to thwart domestic private investment and competition in key*

---

[8] The ICOR is the ratio of the value of new investment to the change in output in a given year. It can be computed by dividing the investment-GDP ratio by the annual GDP growth rate. This measure has to be treated with care, since it does not provide for necessary lags between investment and subsequent changes in output. However, as a measure of overall investment efficiency, its level and changes over time provide a broad estimate of the quality of investment.

[9] The IMF staff report for the 2014 Article IV Consultation estimates that a negative output gap opened after the global financial crisis, and widened to around 1½ percent of potential GDP in 2013.



Nguồn: IMF, and the figure for 2014 from GSO, available at http://www.gso.gov.vn/default.aspx?tabid=507&ItemID=16155

Figure 10. Vietnam: Growth rates of GDP, 2002-2014

sectors, a widening skills gap, constrained access to finance, and relatively high trade logistics costs."

Regarding to TPP, Vietnam is estimated to gain the largest percentage increase in GDP (14 percent, equivalent to 46.1 billions of 2007 dollars) by 2025 due to TPP, compared to 2025 without the TPP. The main reasons for the gain is Vietnam would become a much-expanded manufacturing hub in textile, garment, and other industries (Peter A. Petri and Michael G. Plummer, op. cit.).

4.1.3 *A global perspective from international capital markets*

The third viewpoint on the current account deficit focuses on international flows of financial assets or composition of the capital and financial accounts inflows. Capital and financial account flows have been dominated by foreign direct investment and relatively smaller portfolio flows into the country's two stock markets. Short-term capital outflows (including part of the errors and omissions from 2010) were moderately significant.

Vietnam has access to large foreign direct investment (FDI) inflows, providing significant nondebt-creating financing. Thanks to the large flows of FDI, Vietnam has been increasingly intertwined in the machinery supply chains developed by multinational corporations in East Asia. Machinery is becoming increasingly important in Vietnam's trade structure: it accounted for more than 30 per cent of Vietnam's exports in 2013, compared to only 10 per cent in 2000. Given the expansion of FDI in this field in recent years, this share can be expected to rise further. However, large FDI inflow influenced the growth in imports since foreign investors imported equipment, raw material, furnishings, construction material and the like in order to initiate the production process. In the case of Vietnam, vertical linkages between FDI and local firms are very weak. FDI firms in machinery assembly heavily rely on imports of parts, components and other intermediate goods. They do partially procure

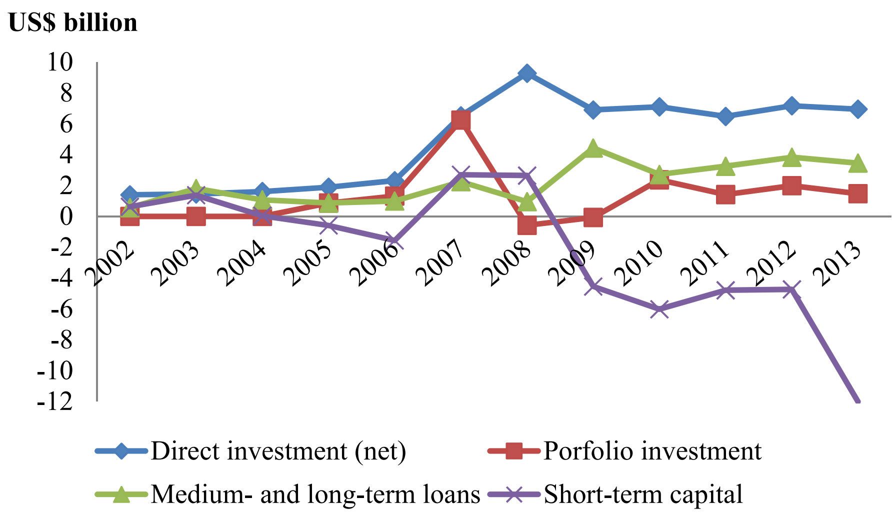


Figure 11. Vietnam's components of capital and financial account balance, 2002–2013

intermediate goods in domestic resources but mainly from the supply of other foreign firms rather than local firms.

On the other hand, portfolio investments have been negligible. After reaching $6.2 billion in 2007, they became slightly negative in the two years 2008 and 2009 (-$0.6 and -$0.1 billion, respectively) and only recovered marginally since then.

Growing errors and omissions

Although the balance of payments accounts are, in principle, balanced, imbalances result in practice from imperfections in source data and compilation. This imbalance is labeled net errors and omissions. In the case of Vietnam, net errors and omissions can be computed by taking reserve assets minus the sum of the current account balance and capital and financial account balances. Negative errors and omissions in the balance of payments have increased sharply since 2009.[10] The cumulative errors and omissions (a proxy for capital flight) in the period 2009-2013 were estimated at $32.4 billions, equivalent to nearly 19 percent of GDP in 2013. According to the common explanation, this may reflect large volumes of gold being held by private individuals in the country and a large amount of hard currency (almost U.S. dollar assets) being held either off-shore or outside the banking system. However, Vũ (2014) has put forward the following possible reasons for Vietnam's large and growing errors and omissions:

(1) The Vietnamese rich has send money abroad. Illegal business of people with the right in Vietnam is likely increasing, and this may be proved through transfering money back into Vietnam increasingly in order to money laundering in the form of remittances.

(2) Money transfers overseas to pay for illegal imports from China.

---

[10] The figures must be bigger because "Data up to 2009 reflect an old presentation; from 2010, part of errors and omissions began to be reflected in net foreign assets." (IMF Country Reports No. 10/281, 12/165, 14/311).

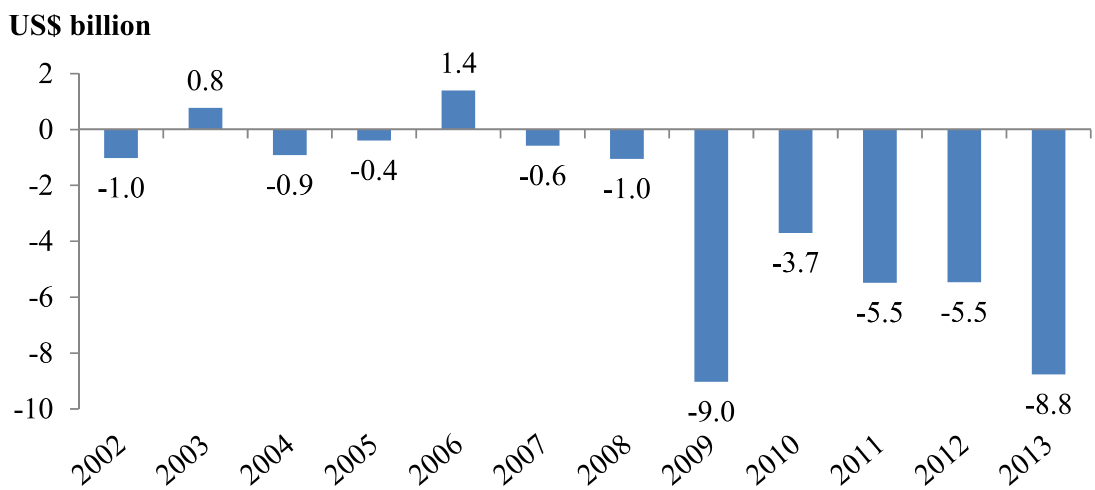

Figure 12. Vietnam, errors and omissions, 2002-2013

According to the IMF Balance of Payments Manual 5 and 6, a large, persistent errors and omission relative to the size of the economy are a cause for concern as they undermine the credibility of the balance of payments statistics.

Gross international reserves

Large international reserves (and a small external debt burden) reduce the risk of current account unsustainability and enable a country to finance a CAD at lower cost.

Vietnam's gross international reserves remain low on account of large, despite declining, domestic shift from Vietnamese dong into U.S. dollars and gold. At the end of 2013, gross international reserves stood at $26.0 billions, providing prospective GNFS import cover for just 2 months (Table 3). This remains well below the 8 months average of regional emerging market countries, and below the minimum level desirable for countries with a fixed exchange rate, according to the Fund's reserve adequacy metric (IMF, 2014). So the balance of payments will receive little support from the country's international reserves.

The stock of external debt

An existing large burden of international debt will make it more difficult to finance a current account imbalance. Moreover, a large debt-servicing burden can easily exhaust export

Table 3. Vietnam: Gross international reserves

(US$ billion)

	2002	2003	2004	2005	2006	2007	2008	2009	2010	2011	2012	2013

Figure 13. Vietnam: Some measures of external debt, 2002-13

revenues and prevent imports of investment goods that are needed for growth. In such a case, investors' behaviour may be altered by uncertainty about the country's *ability* or *willingness* to meet its debt obligations, or by a shift in expectations following an external shock. However, foreign debt may also be the counterpart of productive domestic investment that may later generate the foreign exchange needed to repay the loans. The debt position of a country may be proxied by relating the outstanding debt and debt servicing obligations to some macroeconomic variables, such as GDP and exports. Roubini and Wachtel (1997) suggest that a current account deficit is sustainable if the country maintains *a non-increasing foreign debt to GDP ratio*.

Figure 13 showed Vietnam's all three measures of external debt had fallen to lowest levels at the end of 2008, but risen again somewhat since 2009. In recent years, Vietnam's ratio of external debt to GDP has been relatively stable while the ratio to exports of goods, services and primary income has declined. At the end of 2013, the external debt stocks amounted to 38.2% of GDP and 45.8% exports of goods, services and primary income. The debt-service ratio reduced slightly from 3.9% in 2011 to 3.5% in 2013. Based on the LIC Debt Sustainability Analysis (DSA), Vietnam is at low risk of external debt distress (IMF, 2014).

4.1.4 *Stationarity of Vietnam's current account balance*

Now we perform a number of different unit root tests to determine the univariate properties of the Vietnam's CAB/GDP. We use 4 traditional unit root tests that include Augmented Dickey-Fuller (ADF), Phillips-Perron (PP), Kwiatkowski-Phillips-Schmidt-Shin (KPSS) and Dickey-Fuller Generalized Least Squares (DF-GLS). The test equations are chosen based on the visual inspection of the graph of the Vietnam's CAB/GDP in levels (Figure 1). The unit

Table 4. Unit Root/Stationarity Test

	ADF test		PP test		KPSS test	DF-GLS Test
	No constant included	Constant included	No constant included	Constant included	Constant included	Constant included
CAB	-1.9362*	-2.3834	-1.7586*	-1.8503	0.1902	-2.4406**

Asterisks * and ** indicate rejection of the null hypothesis (H0) for the ADF, PP, KPSS, and DF-GLS tests at 10% and 5% level of significance respectively. The null of the ADF, PP, and DF-GLS tests is non stationary series (unit root) while the null of the KPSS is stationary series.

Notes: Test statistics and critical values are computed by the statistical software EViews 6. Lag lengths or bandwidths were automatically selected by the program. Selection of lag lengths for ADF and DF-GLS tests was based on Schwarz Information Criterion (SIC). In the PP and KPSS tests, Newey-West Bandwidth was selected using Bartlett kernel spectral estimation method. The Critical values in the ADF, PP, and DF-GLS tests refer to critical values computed by Mac Kinnon (1996) while those in the KPSS test refer to Kwiatkowski-Phillips-Schmidt-Shin (1992, Table 1).

root test results are presented in Table 4.

Both the ADF and PP tests reject the null hypothesis of a unit root in favor of the alternative stationary at the 10% level only in the case no constant included. That is CAB/GDP is stationary with zero mean. Based on the KPSS test, the null hypothesis of stationary cannot be rejected at usual critical values. Further evidence is provided by the DF-GLS unit root test, which is more powerful than the ADF unit root test (Elliot et al. 1996). Hence, we conclude that Vietnam's current account deficit is stationary and, therefore, sustainable.

4.1.5 *Cointegration analysis of Vietnam's exports and imports*

The choice of the cointegration method is based on the unit root test results. Most of the evidence shown in Table 5 indicates that both X_t and M_t are I(1). So, we could check for cointegration between these two variables by using Johansen technique of cointegration. Johansen cointegration analysis requires the determination of appropriate lag length with an unrestricted VAR model. In Table 6, we see the statistical results regarding estimations of simple VARs for 6 different lag structures (from lags 5 to 0). Criteria suggest the use of a lag of 5 in the analysis. Hence, for the cointegration, the lag length is 4 (since we are running the model in first difference now, unlike in level when we used VAR to decide the lag length).

Thus, the results of Johansen cointegration test indicate that there is a long-run relationship between exports and imports for Vietnam in the sample period. The coefficients of the cointegrating vector are given in Table 8.

The results of the Johansen cointegration method of maximum likelihood method are reported in Table 7. Both trace statistic and maximum eigenvalue statistic suggest one cointegrating vector between X_t and M_t at 95 percent confidence level.

Table 5. Unit Root/Stationarity Test

	ADF test		PP test		KPSS test		DF-GLS Test	
	Constant included	Constant & trend included	Constant included	Constant & trend included	Constant included	Constant & trend included	Constant included	Constant & trend included
Level								
X	-0.0974	-4.1257**	0.9420	-3.6181*	0.7068**	0.0408	0.2207	-3,5586**
M	-1.5034	-4.0733**	-1.7090	-1.9347	0.6578**	0.0982	-0.8193	-2.1494
First difference								
ΔX	-4.9894***	-4.7564***	-9.0616***	-8.5944***	0.2803	0.1901**	-5.1602***	-5.6558***
ΔM	-4.2445***	-4.4961***	-4.3022***	-6.4624***	0.2166	0.3204***	-4.0479***	-4.5024***

Asterisks *, **, and *** indicate rejection of the null hypothesis (H0) for the ADF, PP, KPSS, and DF-GLS tests at 10%, 5%, and 1% level of significance respectively. The null of the ADF, PP, and DF-GLS tests is non stationary series (unit root) while the null of the KPSS is stationary series.

Notes: In the DF-GLS test with a constant and a trend included, the Critical values refer to Elliott-Rothenberg-Stock (1996, Table 1). Eviews 6 warns: "Test critical values calculated for 50 observations and may not be accurate for a sample size of 22". The rest is the same as above.

Table 6. Statistical values of the VAR lag order selection criteria

**MacKinnon-Haug-Michelis (1999) p-values

While the existence of a cointegration relationship between imports and exports is a necessary condition to sustain the foreign deficit, it is not an enough condition. Along with the existence of a cointegration relationship between imports and exports the slope coefficients obtained from the equations derived from these series should also be equal to 1 to put forth clearly that the current account deficit is sustainable. Failure to fulfill the second condition (sufficient condition) in Vietnam case requires that the sustainability of foreign deficit must be considered with doubt.

Since we found a cointegration relation between exports and imports with the estimated value of β coefficient, 0.900195, which is significantly not equal to one (Table 9); we can conclude the CAD of Vietnam may not be sustainable in the long-run because of faster rise in the Vietnam imports relative to the exports. In other words, based on the results of Johansen cointegration analysis, we can argue that the sustainability of the Vietnam's CAD is weak.

Table 8. Normalized cointegrating coefficients and adjustment coefficients

5. Conclusion

The results from the unit root/stationarity tests and the Johansen cointegration test attest to the fact that the country's current account deficit is sustainable. However, the results of the Johansen cointegration analysis on intertemporal balance model indicate that there is a weak evidence for sustainability of CAD in Vietnam for the 1990-2013 period.

The use of various relevant indicator to assess the sustainability of the Vietnamese current account deficits reveals a key insight. Current account deficits associated with sizable fiscal deficits, low efficiency of the economy, medium GDP growth, and the risk of the exchange rate becoming overvalued. When associated with growing external debt, inadquate foreign exchange reserves, and large errors and omissions, current account deficits may lead the vulnerability of the economy to spillovers from external shocks.

Even though findings of the study indicates a weak evidence for the sustainability of CAD in Vietnam, the lack of action to to reinforce the sustainability of CAD might give scope for misinterpretation on the part of markets, and to possible destabilizing capital flows. The annual economic growth rate is expected to be 5-6 percent over the period 2015-19 (IMF, 2014a, b). For a country of per capita income of about US$2000, that rate of growth is not high enough to escape from the so-called middle income trap.[11] Therefore, there is an urgent need to implement some economic policies, such as allowing greater exchange rate flexibility, enhancing the efficiency of public investment activities, developing human capacity, improving infrastructure and business environment, and promoting supporting industries.

This paper investigates the dynamic movements between the China macroeconomic fundamentals and the stock market volatility of the China enterprises in Hong Kong. By using the Generalized Autoregressive Conditional Heteroskedasticity with Mixed Data Sampling (GARCH-MIDAS) model, our empirical evidence from monthly data on both stock market indexes and 36 cross listed China enterprises in Shanghai and Hong Kong stock markets shows that industrial production growth, short term interest rate, industrial product price index and consumer price index, all contribute significantly to the stock volatility in Hong Kong with different magnitudes. These findings have implications to investors and policy makers on portfolio management and policy formulation respectively.

Keywords: Information Transmission, Mixed Data Sampling, GARCH, Macroeconomic fundamentals, volatility.

JEL Classifications: C22, C58, G10

1. Introduction

The study on relationship between the volatility of stock returns and macroeconomic fundamentals has been a major topic in financial literature. Contemporary financial theory suggests that stock return volatility is closely related to the movements of macroeconomic variables and many empirical researchers have examined the pattern in stock return movements with factors determining such movements. Chen et al (1986) examined the macroeconomic variables, such as industrial production, inflation and spread between long and short term interest rates and indicated that such macro variables affected stock returns. Schwert (1989) performed testing to examine the causes of stock market volatility in the United States (U.S.) for period 1859 to 1987 and found that the volatilities of money supply growth and real economic activity were helpful in forecasting the volatility of stock returns. These studies unfolded extensive research areas on using various sophisticated econometric methods for analyzing stock returns and macroeconomic varies.

Dhaka et al (1993) investigated the relationship between the money supply, industrial production (IP), short term three-month Treasury bill rate, consumer price index (CPI) and share prices in U.S. by employing the vector autoregressive (VAR) model. They found that money supply has a significant effect on share prices through the changes in interest rate and inflation rate. Chiang and Chiang (1996) examined the dynamic behavior of stock return volatility for Canada, Japan, Germany and the United Kingdom (U.K.) and found that the international stock return volatility was mainly influenced by the U.S. stock return volatility which supported the market information transmission hypothesis. Their findings evidenced that correlation existed between stock return volatility and volatility in macroeconomic variables although the effects were not substantial at that moment. Apergis (1998) applied the generalized autoregressive conditional heteroskedatic (GARCH) and GARCH-X models to study the effects of short-run deviations between S&P500 index and money supply, CPI, IP and the exchange rate. He found that forecasting U.S. stock prices were harder as they move apart from the pattern for volatility was more persistent.

Chaudhuri and Koo (2001) investigated the volatility of stocks in Asian emerging markets from both the volatility of domestic and external factors. They evidenced that both domestic macroeconomic fundamentals and international variables have positive influence stock return volatility and there were strong contagion effect in the region. Beltratti and Morana (2006) studied the relationship between macroeconomic and stock market volatility using S&P500 data for period 1970-2001 by using a multi-component econometric model which acknowledged structural breaks and estimates dynamics with different persistence characteristics. They found a bidirectional links between volatilities in stock market and in macroeconomic variables and there was a stronger evidence of causality running from macroeconomic to stock market volatility than the other way round. Ratanapakorn and Sharma (2007) investigated the long term and short term relationship S&P500 and six macroeconomic variables over the period 1984 to 1999 and observed a negative relationship between stock prices and long term interest rates and a positive relation between stock prices and money supply, IP, inflation, the exchange rate and the short term interest rate. In the Granger causality sense, every macroeconomic variable caused the stock prices in the long run. Abugri (2008) examined the dynamics in key macroeconomic indicators such as interest rates, and IP in four Latin American countries by using a six-variable vector autoregressive (VAR) model, the study found that those factors significantly explained market returns in all the markets. The country variables were found to impact the markets at varying significance and magnitudes. The study also implied that the increasing integration of these markets with the global economy may increase the exposure to external shocks such as capital reversals and performance of the international capital markets.

By investigating a broad international cross section of stock markets covering about 40 countries and focused on the cross section obtained by averaging over time, Diebold and Yilmaz (2008) used time series data on real GDP, real consumption expenditures, stock market returns and consumer price inflation for each country. They found a clear link between macroeconomic fundamentals and stock market volatilities, with volatile fundamentals translating into volatile stock markets. In an international study relating to volatility to macroeconomic variables, Engle and Rangel (2008) used the spline-GARCH model found that high frequency aggregate stock volatility has both a short run and long run component. They suggested that the long run component was related to the business cycle. Engle et al. (2009) further examined the relation between U.S. series of aggregate stock market volatility and macroeconomic variables by using a new mixed data sampling, the GARCH-MIDAS model, which used a mean-reverting unit daily GARCH process, similar to Engle and Rangel (2008), and found that the long term component of return volatility was driven by inflation and industrial production growth.

Chen (2009) extended the study to investigate whether macro-variables, such as interest rate spread, inflation rate, money stocks and aggregate output, were useful in predicting recession in stock market. The empirical evidence from monthly data on the S&P500 price index revealed that yield curve spreads and inflation rates were the most useful predictors of recessions in the U.S. stock market. Macro-variables performed better in predicting bear markets than predicating returns in the stock market. The forecasting on bear market was useful for market participants to conduct a market timing strategy. This was also benefit to monetary authorities when deciding the monetary policy which would affect the stock market finally.

Corradi, Distaso and Mele (2013) studied the relationship between stock market volatility and business cycle. They developed and estimated a no-arbitrage model which stock market volatility was related to a number of macroeconomic and unobservable factors. They also used the model to assess how market volatility and volatility related risk premiums change in response to business cycle conditions. Their model found that macroeconomic factors substantially helped explaining the variability of stock volatility and volatility risk premiums was strongly countercyclical, which even greater than the stock volatility. The key aspect was that the relations among market, stock volatility, volatility risk premiums and the macroeconomic factors were consistent with no arbitrage.

Girardin and Joyeux (2013) followed the methodology proposed by Engle et al. (2009) and Engle and Rangel (2008) to explain the effects of macro fundamentals and the relationship with speculative factors. By applying the MIDAS to analyze the Chinese A- and B-shares markets' long run volatility, they found that the Chinese A-share market has speculative characteristics before entering into the WTO. However, afterwards, macroeconomic fundamentals contributed substantially to the volatility of the A-share market, in particular the CPI information.

Engle, Ghysels and Sohn (2013) reviewed the linkage between stock market volatility and macroeconomic fundamentals by employing the GARCH-MIDAS model. The model combines the insights of spline-GARCH and MIDAS filtered and distinguished short and long sources of volatility and linked them directly to economic variables. Followed the series constructed by Schwert (1989), they used monthly Producer Index Index (PPI), IP and IP growth rate to see the relation between stock market volatility and macroeconomic volatility. The results found that for the full sample period, the long run component typically accounted for about half of predicted volatility. As for the most recent period, the results contributed about one-third of the explanation.

Regarding the China related stock markets, mainly there are three different kinds of stock, in terms of ownership structure, the A-share, B-share and H-share markets. The study of the relationship between the A-share and H-share is also an extensive research area in financial literature. Wang and Iorio (2007) investigated the integration of the three stock markets and found that a high level integration between the A-share and Hong Kong H-share market after 2004. Qiao, Chiang and Wong (2008) applied the FIVECM-BEKK GARCH model to examine the relationships among A-share and B-share stock markets in China and the Hong Kong H-share market. They found a unidirectional volatility spillover effects from the A-share stock market to the Hong Kong stock market. The evidence indicated that A-share market had an influential effect in both mean and volatility spillover effects to the H-share market in Hong Kong. Ke, Wang and Murray (2010) by employing the GARCH and EGARCH model to examine the volatility spillovers between the A-share market and both main and merging stock markets, including H-share in Hong Kong. They found that the mainland China A-share market had shown a unidirectional influence on the Hong Kong market.

Cai, McGuinness and Zhang (2011) examined the co-integration relation between the A-share and H-share prices of cross listed Chinese stock for period for period January 1999 to March 2009. They found that the movement of A- and H-shares highly co-related during the period owing to the congruence with the two economies' growing interdependence. It was suggested that the mainland China macroeconomic policy initiatives had contributed to the above phenomena. Li, Yi and Su (2011) used the VAR modeling to exam the spillover of same day return effect of cross listed equities which were traded in Shanghai (A-share) and Hong Kong (H-share), they found it occurred from A-share to H-share. Yip, Cheng and So (2014) by employing the DDC-MGARCH model to examine the information transmission and spillover processes among U.S., China and Hong Kong stock market and found that the volatility of China market had shown greater spillover effect on to Hong Kong since the 2007 financial crisis and the interaction between the China and Hong Kong stock markets was more prominent than those between the U.S. and China.

This paper aims to provide systematic evidence of the role of China macroeconomic fundamentals to the Hong Kong stock market volatility by employing the Engle's GARCH-MIDAS model to link macroeconomic variables to the component of stock market volatility on 36 cross listed equities in both A-share and H-share for period August 2010 to September 2014. The broad sets of macroeconomic variables include Industrial Production Growth, Industrial Product Price Index, Consumer Price Index and 3-month short term SHIBOR. The selection of the state variables is the key macroeconomic indicators which can reflect the economy activities and monetary movements in mainland China. They serve as the thermometer in measuring the growth or slowdown of the China economy. Both the industrial production growth and industrial price index belong to the producer's goods market. The 3-month short term SHIBOR represents the money market. Tradition economic literature indicates that interest rate contribute to the movement of stock price through affecting cost of capital and firm's profitability. Whereas the consumer price index provides a mean to measure the effect of consumer's goods market and inflation to the China economy. Furthermore, in line with the findings in Schwert (1989), the GARCH-MIDAS model provides strong evidence on the behaviour of stock market volatility. We, therefore, make reference to the approach of using the Engle et. al. (2013) model by estimating both monthly and quarterly frequency in our study.

The principal contribution of our study lies in the application of a model which enables us to evident the dimensions of dynamic movement between the China macroeconomic variables and the volatility of the Hong Kong stock market. The regression results with significant positive correlation among various estimators strongly support that a high degree of congruence towards the two important economies in Asia. These bring implications to investors and policy makers for the study of financial contagion effect.

This paper is structured as follows. Section 2 presents the research methodology. Section 3 describes the sample data. Section 4 reports the empirical results, analysis and robustness tests. Finally, concluding remark is made in Section 5.

2. Methodology

Different news events may have different impacts on financial markets, depending on whether they have consequences over short or long horizons. Our study relates some recent studies in econometrics modeling. In order to explore the role of China macroeconomic fundamentals on the China and Hong Kong stock markets, we perform our analysis with reference to the methodology introduced by Engle and Randel (2008) and Engle et. al (2013), which states that the unexpected returns can be written as

$$r_{i,t} - E_{i-1,t}\left(r_{i,t} \right) = \sqrt{\tau_t \, h_{i,t}} \, \varepsilon_{i,t}, \tag{1}$$

where $r_{i,t}$ is the log return on day i during month t, $E_{i-1,t}(\cdot)$ is the conditional expectation given information up to time $t-1$. Volatility has two components: $h_{i,t}$ is the short-run component which accounts for daily fluctuations and τ_t is the long-run component assumed initially to be fixed for month t. This specification allows the same news to have a different impact depending on the condition of the economy. Macroeconomic variables are expected to influence the long-run component of volatility but not the short-run component.

As there is little predictability in returns for daily data, the conditional expectation is assumed to be μ, that is $E_{i-1,t}\left(r_{i,t} \right) = \mu$. Thus, Eq. (1) can be rewritten as

$$r_{i,t} = \mu + \sqrt{\tau_t \, h_{i,t}} \, \varepsilon_{i,t}, \quad \forall i = 1, \dots, N_t, \tag{2}$$

where $\varepsilon_{i,t} \mid \Phi_{i-1,t} \sim N(0,1)$ and $\Phi_{i-1,t}$ is the information set up to day $(i-1)$ of period t, in which the period may be a month, quarter, or longer. The volatility dynamics of the component $h_{i,t}$ is assumed to follow a GARCH(1,1) process:

$$h_{i,t} = \alpha_0 + \alpha_1 \frac{(r_{i-1,t}-\mu)^2}{\tau_t} + \beta_1 h_{i-1,t}. \tag{3}$$

For the volatility models that directly incorporate macroeconomic time series, Engle et al (2013) proposed fixed span and rolling window specification in the MIDAS filter. Their empirical results show that both specifications have similar results. Thus, we assume τ is fixed for month t. Such a MIDAS filter is defined as

$$\log \tau_t = m + \theta \sum_{k=1}^{K} \varphi_k\,(\,\omega_1\,,\omega_2\,) X_{t-k} \tag{4}$$

where X_{t-k} is the level of a macroeconomic fundamentals, m and θ are the intercept and slope, respectively, of the MIDAS filter. The macroeconomic variables of interest are growth rate of IP, SHIBOR, IPP and CPI. For the weighting function $\varphi_k\,(\,\omega_1\,,\omega_2\,)$ in Eq. (4), we use the Beta lag structure:

$$\varphi_k\,(\,\omega_1\,,\omega_2\,) = \frac{(\,k\,/\,K\,)^{\,\omega_1-1}(\,1-k\,/\,K\,)^{\,\omega_2-1}}{\sum_{j=1}^{K}(\,j\,/\,K\,)^{\,\omega_1-1}(\,1-j\,/\,K\,)^{\,\omega_2-1}} \tag{5}$$

where the weights in Eq. (5) sum up to 1. The beta lag, based on the beta function, is very flexible to accommodate various lag structures. It can represent a monotonically increasing or decreasing weighting scheme and also a hump-shaped weighting scheme. See Ghysel et. al. (2007) for further details regarding the various patterns one can obtain with beta lags. As Engle et. al. (2013) and Girardin and Joyeux (2013) stated that the lag structure in Eq. (5) using beta weights and exponential weights produce almost identical results. Thus, we apply the more flexible Beta lag structure in our model setting.

Eqs. (2) – (5) form a GARCH-MIDAS model for time-varying conditional variance with fixed span macroeconomic time series volatility and parameter space $\Theta = \{\,\mu,\ \alpha_0,\ \alpha_1,\ \beta,\ m,\ \theta,\ \omega_1,\ \omega_2\,\}$. The number of parameters is fixed for different choices of the period t (month or quarter) and the number of lags K.

To estimate GARCH-MIDAS model, we develop a Bayesian approach to generate samples from the joint posterior distribution of all parameters via Markov chain Monte Carlo (MCMC) methods instead of QMLE. One advantage of this approach is that it allows all parameters to be estimated simultaneously and thus incorporates their variations in the statistical inference. In addition, this Bayesian approach allows us to perform the estimation easily even increasing the number of parameters for different model settings. For instance, one extension of the return series in Eq. (2) can be governed by an autoregressive function or the volatility dynamics can be governed by a GARCH(p,q) process. To estimate the GARCH-MIDAS model, we divide the set of parameters into four blocks by the Eqs (2) – (5). The first block of parameters represents the conditional mean in Eq. (1). The second and the third blocks are the parameters associated with the GARCH equation (Eq. (3)) and intercept and slope of Eq. (4), respectively. The fourth block is the weighting function in Eq. (5). See So and Yip (2011) for details of prior settings and sampling scheme. We carry out 20,000 iterations, discarding the first 8,000 MCMC iterations and obtain the final posterior estimates with posterior standard deviations. In each MCMC iteration, we sample the estimates from the prior and maximize the log-likelihood function, which can be written as

$$L(\Theta) = -\frac{1}{2}\sum_{i=1}^{T}\left[\log(2\pi) + \log h_t(\Phi)\tau_t(\Phi) + \frac{(r_t-\mu)^2}{h_t(\Phi)\,\tau_t(\Phi)}\right]. \quad (6)$$

3. Data

Dependent variables

Chinese stock market is a hot topic in recent studies. Lee and Rui (2000) studied the relation between trading volume, stock returns and return volatility in and across China stock exchanges. Yeh et al. (2002) studied stock returns and volatility of China A- and B-shares. Girardin and Joyeux (2013) study China A- and B-shares markets' long run volatility. However, the literature on relationship of stock market volatility and macroeconomic fundamentals in and across China and Hong Kong market context is still limited.

As at September 2014, there were 54 cross listed equities in both A-share and H-share for China and Hong Kong stock market. Out of the 54 cross listed equities, 16 companies were listed after 2010 with less than 4 years data and 2 enterprises were suspended for trading for more than two months during the sample data period. In order to maintain data integrity, they are taken out from the sample data. Accordingly, daily data of 36 cross listed equities from the August 2nd 2010 through September 30th 2014 are selected for analysis. Data sample starting from 2010 is used so as to include one of the biggest Hong Kong IPO listing of the Agricultural Bank of China Limited in the same year. Details of the 36 companies, including their names, corresponding sectors are provided in Table 1. The selected equities are grouped under four sector sub-indexes by making reference to the Hang Seng Indexes Company Limited's industry classification. Regarding market-wide indexes, Shanghai Stock Exchange Composite Index (SSCI), Shanghai A-share Index (SSHA) and Hang Seng China Enterprises Index (HSCE) are of interest so as to represent the dynamic relations between China and Hong Kong stock markets. Daily closing data of the stock equities and indexes are obtained from Bloomberg. Return of equity and indexes i at time t is calculated as:

$$r_{i,t} = \ln P_{i,t} - \ln P_{i,t-1}$$

where P_t is the closing price or index level at time t. Descriptive statistics of the returns of the 36 cross listed equities and 3 indexes are given in Table 2. Most of the mean of these stocks and market indexes are around 0 and have high volatility. In comparing the market indexes in China (SSCI and SSHA) and Hong Kong (HSCE), both average returns are negative, while HSCE is more volatile than SSCI and SSHA. In addition, SSCI and SSHA have a negative skewness while HSCE has a positive skewness. Among these 36 H-shares listed in Hong Kong stock exchange, all 36 stock average returns have a larger volatility than the HSCE. The composition of HSCE consists of 40 China enterprises, in which 21 of them are included in our 36 selected stocks. Regarding 36 A-shares listed in Shanghai stock exchange, three equities, namely Petro China Company Limited, Agricultural Bank of China Limited and Bank of China Limited, are less volatile than its market indexes. Figure 1 show the time series plot of SSCI, SSHA and HSCE indexes, the right panel on this figure demonstrate the daily returns of these indexes. The indexes and returns of SSCI and SSHA are quite similar. There is a substantial drop since the first quarter in 2011. However, the significant drop in HSCE can only be observed until the third quarter in 2011. The volatility of HSCE is increased substantially since August 2011 after the announcement of a series of measures to reinforce the Central Authorities' support for the development of Hong Kong as an offshore Renminbi (RMB) business centre by the Vice-Premier of the State Council. This announcement has a positive impact to Hong Kong market and rebound the market indexes from its lowest point which leads to the high volatility during the period August 2011 to December 2011.

Independent variables

Regarding the selection of macroeconomic variables, they are also obtained from the Bloomberg. According to the Central Intelligence Agency, industrial production growth rate can provide the comparison on the percentage increase in industrial production which includes manufacturing, mining and construction. The producer price index measures the average changes in price received by domestic producers for their output. Both indicators provide valid measure on the producers' goods market. Monetary authority can, through the adjustment on interest rate, affect the money supply. The use of 3-month SHIBOR provides a good measure regarding short term liquidity which in term affecting the money supply in the economy. Abdullah and Hayworth (1993) found that money supply was related to stock prices through portfolio substitution or inflationary expectation. On the other hand, through the change in consumer price index, it shows the economic activities in the consumer's goods market. Their studies also indicated that stock returns were related to inflation. Table 3 gives the descriptive statistics of the four selected China macroeconomic fundamentals. Industrial production has a negative growth rate and negative skewness while others fundamentals have a positive growth rate and positive skewness. Figure 2 shows the growth rates of these macroeconomic factors. The industrial production has a sudden decrease in second quarter of 2012 due to the increasingly violent environmental protests in 2011, which forced the suspension or cancellation of chemical plants, coal-fired power plants and a giant copper smelter. The industrial production index maintained its growth after the announcement by the environment minister that all major industrial projects must pass a "social risk assessment" before they began. The growth rate of industrial producer price index and consumer price index are similar and declines since the third quarter of 2011 due to the government policy on loosen fiscal policy in controlling the high inflation and maintaining the monetary policy stable. Hence, the 3-month short-term interest rate has maintained stable since the third quarter of 2011.

4. Empirical Results and Analysis

Parameter estimates

In this paper, we use the GARCH-MIDAS model described in Section 2 to fit daily returns of three market indices, namely Shanghai Stock Exchange Composite Index (SSCI), Shanghai

A-share Index (SSHA) and Hang Seng China Enterprises Index (HSCE), and 36 cross listed equities in A- and H-share indexes. We choose one year MIDAS lag years ($K = 12$ for monthly data and $K = 4$ for quarterly data).

The estimates of the GARCH-MIDAS parameters with IP, SHIBOR, IPP and CPI are presented in Tables 4 to 7 respectively. The estimates are the posterior means of 12,000 MCMC iterates and posterior standard deviations of these estimates are omitted for clearer presentations. All posterior standard deviations are available upon request. Although the beta lag structure weighting in Eq. (5) includes two parameters ω_1 and ω_2, the optimal ω_1 is always 1 such that the weights are monotonically decreasing over the lags. Therefore, we report a single ω parameter. The larger value of ω indicates a faster decay for the macroeconomic fundamentals. From Tables 4 to 7, all parameters are significance excepts for some conditional expectations μ. This is supported by the evidence from Table 2 in which most of the sample means are close to zero and insignificance. Most of the results show that sum of GARCH coefficients, $\alpha_1 + \beta$, are very close to 1 except for SSCI and SSHA, which indicate high persistence of volatility. All slope coefficients in Eq. (4), θ, of these China macroeconomic variables are statistically significance, which indicate that these China macroeconomic fundamentals are significant in estimating the market volatilities. Positive θ means an increase in the macroeconomic variable would lead to high stock or equity market volatility. The larger the magnitude of θ, the higher the impact of this macroeconomic variable to the equity or market volatility.

From Table 4, IP is used as the macroeconomic fundamentals. The positive θ in Eq.(4) implies an increase in industrial production index would increase the market volatility. In Table 4a, SSCI series with IP macroeconomic fundamental, the value of θ is 0.071, which implies an increase in IP, the conditional volatility would increase. Since the weighting function with with ω = 15.815 puts 0.766 on the first lag and 0.187 on the second lag of SHIBOR (in total of 95.3% of the weights), we find that a 1% increase of IP during the current month would increase the next month market volatility by $e^{0.071 \cdot 0.766} - 1 \approx 0.0559$ or 5.59%. For example, if the IP increases by 1 percentage point (say, from 4% to 5%), the next month market volatility would rise by 5.59% (say, from 15% to 15.84%). Similarly, if the IP of previous month increases by 1 percentage point, we would see $e^{0.071 \cdot 0.187} - 1 \approx 0.0134\%$ or 1.34% increase in market volatility next month. For SSHA, the conditional market volatility of next month would be increased by 15.16% and 4.56% of 1 percentage point increase of current month IP and previous month IP, respectively. In HSCE, the value of θ is -0.487, which implies an increase in IP, the conditional volatility of HSCE would decrease. The magnitude of the value governs the degree of impact on the conditional volatility. The next month market volatility of HSCE would drop 33.68% by 1 percentage point increase of current month IP and drop 6.42% of previous month IP. Figure 3 shows the time-varying conditional volatility of three market indexes with IP and SHIBOR macroeconomic fundamentals. The left panels of time-varying conditional volatility with IP as MIDAS filters demonstrate the impact of IP is significant. The increase in IP would increase the market volatility of SSCI and SSHA but decrease the market volatility of HSCE. And hence, the time-varying conditional volatilities are more volatile in HSCE than SSCI and SSHA.

Similar results can be estimated based on the weights ω and slope coefficients θ. Regarding the 3-month short term SHIBOR, a 1 percentage point increase of current month interest rate and previous month interest rate would decrease the market volatility of SSCI by 0.41% and 0.07% respectively. However, it would increase the market volatility of SSHA by 1.67% and 0.22%, respectively. It is appealing that the degree of impact of SHIBOR is higher in HSCE than SSCI and SSHA. The HSCE market volatility would increase by 10.48% and 3.83% of 1 percentage point increase in SHIBOR. In Figure 3, the right panels show the time-varying conditional volatility with SHIBOR as MIDAS filter. As the volatilities of HSCE and SSHA are positively related with SHIBOR, they are evidenced by the time-varying conditional volatility plots.

In view of the industrial product price index, a 1 percentage point increase of current IPP and previous IPP would increase the market volatility of SSCI by 2.28% and 0.64%, respectively. IPP affects SSHA index similarly by 2.48% and 0.23%, respectively. It is worth noting that the volatility of HSCE has a greater impact of an increase of 1percentage point of current IPP and previous IPP by 5.34% and 0.71%. Figure 4 provides the time-varying conditional volatility of three market indexes with IPP and CPI macroeconomic fundamentals. All three market volatilities have a similar movement as IPP. However, the market volatility of SSCI and SSHA are less volatile than that of HSCE.

With a view to consumer price index, the impact of CPI to HSCE market volatility has the greatest impact among three market indexes. The volatility of HSCE increases by more than 40 times of 1 percentage point increases in current month CPI and previous month CPI, while it increases about 4.5 times of previous month CPI by a 1 percentage point increment. CPI affects negatively in local markets instead of positively related. SSCI will decrease by 31.35% and 13.09% by an increase of 1 percentage point of current month CPI and previous month CPI, respectively. SSHA will decrease by 82.05% and 38.27% of a 1 percentage point increment in current month CPI and previous month CPI, respectively. The right panels of time-varying conditional volatility plots in Figure 4 demonstrate the impact of CPI on three market indexes.

By employing the GARCH-MIDAS model, we find that all examined macroeconomic fundamentals, IP, SHIBOR, IPP and CPI, have an explanatory power for the stock return volatility of the cross listed China enterprise in Shanghai (A-shares) and Hong Kong (H-shares). In addition, the explanatory power is more significant for the H-shares. The empirical result is supported by analyzing both the movements of two market indexes in Shanghai stock exchange (SSCI and SSHA) and one market index in Hong Kong stock exchange (HSCE).

Analysis on macroeconomic fundamentals

From the parameter estimates, the larger the magnitude of θ imply the larger degree of response to the change of the macroeconomic fundamentals. Based on the estimation in Section 4.1, we find that China macroeconomic fundamentals not only useful in explaining the market and stock volatility in China, but also exists a significant contagion effect on the movement of the stock return in Hong Kong, especially for CPI. It increases the HSCE market volatility by more than 40 times of an increase of 1 percentage point of current CPI. Similar results can be drawn for other economic factors. This empirical result which CPI inflation volatility plays an important role with high explanatory power is supported by the findings of Ratanapakorn and Sharma (2007) and Girardin and Joyeux (2013). The volatility on CPI inflation affects the monetary authority's decision on money supply policy which has an indirect impact on stock returns volatility.

To investigate the relationship between the cross listed China enterprises on A-share and H-share markets, we perform *t*-test on the slope coefficient, θ, in Eq. (4) among 4 selected China macroeconomic fundamentals, IP, SHIBOR, IPP and CPI to each of these 36 individuals China enterprises in both Shanghai (A-shares) and Hong Kong markets (H-shares). Table 8 shows the test statistics and the *p*-value of these tests. We apply one-tailed *t*-test to investigate whether positive impact or negative impact exists. In Panel A of Table 8, we perform the test with A-shares. SHIBOR, IPP and CPI show significant negative values on the slope coefficient, while IP has insignificant value different from zero. These results show that significant contagion effect on the movement of the equities return in A-shares by the SHIBOR, IPP and CPI. Similarly, IP, SHIBOR and IPP have shown significant contagion effect on the movement of the equities return in H-shares.

To eliminate the movement due to individual company news or events, a further analysis on paired difference tests are performed. All paired *t*-tests with different economic factors are statistically significance, which indicate the same China fundamentals impact on A-shares and H-shares are statistically significance. The difference of the 36 cross listed China enterprises in Shanghai and Hong Kong markets are all negative with SHIBOR, IPP and CPI macroeconomic fundamentals, while it is positive with IP macroeconomic factor. This implies that the degree of response to their changes is in general larger for Hong Kong market than that for the China market. The expectation of macro-controls on interest rate, production price and CPI on policy makers from international investors in Hong Kong seems to be the best justification for this.

These findings have important implications for investors who would like to adopt a cross market approach to capture the investment opportunities created by exposure to a comprehensive Chinese investment universe, especially on their portfolio diversification and trading strategies. As China macroeconomic variables have shown various degrees of impact and significance on the return of the China enterprise stock market in Hong Kong, investors could view the China and Hong Kong stock markets are heading toward an integrated one. In view of the increasing integration of the two stock markets, in particular under the Shanghai-Hong Kong Stock Connect and the proposed the Shenzhen-Hong Kong Stock Connect arrangements, the stock market volatility of Hong Kong may increase its exposure to the mainland China economy in addition to the other external shocks. The Hong Kong policy makers also benefit from the study since at the time when they formulate the policy, consideration on China macroeconomic fundamentals and sequence of implementation may help to minimize economy risk factors and maintain Hong Kong's financial market stability.

Impact of data frequency

Furthermore, we also apply the GARCH-MIDAS model with these four quarterly macroeconomic variables. Parameter estimates are available upon request. On parameter estimation, we observe similar results as monthly macroeconomic variables. All parameters are significant except for some expected market returns μ. It is worth noting that the values of slope coefficient θ are significant but closer to zero than that in monthly macroeconomic variables. We also perform the t-tests and paired difference tests. It is appealing that all the four quarterly macroeconomic fundamentals also have significant impacts on three market indexes and all 36 cross listed China enterprise in Shanghai and Hong Kong. However, in the paired difference tests, only SHIBOR and IPP show significant larger contagion effect on the movement of the stock return in H-shares than that in A-shares. On the IP and CPI factors, the contagion effect on the movement of the stock return in H-shares and A-shares are insignificantly different from each other. This evidence shows that short term impact running from macroeconomic variables to stock return volatility is found in comparing the monthly and quarterly estimations.

Robustness test

Firstly, in order to provide reliable estimates, we perform simulation study of the Bayesian MCMC approach with 100 simulated time series data under the various parameter settings. Summary statistics and parameter estimates of these 100 simulated time series can be provided upon request. Secondly, in the estimation process with market returns and macroeconomic variables, we start with various initial values and result with similar parameter estimates. Thirdly, in order to provide consistent and efficient estimates, we perform with different MCMC iterations. Sufficiently large MCMC iterations are required to generate reliable estimates. However, it may take a longer time for the estimation. The current selection of 20,000 iterations with first 8,000 iterations discarded can provide consistent and time efficient estimates.

Finally, we perform an ANOVA test to diagnosis the robustness on different sectors of these 36 cross listed China enterprises. In general, there are significant contagion effect on the movement of the individual stock return in H-shares and A-shares among four sectors, namely Commerce and Industry, Finance, Properties and Utilities. Table 1 provides the corresponding sector of each stock into four sectors by making reference to the Hang Seng Indexes Company Limited's industry classification. In general, these analyses show that similar contagion effects are observed among various sectors under the same macroeconomic variables.

5. Conclusion

This paper examines the dynamic relations between various China domestic macroeconomic variables and the causal behaviour of stock market volatility of the China enterprises in Hong Kong. By employing the GARCH-MIDAS model, we find that all the examined variables, Industrial Production Growth (IP), 3-month short term interest rate (SHIBOR), Industrial

Product Price Index (PPI) and Consumer Price Index (CPI) have explanatory power for the stock return volatility of the China enterprise in Hong Kong. The empirical result is supported by analyzing both the movements of the Shanghai Stock Exchange Composite Index and Shanghai A-Share Index against the Hang Seng China Enterprises Index in Hong Kong.

The empirical finding strongly shows that China macroeconomic fundamentals not only useful in explaining the market and stock volatility in China, but also exists a significant contagion effect on the movement of the stock return in Hong Kong, especially for CPI. Further estimation is made by applying the Paired-Difference Test to each of the 36 individual cross listed China enterprises in both Shanghai and Hong Kong markets, the result also evidenced our findings. It is noticeable that among the macroeconomic variables that we considered, the degree of response to their changes is in general larger for Hong Kong market than that for the China market, except for the IP. Our study contributes to the growing body of evidence on the transmission of the influences of macroeconomic variables of cross listed securities under the case of Chinese A- and H- shares. Further research can be studied with longer time horizon to perform the analysis on impact of these four macroeconomic fundamentals for different sub-period with structural breaks analysis.

The 23rd Annual Conference on Pacific Basin Finance, Economics, Accounting, and Management (2015)

A Simple Model on Hong Kong's Price Level

Kenneth Hoi Ki Chung
Department of Economics and Finance
Hang Seng Management College
Hong Kong
hkchung@hsmc.edu.hk

Based on the theory of law of one price and Quantity Theory of money, a simple regression model on the price level of Hong Kong has been created. It is found, during the period 1998Q2-2014Q4, the price level of mainland China, the exchange rate between Hong Kong dollar and Chinese yuan, the amount of Hong Kong money supply per real output, and the unemployment rate of Hong Kong are significant factors in determining the price level of Hong Kong.

1. Introduction

Inflation is always a concern of both residents and government in whatever countries, because of its welfare implications, like redistribution of wealth under anticipated and unanticipated inflation. (Alchian, pp.363-411). However, the problem of inflation becomes less serious after the 2008 financial crisis because many industrialized countries had recorded a fall, rather than a rise, in their price levels. To deal with the stagnant economies, many countries, led by the US, had been expanding their money supply (quantitative easing). However, the rise in money supply seemed ineffective to boost their weak economies much during the initial years. But those increased money stock had been flowing to Asian countries and emerging markets, and had led to rises in the general price and asset prices in latter economies. Hong Kong is one of those Asian economies affected by these capital inflows. In fact, over US$640 billion of foreign capital had come to Hong Kong during 2008 to 2010. (The 2010-11 Budget, pp.8-9)

Through out the five years after 2009, Hong Kong's inflation (measured by consumer price index) has been rising from -0.1% in the second quarter of 2009 to nearly 5% in the last quarter of 2014 (year on year growth rate), see Figure 1.

But unlike many other countries / economies that fiscal and monetary tools can be used to deal with inflation, under the current "currency board system" (also called "linked exchange rate system") adopted since 1983, Hong Kong is deprived of the use of independent monetary policy to tackle inflation. The currency board arrangement requires HK dollar to be pegged to US dollar at a rate around HK$7.8 to US$1 (with fluctuations allowed within the range of HK$7.85 to HK$7.75 per US$1, after refinements in recent years). And the money supply change of Hong Kong is determined by Hong Kong's external balances. When more hot money flows to Hong Kong, Hong Kong's money supply would increase according, and would lead to a rise in price level according to the Quantity Theory of Money.

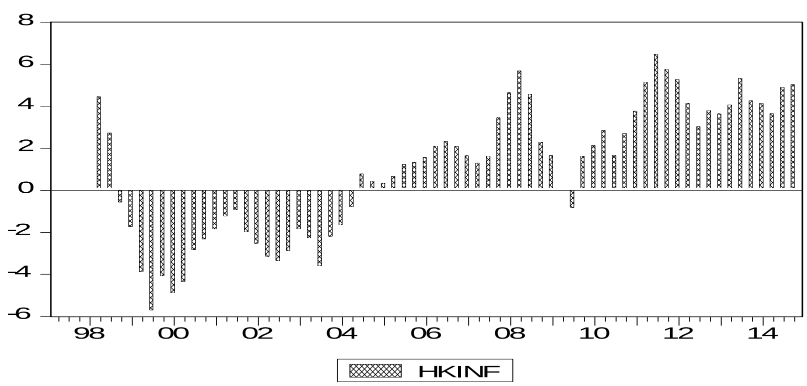

Figure 1: Hong Kong inflation (1998Q2-2014Q4)

Table 1 Correlation coefficients between Hong Kong and mainland China, 1979-2002

	1979-2002	1991-2002
Output growth correlation		
(a) in local currency	0.18	0.42
(b) PPP-based	0.42	0.53
Real per capita Consumption growth rate	0.10	0.37

Apart from the monetary aspect that affects Hong Kong's price level, the price level of Hong Kong is also related to the price level of its trading partners (e.g. mainland China). The higher the price differential between Hong Kong and its trading partners, the greater the volume of arbitrage activities. Due to the geographical proximity between Hong Kong and mainland China, the two places are highly connected. For instance, Cheung, Chinn and Fujii (2007) indicated that a high degree of integration existed between the two economies was reflected by the rise in correlation coefficients of output growth rate and real per capita consumption growth rate, during 1979-2002, between the two economies, see Table 1.

Besides, the close linkage between Hong Kong and mainland can be reflected by trading activities between the two places. Mainland China has long been been the largest single trading partner of Hong Kong (e.g. Table 2).

Table 2 Merchandise trade of Hong Kong with Mainland China (HK$ million)

Type of trade	2003	2008	2009	2010	2011	2012	2013
Imports (supplier) from Mainland China	785625 (43.5%)	1410735 (46.6%)	1249374 (46.4%)	1529751 (45.5%)	1696807 (45.1%)	1840862 (47.1%)	1942131 (47.8%)
Domestic exports to Mainland China	36757 (30.2%)	34758 (38.3%)	26672 (39.3%)	31223 (44.9%)	30699 (46.8%)	26026 (44.2%)	24784 (45.6%)
Re-exports to Mainland China	705787 (43.5%)	1335687 (48.9%)	1236577 (51.3%)	1566999 (52.9%)	1716656 (52.5%)	1831732 (54.3%)	1924463 (54.9%)
Re-exports from Mainland China	967104 (59.7%)	1707696 (62.3%)	1503319 (62.3%)	1820964 (61.5%)	2015046 (61.6%)	2104417 (62.3%)	2159878 (61.6%)

Source: Hong Kong Annual Digest of Statistics 2014. Figures inside parenthesis are percentage to Total Imports, Total Domestic exports, Total Re-exports to, and Total Re-exports from Mainland China respectively.

2. Previous Literature on Hong Kong's price level and inflation

Far before the 2008 financial crisis, researches had been done on the price level and inflation of Hong Kong. For example, Ha and Leung (2001) explained the inflation of Hong Kong, during 1977-2000, by analyzing the output gap and import price changes. Their results showed that a positive output gap of 1 percentage point would raise inflation by ½ percentage point in the short run, and 2½ percentage point in the long run. However, a rise in the domestic price of imports by 1 percent would push inflation up by ¼ percentage points in the short run, and will have full pass-through effect in the long run.

On the other hand, Ha and Fan (2002) investigated the inflation of Hong Kong by looking at the degree of price convergence between Hong Kong and mainland China. They found statistical evidence of price convergence between HK and mainland cities. The average half-life of the price differentials was estimated to be 6½ years. But they had indicated also that the convergence pace may differ significantly across the spectrum of products. The study of Hans, Liu and Jin (2006) focused on HK's integration and business cycle synchronization with mainland and also the US. They constructed a structural vector auto-regression model and found that shocks from US could explain about 45% of the variation in prices in HK, but mainland shocks could explain about 1/3 of HK's price movement.

As Hong Kong imported large amount of goods from other countries, Liu and Tsang (2008) estimated the effect of exchange rate pass-through to Hong Kong's inflation. Empirically, they found that a 10% depreciation of the US dollar against all currencies except for the Hong Kong dollar would raise HK domestic prices by 0.82 and 1.61 percent in the short run and medium run. Thus, the impact of exchange rate change should not be ignored.

Although price convergence between Hong Kong and the US is implied theoretically under the currency board system, Manopimoke (2012), analyzed with a New Keynesian Phillips Curve, found little evidences on the price convergence between Hong Kong and US in the long-run. However, the output gaps of US and of China have opposite effects on the cycle component of HK inflation, with the coefficient of the China output gap twice as large as that of the US. Hence, the proximity of Hong Kong with mainland China may be a relevant factor to consider.

In sum, output gap, price convergence, exchange rate pass-through, economic shocks and business cycle synchronization have been studied separately in the determination of Hong Kong's price level and inflation rate in previous studies.

In this study, we are going to construct a simple model with the consideration of monetary changes as well as price convergence between Hong Kong and mainland China.

3. Model

Inflation is normally described as a monetary phenomenon where a continuous rise is found in the general price level. The two common measurements for general price level are CPI and GDP deflator. In this study, we measure inflation by the change in CPI. A rise in CPI means a rise in the price of a consumer basket of goods and services, thus inflation.

Since those goods in the consumer basket include goods produced domestically and goods imported from other places. The rise in CPI may be the result of rise in either type of goods.

As mentioned above, HK relies heavily on imports (e.g. water, food and basic necessities) from mainland China, so the price level of mainland will affect the price of goods imported to Hong Kong.

Let the price of Chinese products be Pc. If Pc is measured in US$, it is

$$Pc * US\$/CHN$$

where US$ is US dollar; and CHN is Chinese yuan.

The price of Hong Kong products (and services), Phk, if expressed in US$ is:

$$Phk * US\$/HK\$$$

If the law of one price holds and if a non-arbitrage equilibrium on tradable goods between Hong Kong and mainland China exists, then

$$Pc*(US\$/CHN) - Phk*(US\$/HK\$) = \text{transportation cost}$$

However, if transportation cost is considered to be small due to the close proximity between the two economies, the above relationship can be simplified to:

$$Pc* (US\$/CHN) = Phk*(US\$/HK\$)$$

Rearrange the terms gives

$$Phk = Pc* (US\$/CHN) * (HK\$/US\$) \qquad (1)$$

or

$$Phk = Pc* (HK\$/CHN) \qquad (2)$$

Therefore, the price level (of tradable goods) of Hong Kong is related to the price level of mainland, given the existence of good arbitrage.

On the other hand, as mentioned above, CPI can rise when the price of domestic products increases. According to a simple production function, the potential domestic output of an economy is determined by the factor endowment as well as technological level. But if unemployment exists in an economy, and if that unemployment is not of the frictional and structural types, unemployment would acts as a constraint on inflation. In the traditional Phillips Curve analysis, a rise in inflation is normally accompanied by a fall in unemployment rate. The negative relationship between HK inflation (HKINF) and unemployment rate (HKUR), seems existed in Hong Kong during 1998-2014, is shown in Figures 2 and 3.

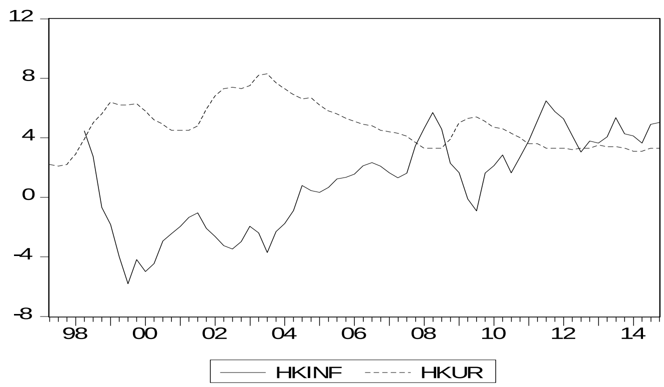

Figure 2 Line-graph of Inflation and Unemployment rates of Hong Kong (1998Q2-2014Q4)

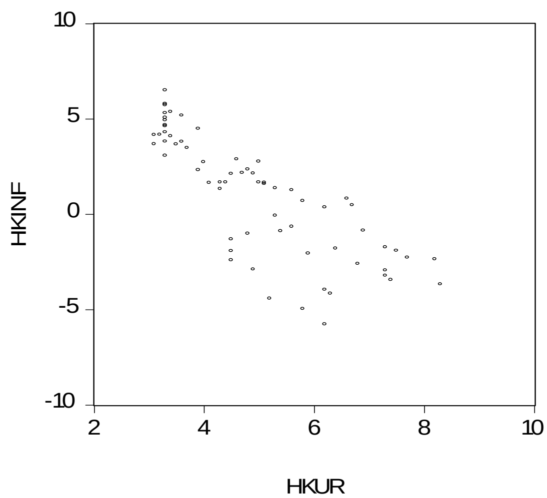

Figure 3 Scatters of Inflation and Unemployment rates of Hong Kong (1998Q2-2014Q4)

Equation (1) above tells us that Hong Kong's price level (of tradable goods) is related to that of mainland China. But according to Milton Friedman (1994, p.193), long-term price movements should be related to changes in the money stock. Base on Quantity theory of money, we have

$$MV = Py$$

where M is money supply; V is the velocity of money in circulation; P is general price level; and y is real output.

Rearranging the terms gives

$$P = (M/y)V \qquad (3)$$

where M/y is money per unit of real output and sometimes it described as "excess liquidity". (Chung, p.57) If V remains unchanged, a change in M/y will lead to a proportionate change in P.

Regression Equation

Combining the ideas that Hong Kong's price level is related to mainland's price level and also affected by excess liquidity, a regression model on Hong Kong price level is established as follow:

$$Phk = \beta 0 + \beta 1\ Pc + \beta 2\ EXHKCHN + \beta 3\ EXLIQM2 + \beta 4\ HKUR + \mu \qquad (4)$$

where Phk is the price level of HK; Pc price level of mainland; EXHKCHN is HK$/CHN exchange rate; EXLIQM2 is excess liquidity (calculated as M/y, and we use M2 to represent M); HKUR is unemployment rate of Hong Kong that acts as a constraint on the rise in price level; and μ is the error term. The values of β1, β2 and β3 are expected to be positive, but that of β4 is negative.

Data

Data on mainland China and Hong Kong is obtained from Datastream, Hong Kong Census and Statistics Department, and Hong Kong Monetary Authority. For comparison sake, CPIs

Table 3 Results of Unit Root Test (Sample: 1998Q2-2014Q4)

Variable	ADF statistics	1% critical value	5% critical value

HKUR	-0.881460 (0, 0, 5)	-2.5983	-1.9454
Δ HKUR	-4.229264 (0, 0, 3)**	-2.5978	-1.9453

Note: **(*) indicates rejection of unit root at 1% (5%) critical value. Terms inside parenthesis represents the existence of an intercept (C), a trend (T) and lag differences. 0 indicates neither intercept nor trend.

of mainland China and of Hong Kong have been adjusted to 100 at 1997Q2. Since the Hong Kong GDP estimates exhibit seasonal patterns, they have been adjusted with X11 (additive) method. All variables in Equation (4), except HKUR, have taken logarithmic values.

Stationarity and Unit root test

To avoid spurious regression, the several series of variables have been tested for unit roots. The Augmented Dickey Fuller (ADF) test has been employed and the series of mainland CPI, Hong Kong CPI, US$/CHN exchange rate, HK$/US$ exchange rate, Hong Kong money supply M2, Hong Kong real GDP (seasonally adjusted), excess liquidity (M2 / real GDP), and Hong Kong unemployment rate are all found non-stationary. However, the first-differences of these series are stationary, and they are all I(1). For details, see Table 3.

Cointegration Test

Johansen cointegration test has been applied to series of Hong Kong CPI, mainland CPI, HK$/CHN exchange rate, excess liquidity M2, and HK unemployment rate, to see if they can be cointegrated. The result (Table 4) shows that are cointegrated and thus there are long-run relationship among them.

4. Regression Results

Since the variables are cointegrated, OLS can be been applied to estimate equation (4) and results are shown in the second column of Table 5.

Table 4 Result of Johansen Cointegration Test

Sample: 1997:2 2014:4

Table 5 Regression Results

	Equation (4)	Equation (5)
C	10.33997	9.103443
	(8.986423)	(10.78687)
LPC	-1.354158	-1.061955
	(-5.789660)	(-6.153028)
LEXHKCHN	-0.011663	0.314156
	(-0.065371)	(2.326074)
LEXLIQM2	0.245147	0.220125
	(2.809740)	(2.396386)
HKUR	-0.031062	-0.032524
	(-7.761396)	(-11.25347)
Dummy		-0.090626
		(-7.878995)
R-squared	0.819423	0.907636
Adjusted R-squared	0.808479	0.900531
Durbin-Watson stat	0.228143	0.496489
F-statistic	74.87366	127.7471
	Prob (F-stat) 0.0000	Prob (F-stat) 0.0000

Note: numbers inside parenthesis are t-statistics.

The regression model basically fits the data well and the Adjusted R-squared is 0.8. It means around 80% of the variation in Hong Kong CPI can be explanatory variables. However, the sign of mainland CPI is different from what we have expected. Besides, the variable HK$/CHN is insignificant.

After checking with the data again, as China had undergone a reformation in its exchange rate system, CHN was no longer pegged to US$ at a fixed rate in 2005Q3. Therefore, a dummy variable is added to the regression equation to separate the stage before and after the reformation. The equation is modified to:

$$Phk = \beta 0 + \beta 1\ Pc + \beta 2\ EXHKCHN + \beta 3\ EXLIQM2 + \beta 4\ HKUR + \beta 5 DUMMY + \mu \qquad (5)$$

The regression results of Equation (5) are shown in the last column of Table 5. The Adjusted R-squared has increased to 0.9. The exchange rate HK$/CHN becomes significant. But the variable LPC is still of an unexpected sign. Further research has to be done to investigate this problem. The coefficient of LEXHKCHN indicates that a depreciation of HK$ by 1%, Hong Kong's price level will increase by 0.3%. The rise in excess liquidity by 1% will lead to a rise in Hong Kong CPI by 0.22%. If the unemployment rate falls, Hong Kong CPI will rise.

5. Conclusion

Based on the above regression model, we found that the exchange rate between HK$ and Chinese yuan, excess liquidity and the change in unemployment do affect the price level of Hong Kong. The results are basically consistent with the implications of Quantity theory of money. Although the price level of mainland China is a significant factor in determining the price level of Hong Kong, the price convergence may not be so apparent and further studies have to be done in that area.

This article discusses the determinants of service quality and user satisfaction of electronic government (e-government) services. Adopting the Technology Acceptance Model as the core component in the model development, this study introduces perceived security as a construct that may affect service quality and e-government services user satisfaction. Our data was collected from an online survey of 229 users of the e-government services in Hong Kong. The results showed relationships among perceived usefulness, perceived ease of use, perceived security, service quality and e-government services user satisfaction. Perceived security was the most significant antecedent of service quality which in turn heavily affected e-government services user satisfaction. In addition, assurance and reliability were found to be the most important aspects of service quality that affected the satisfaction level of users. We present implications for research and practice to e-government services.

Keywords: e-government, satisfaction, security, service, TAM (Technology Acceptance Model).

1. Introduction

Research on the management of information in public sector has aroused much attention in recent years. Many governments have disseminated information and provided electronic services (e-services) through the government Web sites (Musso et al., 2000; Welch et al., 2005). These governments are commonly known as the electronic governments (e-governments) which are defined as "the use of information technologies to improve the efficiency, effectiveness, transparency, and responsibility of public governments". (Titah & Barki, 2008, p. 43). The e-government is also named as "digital government", "internetworked government" and "government online" (Tapscott, 1995; Yong & Lim, 2003). Layne and Lee (2001) found that governments realized the value of Internet as a channel to provide government services to citizens who could comply with the government requirements online and enjoy a saving of travelling time. Since 1998, the e-government system in Hong Kong has been launched as a part of the Digital 21 Strategy which provides Hong Kong people with e-services. It has undergone three major enhancements in 2001, 2004 and 2008. A new government portal known as GovHK has been in operation since August 2007 (HKSAR Government, 2008).

Developed by Davis (1986), the Technology Acceptance Model has been widely applied in the context of information systems (Davis, 1989; Davis et al., 1989; Venkatesh et al., 2003). In particular, it has been used in the examination of the acceptance rate of information systems (Al-Khaldi & Wallace, 1999; Gefen et al., 2003). Using the Technology Acceptance Model as the core component in the model development of this study, we examine the effects of different constructs on service quality and e-government services user satisfaction in Hong Kong. Although research has been carried out to study satisfaction in online systems (e.g., Oliver, 1980, 2000; Szymanski & Hise, 2000), the determinants of user satisfaction with e-government services have not been studied. To fill the research gap, this study investigates the direct and indirect effects of different variables on the user satisfaction with e-government services. A better understanding of user satisfaction is important to improve the effectiveness of an e-government system.

This study contributes to the literature by investigating the impacts of the construct of security, which has not been studied in the Technology Acceptance Model. The objectives of this study are as follows: firstly identifying the determinants of service quality and user satisfaction of e-government services; secondly examining the relationship between these determinants; and finally exploring the relative importance of each determinant for service quality and user satisfaction of e-government services.

2. Theoretical Foundation

The most salient constructs of the Technology Acceptance Model, namely perceived usefulness and perceived ease of use, are used in this study to examine their effects on service quality and user satisfaction of the e-government services.

The Technology Acceptance Model, which is firstly proposed by Davis (1986), is a prominent model that explains and predicts the phenomenon of technology acceptance (Venkatesh et al., 2003). It aims to explore the determinants of computer acceptance, which in turn affect the behavior of different computing technology end-users, and is parsimonious and theoretically justified (Davis et al., 1989). The Technology Acceptance Model is developed from Fishbein and Ajzen (1975)'s Theory of Reasoned Action which is used in the social psychology field and is typically represented by the following equation:

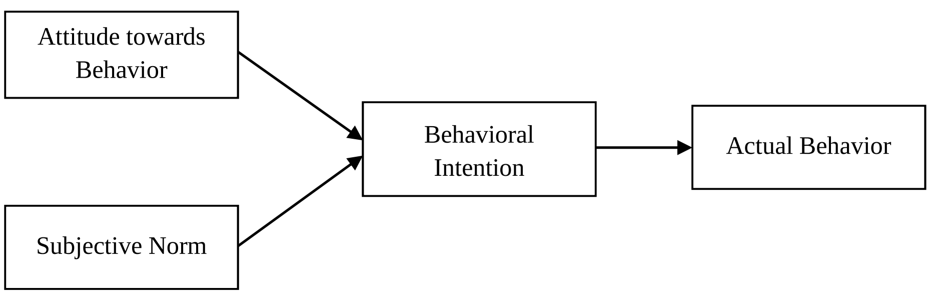
$$BI = A + SN$$

where

BI = behavioral intention,
A = person's attitude, and
SN = subjective norm

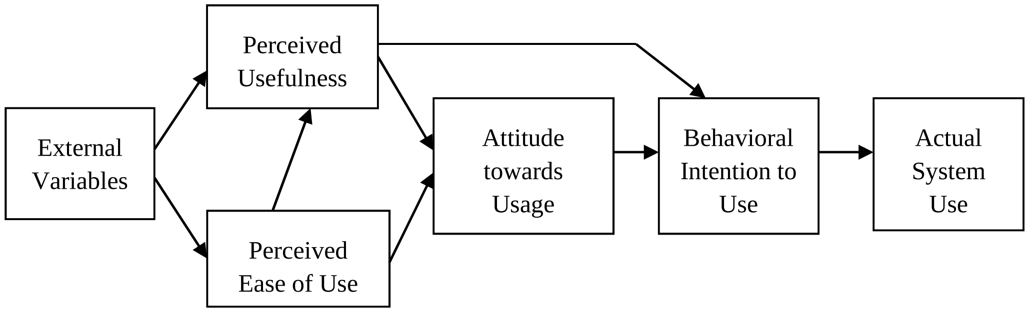
While a person's attitude is defined as his or her positive or negative feelings (i.e., evaluating effect) about performing the target behavior, subjective norm means a person's perception in which most people who are important to him or her think whether he or she should perform the behavior (Davis et al., 1989; Fishbein & Ajzen, 1975). Behavioral intention is defined as a measure of the strength of a person's intention to perform a specified behavior. Figure 1 highlights the key components underlying the Theory of Reasoned Action.

Figure 1: Theory of Reasoned Action



Built on the Theory of Reasoned Action, perceived ease of use and perceived usefulness are the two most salient constructs developed in the Technology Acceptance Model which examines their effects on computer system usage. Figure 2 depicts a typical Technology Acceptance Model. Behavioral intention to use is determined by attitude towards usage as well as by both the direct and indirect effects of perceived usefulness and the indirect effect of perceived ease of use. In addition, perceived ease of use is a predictor of perceived usefulness and actual system usage is determined by behavioral intention to use (Davis, 1989; Taylor & Todd, 2001). Subjective norm is omitted from the Technology Acceptance Model because of its uncertain theoretical and psychometric status (Davis et al., 1989). It is noted that the construct of attitude towards usage is often disregarded in recent studies as the constructs of perceived usefulness and perceived ease of use have already explained a large portion of variance of behavioral intention to use, with perceived usefulness serves as a stronger predictor (Gefen et al., 2003; Venkatesh et al., 2003).

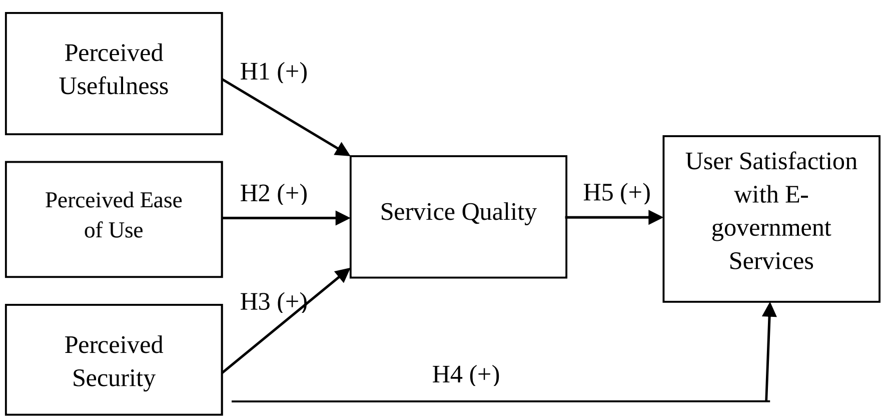
Figure 2: Technology Acceptance Model



3. Model Development

The overall research model and hypotheses of this study are shown in Figure 3. Similar to other studies (e.g., Chau, 1996; Hong et al., 2001; Lu & Gustafson, 1994; Wang, 2002), the construct of attitude towards usage is excluded in order to simplify the model. The proposed research model includes three variables (i.e., perceived usefulness, perceived ease of use, and perceived security) in the service quality and user satisfaction context. Oliver (1980) refers satisfaction as a summary of affective reactions to a service incident. User satisfaction is crucial to the success of information systems (Szajna & Scamell, 1993) and is a fundamental determinant of long-term consumer behavior (Oliver, 1980). The level of satisfaction of citizens who have used online government services is used as one of the indicators to evaluate the e-government system in Hong Kong (HKSAR Government, 2008).

Figure 3: Research Model and Hypotheses



Perceived Usefulness

Perceived usefulness is defined as "the degree to which a person believes that using a particular system would enhance his or her job performance" (Davis, 1989, p. 320) and is widely adopted as an antecedent toward other constructs in technology context (Tan & Chou, 2008).

The relationship between perceived usefulness and service quality has not been empirically tested until recently. Hu et al. (2009) used the Technology Acceptance Model as their model framework and conducted a two-stage longitudinal research with 518 respondents by comparing their perception before and after using the eTax service in Hong Kong. They found that perceived usefulness serves as a significant and positive determinant of eTax service quality. The perceived usefulness will positively affect the e-government service quality because e-government is a system which provides citizens with various online services (e.g., applying for a government job online, making an online appointment booking, using library services online, and using eTax). Therefore, we hypothesize that:

H1: Perceived usefulness of the e-government services will positively influence the perception of service quality of the e-government.

Perceived Ease of Use

Similar to perceived usefulness, perceived ease of use is a popular construct in studying new technology system. Perceived ease of use refers to "the degree to which a person believes that using a particular system would be free of effort" (Davis, 1989, p. 320) and is sometimes denoted as "usability" (Venkatesh & Davis, 1996; Zeithaml et al., 2002). The perceived ease of use is suggested to be a positive antecedent of service quality in several research works (e.g., Shin, 2003; Hu et al., 2009). In this regard, a different but related construct of "complexity" was explored in earlier research (Roger & Shoemaker, 1971; Tornatzky & Klein, 1982), and is defined as "the degree to which an innovation is perceived as relatively difficult to understand and use" (Roger & Shoemaker, 1971, p. 154). If complexity is a strong and negative antecedent of the rate of adoption of an innovation (Thompson et al., 1991; Tornatzky & Klein, 1982), perceived ease of use will positively affect the service quality of a new technology system. Accordingly, we hypothesize that:

H2: Perceived ease of use of the e-government services will positively influence the perception of service quality of the e-government.

Perceived Security

Salisbury et al. (2001, p. 166) defined security as "the extent to which one believes that the Web is secure for transmitting sensitive information". Recently, Flavián and Guinalíu (2006, p. 604) provided a comprehensive interpretation of perceived security as "the subjective probability with which consumers believe that their personal information will not be viewed, stored, and manipulated during transit and storage by inappropriate parties in a manner consistent with their confident expectations". Flavián and Guinalíu (2006) further pointed out that perceived security refers to the technical aspects that ensure the integrity, confidentiality, authentication and non-recognition of transactions. Whilst integrity provides that unauthorized third parties cannot modify the transmitted or stored data, confidentiality ensures that the data can only been viewed by authorized individuals. In addition, authentication, which is often adopted in a Web site, means that a party can carry out certain operations only after his identity is confirmed or guaranteed. Furthermore, non-recognition of transactions involves an information system which avoids a party from denying his action (e.g., a purchasing order on a Web site).

Many scholars agreed that the lack of security in an online platform is one of the major obstacles to the development of information systems (Chou et al., 1999; Dong-Her et al., 2004; Flavián & Guinalíu, 2006; Furnell & Karweni, 1999). In this regard, the user perception of a more secured service is found to be the most important feature of an online banking system (Aladwani, 2001).

Janda et al. (2002) suggested that there are two forms of security from the user perspective of information systems, namely financial security and non-financial security. Non-financial security primarily refers to the security of disclosing personal information online. Prior studies showed that financial security and personal security are antecedents of perceived service quality (Liljander et al., 2002; Yoo & Donthu, 2001; Zeithaml et al., 2000). Since an e-government system will collect both financial and non-financial data about the users, the perceived security will positively influence the service quality of the system. Therefore, we hypothesize that:

H3: Perceived security of the e-government services will positively influence the perception of service quality of the e-government.

It has been shown that financial security will directly affect the user satisfaction of e-commerce (Szymanski & Hise, 2000). In addition, Bailey and Pearson (1983) found that perceived security is an antecedent of user satisfaction in technology context. As e-government services will capture a considerable amount of user information, the perceived security will positively affect the satisfaction level of the users. Hence, we hypothesize that:

H4: Perceived security of the e-government services will positively influence the perception of user satisfaction with the e-government services.

Service Quality

Service quality refers to a form of attitude, related but not equivalent to satisfaction, which represents a long-term overall evaluation toward a service (Cronin & Taylor, 1992; Bolton & Drew, 1991; Parasuraman et al., 1988; Teas, 1993, 1994). Recently, researchers (e.g., Brady et al., 2002; Cronin & Taylor, 1992; Parasuraman et al., 1985) tend to adopt a more performance-based perspective rather than the gap view (i.e., the difference between user's expectation and a firm's actual performance) to measure service quality.

Since service quality is important in measuring the effectiveness of information systems (e.g., Kettinger & Lee, 1995; Li, 1997; Pitt et al., 1995; Wilkin & Hewitt, 1999), the service quality of the e-government system will play an important role in measuring the user satisfaction of the e-government services. Prior studies indicated that online service quality is a strong antecedent construct of customer satisfaction (Anderson & Sullivan, 1993; Carlson & O'Cass, 2010; Carrillat et al., 2009; Cronin & Taylor, 1992; DeLone & McLean, 1992, 2003; Shemwell et al., 1998; Oliver, 2000). Hence, we hypothesize that:

H5: Service quality of the e-government system will positively influence the user satisfaction with e-government services.

4. Research Methodology

Measurement

We used previously validated scales to measure all the constructs in the model (see Appendix A). Both perceived usefulness and perceived ease of use were measured with four items from Davis (1989). Perceived security was measured with 3 items from Flavián and Guinalíu (2006) and 1 item from Ranganathan and Ganapathy (2002). The 22-item SERVQUAL developed by Parasuraman et al. (1988) was used to measure service quality because it has been widely applied in various studies, in particular, for measurement of the online service quality (e.g. Devaraj et al., 2002; Gefen, 2002; Hu et al., 2009; Kuo et al., 2005; Li et al., 2002). In order to better fit for the context in our study, the 22-item SERVQUAL was revised as follows: four items are removed and some wordings were adjusted slightly. Also, a single-item measure was added to measure the overall service quality. User satisfaction with e-government services was measured with 3 items from Oliver (1980) and 1 item from Janda et al. (2002). In addition, a new single-item measure was added to measure the overall user satisfaction. All items were evaluated using a 7-point Likert scale anchored from “1 = strongly disagree” to “7 = strongly agree”.

Participants

Adults who have used the e-government services in Hong Kong are identified as the target respondents of this study. Data was collected through a Web survey instrument in Chinese and English. The survey was posted on a popular Web site in Hong Kong. Screening questions were included in the system to check if the respondents had used the e-government services and their ages were 18 or above.

A total of 340 responses were received, but only 229 questionnaires were fully completed. Table 1 indicates that 61% of the respondents were female and 39% were male. Over 80% of the respondents fell into the range of 18-27 years old, 14% of the respondents were within 28-37 years old, 3.1% of them were within 38-47 years old and 1.3% of them were within 48-57 years old.

Table 1: Demographic Data of the Respondents

	Number	Percentage (%)
1. Gender		
Male	89	38.9
Female	140	61.1
Total	**229**	**100.0**
2. Age Group		
Under 18	0	0

	Number	Percentage (%)
18-27	187	81.7
28-37	32	14.0
38-47	7	3.1
48-57	3	1.3
58 or above	0	0
Total	**229**	**100.0**

5. Results

Instrument Validation

We conducted reliability and validity tests of the measurement items using Cronbach's alpha and factor analysis. Table 2 presents the reliabilities, descriptive statistics and correlations. The reliability of the single-item measures of service quality and user satisfaction with e-government services were not reported because they cannot be estimated by traditional reliability estimation techniques (see Wanous & Hudy, 2001, pp. 361-375, for further discussions). Cronbach's alpha values of other multi-item variables were greater than or equal to 0.92 (which were above the threshold level of 0.8 as suggested by Nunnally (1978)), indicating the variables had high reliability. A factor analysis using principal component factor analysis with oblimin rotation was also conducted on the multi-item independent variables to examine the convergent and discriminatory validity. Table 3 shows that all the items loaded highly on their corresponding latent variables, with little cross-loadings on other variables. These results suggest that the scales exhibit adequate convergent and discriminatory validity.

Table 2: Reliabilities, Descriptive Statistics and Correlations

	Mean	Std.	PU	PEOU	PS	SQ1	SQ2	EGO	EGO

Note PU: perceived usefulness; PEOU: perceived ease of use; PS: perceived security

Hypotheses Testing

Regression analysis was conducted in order to test our hypotheses. The results of the regression analysis were shown in Table 4. Perceived usefulness, perceived ease of use and perceived security were significant and positive determinants of service quality, hence supporting H1, H2 and H3. User satisfaction with e-government services was significantly determined by perceived security and service quality, as predicted by H4 and H5. In examining the mediation effect of the variables on user satisfaction with e-government services, we found that only perceived security had an effect on user satisfaction over and above its effect through service quality. The variance explained in service quality and user satisfaction was 57% and 78% respectively.

Given that we used an index measure for service quality and user satisfaction with e-government services in our analyses, we benchmarked the results using the single-item overall service quality and user satisfaction with e-government services measures. Table 4 indicates that the regression results with single-item of service quality and e-government services user satisfaction were highly consistent with that of their index measure. Also, the correlations between the index measure and the single-item measure of service quality (0.86) and user satisfaction with e-government services (0.91) were extremely high (see Table 2).

Table 4: Service Quality and Satisfaction with E-government Services

	SQ1	SQ2	EGOV_S1		EGOV_S2	
Adjusted R^2	0.57	(0.52)	0.78	(0.77)	0.74	(0.76)

Note 2 The results of regression with the single-item measure of service quality are shown in parentheses.

*p<0.05, **p<0.01, ***p<0.001.

Post-hoc Analysis

Further analysis was carried out in order to explore the relationship between the three variables (namely perceived usefulness, perceived ease of use and perceived security) and the five dimensions of service quality (namely tangibles, reliability, responsiveness, assurance and empathy) as well as between these factors and the user satisfaction with e-government services. Whilst tangibles means the physical evidence of the services (i.e., the Web technologies and Web layout in the e-government context), reliability ensures that e-government system provides consistent and accurate services. In addition, responsiveness measures the willingness of performing real time services as per user request. Furthermore, assurance involves the ability to inspire the trust and confidence of users politely while empathy means the offering of individualized attention and caring (Parasuraman et al., 1988).

Table 5 presents the result of the post-hoc analysis. Perceived security had the strongest influence on all dimensions of service quality except tangibles. On the other hand, only reliability, assurance and empathy of service quality were significant and positive determinants of user satisfaction with e-government services in index measure. These results were highly consistent with that of the user satisfaction e-government services in single-item measure except that empathy was not a significant determinant in the single-item measure. In order to avoid the problem of multicollinearity, the variance inflation factors (VIF) were checked. The VIF for all independent variables were all smaller than the cutoff value of 10.0 as suggested by Chatterjee and Price (1977), thus minimizing concerns about multicollinearity.

Table 5: Individual Dimensions of Service Quality and User Satisfaction with E-government Services

	Tangibles	Reliability	Responsiveness	Assurance	Empathy	EGOV_	EGOV_
Adjusted R^2	0.43	0.54	0.44	0.58	0.32	0.79	0.75
PU	0.35***	0.27***	0.30***	0.28***	0.26***	0.18***	0.20***
PEOU	0.17*	0.27***	0.18**	0.27***	0.19*	0.14**	0.13**
PS	0.31***	0.40***	0.35***	0.40***	0.27***	0.01	0.06
Tangibles						-0.01	0.01
Reliability						0.23***	0.22**
Responsiveness						0.09	0.11
Assurance						0.29***	0.24**
Empathy						0.11*	0.08

Note PU: perceived usefulness; PEOU: perceived ease of use; PS: perceived security; EGOV_S1 is the index measure of the satisfaction with e-government services; EGOV_S2 is the single-item measure of the satisfaction with e-government services.

6. Discussion

Theoretical Implication

User satisfaction of information system is a perceptual measure of system effectiveness and system success (Ives et al., 1983). Built on the Technology Acceptance Model, a new construct of perceived security was examined in this study for its effects on service quality and satisfaction with e-government services. This study imposes several implications for e-government services in Hong Kong and is expected to be applied to government in other nations.

In this study, we argue that the security of an online platform is important in the e-government services. Every day, there is abundant personal and financial data transferred via the e-government system. The security level of the service should be high enough to protect the information. In line with our expectation, perceived security contributes most to service quality. The perceived high security of the e-government system will lead to perceived high service quality, which in turn will improve the development of e-government system.

Prior research has examined the relationship between service quality and user satisfaction (e.g., Anderson & Sullivan, 1993; Cronin & Taylor, 1992; DeLone & McLean, 1992, 2003; Shemwell et al., 1998). However, few have applied the well-founded Technology Acceptance Model in model formulation. This present study applies the Technology Acceptance Model, which is added with the perceived security and service quality constructs, in examining user satisfaction of e-government services. We found that service quality was a significant determinant of user satisfaction. This present study stimulates other possibilities in adopting these constructs in investigating other aspects of behavioral intention.

Practical Implication

This study offers several important implications for developing and promoting e-government services. More resources should be allocated to improve the security measures of e-government system. The practices adopted by the eTax system, which is a part of the e-government services in Hong Kong, serve as a good example. In order to ensure the security level of the service, eTax service implemented the following measures (HKSAR Government, 2008):

- followed the latest best practice for information security management; and
- adopted the latest encryption technology.

These security measures should be widely applied to other e-government services. In addition to the advanced technology measures like firewalls, digital certificates and anti-virus programmes, more enhanced legislative measures can be introduced to improve the effectiveness of various security measures.

Research and development is needed to upgrade the e-government system with more functions and services. Attention will also be given to the ease of use of the portal. Free training courses, publicity events and exhibitions shall also organized to develop people's beliefs of usefulness, ease of use and security of the service, which in turn will increase the perceived service quality, and ultimately the user satisfaction with e-government services.

Furthermore, the assurance and reliability aspects of service quality can be enhanced through adopting better monitoring system, maintaining a more stable online server with proper pilot testing before the launch of new functions, and ensuring the services are tailor-made for their specific user groups.

Limitation and Further Research

There are several limitations in this study. First, user satisfaction of e-government services is a relatively new area of research. Comparisons of results with other studies are difficult. Second, the respondents of this study are from Hong Kong and majority of them are quite young. Last, this study is cross-sectional in nature. Further longitudinal work might advance the understanding of various variables of e-government services user satisfaction.

There are other variables which may be worth exploring in future research. System characteristics like screen design, terminology and result demonstrability can be added to the existing model. Social characteristics like subjective norm can also be tested for the relationship with service quality and e-government services user satisfaction. Individual characteristics like age and gender are other possible dimensions to examine. In addition, the trust in government (which is found to be strongly associated with e-government services user satisfaction (Welch et al., 2005)), can be investigated.

7. Conclusion

This study examined the impact of the two constructs adopted from the Technology Acceptance Model, namely perceived ease of use and perceived usefulness, and a new construct of perceived security on service quality and user satisfaction of the e-government services in Hong Kong. There are three major findings. First, perceived usefulness, perceived ease of use and perceived security of the e-government services contribute significantly to the service quality, with perceived security having the strongest influence. Second, service quality is a significant contributor to the e-government services user satisfaction. Third, assurance and reliability empathy are the most important aspects of service quality. Results of the study highlight the escalating importance of security of an online service which ultimately leads to a higher level of service quality and user satisfaction.

Appendix

Perceived Usefulness (PU; 7-point Likert scale, ranging from “1=strongly disagree” to “7=strongly agree”)

PU1. Using e-government services would enable me to accomplish tasks more quickly.

PU2. Using e-government services would improve my task performance.

PU3. Using e-government services would enhance my effectiveness on accomplishing tasks.

PU4. Using e-government services would make it easier to accomplish tasks.

Perceived Ease of Use (PEOU; 7-point Likert scale, ranging from “1=strongly disagree” to “7=strongly agree”)

PEOU1. Learning to operate e-government services would be easy for me.

PEOU2. I would find it easy to get e-government services to accomplish tasks.

PEOU3. My interaction with e-government services would be clear and understandable.

PEOU4. It would be easy for me to become skillful at using e-government services.

Perceived Security (PS; 7-point Likert scale, ranging from “1=strongly disagree” to “7=strongly agree”)

PS1. I think e-government services have sufficient technical capacity to ensure that the data I send cannot be modified by a third party.

PS2. When I send data to e-government services, I am sure that they will not be intercepted by unauthorized third parties.

PS3. I think e-government services have sufficient technical capacity to ensure that the data I send will not be intercepted by hackers.

PS4. I think e-government services have adequate mechanisms to ensure the safe transmission of my personal information.

Service quality (SQ; 7-point Likert scale, ranging from “1=strongly disagree” to “7=strongly agree”)

1. E-government services have up-to-date Web technologies.
2. The portal of e-government services, GovHK, is visually appealing.
3. The portal of e-government services, GovHK, looks professional and neat.

4. The portal of e-government services, GovHK, has an appropriate style of design for site type.
5. When e-government services promise to do something by a certain time, e-government services can do so.
6. E-government services are dependable.
7. E-government provides services at the time it promises to do so.
8. E-government provides error-free services.
9. E-government keeps me informed about when services will be performed.
10. E-government provides prompt service.
11. E-government services are always willing to help me.
12. E-government services can respond to user requests promptly.
13. I can trust e-government services.
14. The portal of e-government services, GovHK, provides polite feedbacks and content.
15. E-government services have ability to do the job well.
16. E-government services give users individual attention.
17. The portal of e-government services, GovHK, gives users personal attention.
18. E-government services know my need.

Overall Service quality (7-point Likert scale, ranging from "1=strongly disagree" to "7=strongly agree")

Overall, I think the service quality of e-government is excellent

User Satisfaction with E-Government Services (EGOV; 7-point Likert scale, ranging from "1=strongly disagree" to "7=strongly agree")

1. I think I did a right thing when I decided to use e-government services for accomplishing tasks.
2. My choice to use e-government services was a wise one.
3. I feel good about my decision concerning the e-government services.
4. Based on my all my experience with e-government services, I feel satisfied.

Overall User Satisfaction with E-Government Services (7-point Likert scale, ranging from "1=strongly disagree" to "7=strongly agree")

Overall, I am satisfied with e-government.

The 23rd Annual Conference on Pacific Basin Finance, Economics, Accounting, and Management (2015)

□ □ □ □ □ □ Gatekeeper and Whistle Blower in Transition Economy: Examples of Auditors in China’s Financial Market

Heather LEE (Corresponding Author)
Department of Accountancy
Hang Seng Management College
heatherlee@hsmc.edu.hk,

This paper discusses the roles of auditors in China’s financial market, in particular the banking sector, from a legal perspective. After the outbreak of the financial crisis, there was comment that auditor was a significant contributory factor to the financial crisis for his inability to be aware of and alert the failure of the companies. The role of auditor in providing sufficient and relevant information is in the top agenda for discussion in various western countries and international orgainzations. In China, with repeated accounting scandals, there is a more fundamental problem rasied to the roles of auditors in enhancing the accuracy and timeliness of information disclosed, in addition to the sufficiency and relevancy of information disclosed. Weak legal and regulatory system in regulating the auditors may be one of the key factors for the above accounting issues. There are ambiguous provisions on external audit requirement, insufficient regulations relating to audit independence, legal constraint during the audit process, insufficient guidance on communication with regulators and limited liability risks to auditors. Auditors in China’s financial market could be more proactive and act as a whistle blower, a more vigilant gatekeeper, to protect the public interest as well as a conduit between companies and regulators to enhance the accuracy and reliability of accounting information in building a healthy and substainable financial system in China.

Keywords: auditor, bank, gatekeeper, law and financial reporting.

Introduction

A well-functioned disclosure system in a financial market is important as it can help reduce information asymmetry and enhance transparency of companies. Auditors, one of the gatekeepers of the financial market, can help to enhance credibility and reliability of information disclosed, in particular financial information. After the outbreak of the financial crisis in 2008, auditors were blamed for their inability to be aware of and alert the failure of the companies. There are studies initiated by various supervisors and international bodies as discussed below on improving auditors' roles in providing quality services. Despite the adverse economic impact of the financial crisis on China is comparatively less prominent, a lesson from the financial crisis is a caveat to China.

In China, information disclosed, in particular audited financial information disclosed, is always questionable. Accounting scandals of Chinese companies for false business performance, not up-to-date information and manipulating profits have repeatedly occurred in China and overseas. There were also cases triggering lawsuits and regulatory probes against the Chinese listed companies and their auditors. Despite the concerns of regulators of western countries and international bodies after the financial crisis are more on the sufficiency and relevancy of information disclosed, it appears that the concern for information disclosed in China should be more on the fundamental problem, i.e. accuracy and timeliness of information disclosed. Auditors in China appear not be able to function effectively in their roles to enhance the credibility and reliability of information provided, at least in light of previous accounting scandals in China. The weak legal and regulatory framework in regulating auditors may be one of the key factors that failing to uphold auditors' independent role in practice and may lead auditors to trade off the quality of their services for profitability possibly leading to the inaccuracy of information disclosed. Auditor who possesses professional knowledge and knowledge of his client's business and operation may be able to smell the fishy acts of the company. After the financial crisis, auditor's duty of care and skills excercised to the engagement is beyond the traditional expectation. In compliance with relevant regulations, auditor could act more proactively as a whistle blower to initiate timely communication with regulator on suspicious worngdoings to protect the public interest in the financial market instead of last minute resignation from his engagement like the recent accounting scandals overseas leaving the monies of investors and creditors probably in vain. Auditor could also act as a conduit between company and regulator to communicate, clarify and ascertain some significant accounting information to enhance a healthy and transparent financial market.

This paper focuses on the discussion of the roles of the auditors to the disclosure system relating to disclosure of financial information in China's financial market, in particular the banking sector, after the financial crisis from a legal perspective. The following sections will first briefly discuss the the roles of auditors in the financial market after the financial crisis. Then, this paper will discuss the issues facing the auditors in China's financial market, in particular banks, from a legal perspective and the related possible sugestions, followed by a concluding remark.

Roles of auditors in the financial market after the financial crisis

After the financial crisis, transparency and disclosure have been at the top agenda for discussion and improvement. Transparency is an essential element of a well-functioning system of corporate governance and disclosure to stakeholders is the principal means by which companies can become transparent.[1] Among various information disclosed, periodic reports, like financial reports, are important for a well-functioning disclosure system.[2] Financial report is also considered as one of the most important and comprehensive sources of corporate information.[3] Auditors who provide certification services to investors are gatekeepers to the financial markets.[4] For financial reports, under International Standards on Auditing (ISAs), auditors are required to consider the overall presentation of the financial statements and whether the financial statements, including the related disclosures, represent the underlying transactions and events in manner that achieve fair presentation.[5] As an independent watchdog, auditors' services provided can help screen out flaws and verifies compliance with standards or procedures.[6] With these functions, auditors could help improve the reliability of information,[7] facilitate the function of market discipline[8] and promote good corporate governance of companies.[9] Nevertheless, disclosure alone may not be sufficient. The quality of information disclosed is important. Information disclosed must be accurate, sufficient, relelvant and timely to enhance transparency of companies.[10]

Auditors were blamed not doing their jobs well in the recent financial crisis. There was comment that bank auditor was a significant contributory factor to the financial crisis for auditors' failure to be aware of the mounting dangers.[11] There are recently many studies regarding the improvement of auditors' work and their respective regulatory framework.[12] In

addition, the G20 during the Summit in Seoul in 2010 pinpointed that there should be actions to be taken to improve the convergence of financial instrument accounting standards,[13] which are relied on by auditors in providing their services.

For disclosure in the financial reporting, after the financial crisis, it was found that information disclosed was not sufficient in the financial market, like information of structured products and the work process of auditors, and there is a cry for more information disclosed on the financial reports and on the auditor's report. Various accounting standards which are related to information disclosure are revised after the financial crisis.[14] The new standards will promote better disclosures about valuations, methodologies and the uncertainty associated with valuations.[15] Moreover, for audits of financial statement for periods ending on or after December 15, 2016, in accordance with ISAs, format of auditor's report, which is attached together with the financial reports, is revised, with one of the focuses to provide more professional and material information for the users.[16] In line with the above revised format of auditor's report as stipulated in the ISAs, the EU also requires more information to be included in the auditor's report to provide more useful and relevant information to the users.[17] This revised format of auditor's report will help fill out the gap for information expected by the users.

In additional to the sufficiency of information provided, internationally, there is also a call for disclosing of more relevant information on financial reports. In view of the broad variety of information disclosed, the content and length of the financial reports are of concern lately. It is found that the length of financial reports has increased significantly,[18] in particular narrative disclosures.[19] It is also found that information is disclosed mainly for compliance-based purpose, using a checklist requirement approach and overall result is disclosure of immaterial information that leads to clutter.[20] A recent reportd commented that the length of

financial reports could be reduced by 30% to better serve the needs of users of the financial statements which contain meaningful information and less irrelevant details.[21] The revised format of auditor's report as mentioned above is also amied at providing more relevant information to the users.[22] It is important to achieve the right balance of the quantity of information disclosed on the financial reports that can provide relevant and quality information.

One of the focuses of the western countries after the financial crisis is more on the sufficiency and relevancy of information provided by auditors to the users. However, in addition to sufficiency and relevancy of information disclosed, information disclosed being inaccurate and not in a timely manner has long been posed a bigger challenge to auditors in China.

Audit failures of Chinese companies in the financial market

In China, inaccurate and not up-to-date accounting information have always been found in companies in the financial market. For accounting information of banks, the financial statements are always found to underestimate their loan losses and overestimated their assets, etc.[23] For listed companies, a study by Shanghai Stock Exchange (SHSE) found that most of the violation cases for listed companies were related to violation of disclosure, representing 78% of total cases for the period from 1996 to 2007.[24] Besides, most of violation cases during the period of the survey were related to the non-disclosure of major events in timely manner, representing more than 50% of total violation cases relating to disclosure issues.[25] In addition to the above non-compliance cases, financial data of listed companies are also inaccurate, with quite a number of companies required to provide supplementary data or restatements after the issuance of the periodic reports.[26] Worse still, it is quite common to find companies in China to maintain multiples sets of financial books – for management, the tax authorities and the auditors.[27] It is no doubt that investors are sceptical of the truthfulness of the audited

financial reports of even listed companies which are already considered comparatively more regulated in China.

Other than in China, Chinese companies listed overseas are also afflicted with accounting problems relating to inaccurate information. Chinese companies have increased their presence in overseas Exchanges in the recent decade. However, questionable accounting issues are kept surfacing and draw concerns to investors and oversea regulators. There were various accounting scandals for Chinese listed companies in the US, Canada and Hong Kong. More remarkable cases are relating to Chinese listed companies in the US where there has been a proliferation of Chinese-listed companies engaged in accounting fraud after their listing. US regulator probes against the Chinese companies and their auditors and there have been increasing numbers of claims against them in US courts every year since 2004, like securities class action filings with majority of the cases being accounting-related allegations.[28] The common accounting issues for Chinese listed companies are related to the accuracy of accounting information, like financial results reported to Chinese authorities differ significantly from the filings in the US, cash balances cannot be verified, etc.[29] The above cases shed light as to the imminent accounting and audit problems in China.

Low audit quality may be one of the reasons for the widespread fraudulent financial reporting of companies in China. Examinations on the quality of audit services conducted by various organs, i.e. National Audit Office of the PRC (NAO), MOF, the regulator of the accounting profession in China, Chinese Institute of Certified Public Accountants (CICPA) and WB, find that there is some room for improvement in audit services performed by auditors in China, including areas like lack of professional skepticism, incomplete disclosure, insufficient audit procedures, insufficient audit evidence, etc., especially for those which are usually relatively smaller in size.[30] Nevertheless, large or even global accounting firms may also show issues relating to audit quality. For overseas accounting scandals, though most of the Chinese companies in trouble were audited by small accounting firms, there were some cases which also involved the large global accounting firms, which relied on the work of their Chinese arms and signed off on the financial statements of overseas listed Chinese companies that were later accused of fraud and misrepresentation.[31] In addition to the above, a study

[31] The Wall Street Journal, Dinny McMahon & Shen Hong, China Wants Local Control of Foreign Auditing Firms, May 10, 2012, available at:

http://online.wsj.com/article/SB10001424052702304203604577395423545473012.html. See The Economist, conducted by Canadian Public Accountability Board (CPAB), audit regulator in Canada, on China-based listed companies found that their auditors very often did not properly apply procedures that would be considered fundamental in Canada, such as maintaining control over the confirmation process.[32]

Problems with audits are not only specific to auditors in China. According to inspections performed by Public Company Accounting Oversight Board (PCAOB), supervisor to oversee the audits of public companies, in the US, CPAB in Canada and audit supervisors in the UK, inspectors continue to find deficiencies in important audit areas.[33] These deficiencies of audit are not country-specific but related to the profession at large, like concerns about a lack of professional skepticism, inadequate supervision and review, ineffective substantive analytical procedures, and the poor quality of evidence in the audit files.[34] In the UK, the quality review conducted by professional bodies in 2011 also reviewed a high number of unsatisfactory operations of audit firms, with a situation that 28% of visits conducted by a professional body were regarded as unsatisfactory on successive monitoring visits.[35]

Despite the above audit issues, accuracy and reliability of the accounting information in these countries at large is not in doubt. Nevertheless, this is not the case in China. The deficiency of audit work shows a more profound and adverse impact on the quality of information disclosed in China. The weak legal and regulatory framework regulating the audit profession may be one of the key factors of the low audit quality in China.

1. Ambiguous provisions on external audit requirement

In the past, in China, the external audit requirement for companies in the financial market in particular banks has been "neglected" by the Chinese government as only limited numbers of the companies, i.e. foreign companies, certain state-owmed enterprises (SOEs) and listed companies, were required to prepare audited reports prepared by external auditors. Lack of clear provisions in regulations stipulating the requirement of external audit may hinder the healthy development of the audit profession in China.

In the banking sector, the first regulation regarding the preparation of audited reported by external Chinese auditors was promulgated as early as in 1985 but the requirement only applied to foreign banks and joint Chinese-foreign banks which operated business in the Special Economic Zones in China.[36] There were some other regulations and rules issued later

but still only elaborated the external audit for foreign banks only.[37] Local banks were always exempted from audit requirement in the past. It appears that clearer and stricter control on external audit requirement was applied to foreign banks but not local banks.

Moreover, state-owned commercial banks (SOCBs) in the past were also exempted from external audit requirement which applied to SOEs. Though MOF issued the Interim Measures of SOEs' Annual Accounting Reports Audited by Registered CPAs which stipulated that SOEs were required to issue annual financial reports audited by the Chinese auditors,[38] SOCBs were excluded from the requirement to prepare audited reports performed by the audit firms.[39] Even being state-owned, banks are treated differently for external audit requirement from other SOEs, at least they are selected to be applied the requirement at a later stage.

Comparatively, the more enforceable rules for external audit requirement are found for listed companies. As early as in 1993, according to the Interim Provisions on the Management of the Issuing and Trading of Stocks issue by the SC, for listed companies, the annual financial reports should be audited by registered auditors.[40] Subsequently, China Securities Regulatory Commission (CSRC), the regulator of the exchange markets in China, also issue a measure requires listed companies to furnish audited financial statements.[41] Despite there is a clearer requirement for external audit in the stock markets, in the past, only a very limited number of banks were listed in the Exchanges. Moreover, according to Securities Law, listed companies are only required the preparation and submission of annual financial reports to CSRC and the Stock Exchanges, without specifying the external audit requirement.[42] Though audit requirement is stipulated in both SC Interim Provisions and CSRC Administrative Measure, the above Interim Provision is a regulation issued by the SC and the CSRC Administrative Measure is a departmental rule while the Securities Law is a

law issued by the Standing Committee of the NPC, which has a higher level of legal effect than regulation and rule.[43] It appears that the Chinese government is not willing to place external audit requirement at the highest level of laws.

For unlisted or local Chinese banks, though there are requirements in various laws, regulations and rules regarding the "audit" of financial reports,[44] in the past, the word "audit" had been interpreted broadly as internal audit or audit by one of the ministries of the SC, NAO, instead of performing by external accounting firms, and the audit results were not disclosed to the public.[45] Moreover, NAO mainly focused on auditing the losses of state-owned assets,[46] unlike the scope of work of external auditors. Furthermore, during implementation of laws or rules regarding audit requirement, the authorities are allowed to grant exemption to certain banks. Currently, CBRC, the regulator of the banking sector, only requires banks with total assets exceeding RMB1 billion to have their financial statements audited by qualified external accounting firms.[47] It appears that the Chinese government

prefers to use lower level of regulations or rules to gradually implement the audit requirement and preferably to larger banks first.

With insufficient attention by the Chinese government to external audit requirement, the development of the audit profession in China is still in its nascent stage. Most of the audit firms in China are still very small with insfficient resources in terms of qualified auditors,[48] which will have impact on the quality of audit. Even though the Chinese government is currently encouraging the development of local firms especially in the securities market and the banking sector,[49] the global big four accounting firms i.e. PWC, Deloitte Touche Tohmatsu, KPMG and Ernst & Young (E&Y), occupy the audit market in China in terms of revenue earned[50] and total capitalization of the listed companies audited.[51] Probably, the local firms are still lack of the experience and capacity to deal with complicated and complex companies.

2. Insufficient regulations relating to audit independence

Audit independence can help maintain the quality of audit services. Auditor should be free of any influence, interest or relationship that might impair professional judgment or objectivity or, in the view of the reasonable investor, might impair professional judgment or objectivity.[52] Auditors must be independent of the entities they audit, in both fact and appearance.[53] However, audit firms which rely on the fees of clients for their services could inherently lead to conflict of interest issue.[54]

Audit independence is always a challenging issue not only in China but also in other countries, like the US and the EU. There are various measures to help improve the audit independence as implemented by the above countries. In the US, one of the key issues addressed by the audit profession and by regulators involves auditor independence after a series of serious accounting scandals in early 2000s.[55] In response to the accounting scandals, Sarbanes-Oxley Act (SO Act) was enacted in 2002 to protect investors by improving the

accuracy and reliability of corporate disclosures, including some sections on the enhancement of auditor independence.[56] For instance, SO Act specifies that certain non-audit services, including bookkeeping or other services related to the audit client's accounting records or financial statements; financial information systems design and implementation; appraisal or valuation services; internal audits outsourcing services; management functions or human resources; legal services and expert services unrelated to the audit; etc., are prohibited.[57] Also, the Act requires a five-year lead (or coordinating) audit partner mandatory rotation on public company engagements.[58] There has been also discussion on mandatory rotation of audit firm as a way to enhance auditor independence, objectivity and skepticism.[59]

In the EU, lately, there is a concern regarding the low switching rates of audit firms which may pose the risk of over familiarity between auditor and auditee and may in turn impair professional skepticism and audit independence.[60] Joint audit, i.e. two firms appointed for one audit engagement, is currently a mandatory requirement in France, the only Member State in the EU implementing this measure.[61] Moreover, the EU will implement the rotation of audit firms, despite their existing requirement for rotation of audit partner.[62] Currently, the rotation of audit firm is a mandatory requirement in Italy.[63] In the UK, according to the revised UK Corporate Governance Code, FTSE 350 companies are required to put the external audit contract out to tender at least every ten years,[64] though this Code adopts a "comply or explain" approach.[65] To enhance independence of auditors, a new statutory audit framework will be implemented for mandatory rotation of audit firms for public-interest entities in the EU, including banks, listed companies, etc., applicable on June 17, 2016.[66]

In addition, like the US, in the EU, there is also a concern regarding the relatively high

[66] Regulation No 537/2014, supra note 62.

level of audit firms' revenues deriving from non-audit services as it is also considered as one of the factors that affects the independence of audit firms. There may be a risk of cross-subsidization using audit as a loss leader to sell higher margin consulting services, especially big four accounting firms have targeted non-audit services.[67] Currently, in France, there is a strict restriction of the provision of non-audit services to statutory audit clients within the EU.[68] In the UK, FRC provides Ethical Standards on how to deal with non-audit services.[69] The new statutory audit framework to be implemented in the EU in 2016 also covers the non-audit services provided by auditors.[70] To enhance independence of auditors, regulators in the US and the EU are in the process of working and implementing tougher measures to ensure the provision of quality audit services.

In addition to all of the above, to maintain independent, as auditors, they are also required to comply with ethical standards issued by their professional bodies, which issue ethical standards usually in line with those issued by IFAC. IFAC, which is a global organization for accountancy profession, issues code of ethics to deal with independence of auditors.[71] However, these standards are relied on auditors' compliance, though auditors may be subject to disciplinary actions for violation by their professional bodies. The revised format of auditor's report in accordance with ISAs requiring auditors to include a statement of their independence in the auditor's report may place more accountability to auditors during their audits.[72]

In China, independence of auditor may be particularly required of attention. The accounting market in China is in keen competition. To secure business, audit firms must maintain good "guanxi", i.e. good relationship, with their clients for business. To maintain a good relationship for business, there is a concern that clients may become too close to their auditors and clients may also be able to exert certain influence on the audit. It may result in a situation where auditors trade off quality standards for profitability. Moreover, the competition could result in cases of predatory pricing by audit firms as they try to maintain or increase their market share.[73] An audit work in China can be as low as RMB50.[74] From a longer term perspective, reduced audit fees could result in audit firms scaling back investments in people, training and methodology improvements which may put the long term sustainability of a quality audit in jeopardy.[75] To further complicate the issue, other than clients' influence, political interference may also affect the independence of auditors, e.g. local government requests for a favorable audit report for companies to be listed to benefit

the local economy.[76]

There are more measures implemented in China lately to ensure the independence of auditors but their results remain to be seen. Similar to the measure in the US and the EU, in China, change of the signatory auditors after five years is required.[77] In addition, since 2011, for hiring auditors, financial institutions require to follow the stipulated bidding process and re-start the bidding process again for the continuous of employment of the audit firms after five years.[78] Though China took an early lead in audit rotation, the rotation resulted in a downward of audit fees due to competition in the first round of the rotation, leading to the concern of long-term audit quality.[79]

Moreover, in China, some of the measures to enhance audit independence seem lack of clarity. According to the Law on the CPAs, auditors can provide accounting consultancy and accounting services to clients and there is currently no other law, regulation or rule on how to deal with non-audit services,[80] except normative documents, which are strictly speaking not legal documents, stipulating that an accounting firm which provides internal control consultancy services for an enterprise cannot concurrently provide internal control auditing services for the enterprise.[81] In addition, according to CBRC's normative document, accounting firms in China are only advised not to provide consultation service to its audited clients.[82] It is not a mandatory requirement, meaning accounting firms could provide various types of consultation services to their clients.

It appears that in theory auditors in China are independent in their provision of services. However, it may be difficult for them to carry out their jobs independently in practice. Although there are some measures implemented in line with those of western countries to deal with independent issues, the measures are not comprehensive and not specific to the situations for China. In particular the issue of political pressure, it relies solely on auditor to uphold the accounting and auditing standards, which apparently is not an effective way of resolution. MOF and CICPA could provide more guidance on a mechanism for audit independence and establish a mechanism that performs regular reviews of audit firms and auditors in the area of independence.

3. Legal constraint during the audit process

[81] Notice of the MOF, CSRC, NAO, CBRC and China Insurance Regulatory Commission (CIRC) on Issuing the Basic Internal Control Norms for Enterprises (promulgated by the MOF, CSRC, NAO, CBRC and CIRC on May 22, 2008 and was effective from July 1, 2009) (PRC) Article 10.

[82] CBRC Guidelines on External Audit, supra note 77, Article 12.

In China, further complicating the above issues, certain legal provisions may constraint the audit process and auditors leave no choice but may passively choose to comply with these laws and regulations. According to the Law of the PRC on Guarding State Secrets (Secrecy Law), matters which relate to the national security and interests and the leakage of which may damage the national security and interests in the field of politics, economy, national defence, foreign affairs, etc. should be regarded as state secrets.[83] State secrets are broadly determined in Article 9 of Secrecy Law with one of the state secrets including other matters as determined by the state secrecy administrative department.[84] In addition to the above, in accordance with Measures on the Strengthening of the Works of Confidentiality and File Management for Overseas Securities Issued and Listing, accounting records, including audit working papers, may be subject to claims of state secrecy and also they should be stored in China.[85] Without the approval of relevant authorities, the above materials cannot be taken, sent or transmitted outside China.[86] Further, everyone, including accounting firm, should have the obligation of guarding state secrets and any violation will be subject to legal liability, or even criminal liability.[87]

In light of the above law and rule, auditors encounter a difficult situation to balance their obligations to provide professional services and their obligations to comply with regulator's oversight while at the same time their compliance with PRC law and rule. Based on the claim of state secret, currently, auditors may encounter two types of issues. Firstly, state secret may be used as a ground for companies to refuse to disclose information to auditors, like the China High Precision Automation Group Limited (High Precision) case in Hong Kong. High Precision used state secret as the reason for not giving information to its auditor, KPMG. Secondly, Chinese auditors are restricted to disclose information to overseas regulators due to state secret. For the recent accounting failures of Chinese listed companies, overseas regulators were unable to obtain or review the relevant materials of the audit which were performed by auditors in China, claiming the violation of the state secrecy,[88] like the Longtop Financial Technologies (Longtop) case in the US and the Standard Water Limited (SWL) case in Hong Kong. Without audit information from Chinese auditors, it is difficult for regulators to pursue legal action and usually regulators just suspend trading or delist a stock after a company refuses to provide information, like Longtop.[89]

The above cases show some deficencies of the regulatory systems in these jurisdictions where China's secrecy law and regulation may be used to prevent disclosure of information to auditors and regulators. There is no stipulated procedure to handle this kind of issue.

[89] Id.

Moreover, there is no international auditing standard provided to auditors on how to handle state secrets. There should be some institutional changes to prevent any potential systemic risk and for the healthy development of the economy. For the first issue, regulators and the Exchanges may consider measures to tackle companies' refusal of information disclosure for securities issued when companies use state secrets as basis. For auditors, there should be more audit procedures to obtain evidence for their audits of Chinese companies, if certain information is refused to be disclosed by client. Even for SOEs or SOCBs, which may probably be bailed out by the government in difficulties, auditor should not at any time take this as a decisive consideration in making the going concern judgment.[90] Besides, not only SOEs but also privately-owned enterprises could use state secrets as reasons for non-disclosure. Professional skepticism should be exercised to ensure the reliability of information. Auditor may resign from the job engagement and/or communicate with regulators, if deemed necessary or required. For the second issue, legal proceedings or reforms could be proceeded. In the US, on May 9, 2012, Securities and Exchange Commission (SEC), the regulator of the securities market in the US, brought a public administrative proceedings against Deloitte Shanghai pursuant to Rule 102(e)(1)(iii) of the Commission's Rules of Practice for Deloitte Shanghai's willful failure to provide audit work papers of a client which was in violation of Section 106 of SO Act of 2002.[91] In violation, the court will determine if the auditor in China be censured or denied the privilege of appearance and practice.[92] In 2015, a settlement of US$2 million for failing to provide audit papers for investigation was finally made between the SEC and the big four accounting fims, with each of the firm paying US$500,000.[93] In addition to the involvement of judicial proceedings, in the US, the PCAOB issued a policy in October, 2010 making the inability to inspect auditors in nations such as China a factor when considering whether to approve for registration of CPA firm in the US.[94] The accounting board rejected an application by Hong Kong-based Zhonglei CPA Co. to become a registered US auditor in 2011, citing an inability to inspect its work for companies based in China.[95] It was the first time the PCAOB had rejected an application since tightening rules in October 2010.[96] PCAOB also sought to resolve the obstacles to PCAOB inspections with the relevant authorities in 16 jurisdictions, including

China.[97] Meanwhile, in Hong Kong, in August 2012, pursuant to Section 185 of the Securities and Futures Ordinance, the Securities and Futures Commission (SFC), regulator of the exchange market in Hong Kong, has commenced legal proceedings against E&Y, the auditor of SWL, for failing to produce to the SFC specified accounting records.[98] The court could order E&Y to comply with SFC's requirement within a specified period if the court is satisfied that there is no reasonable excurse for E&Y not to comply with the requirement.[99] Moreover, the court could punish E&Y and any other person knowingly involved in the failure in the same manner as if he had been guilty of contempt of court.[100]

The above court cases in the US and Hong Kong vindicated, though in a long process, that auditors' refusal to provide audit papers based on state secret is not able to challenge the supremacy of the laws in respective jurisdictions.

4. Insufficient guidance on communication and coordination with regulators

The audit failure cases overseas showed that, in cases if there were any irrevocable conflicts with clients, auditors usually chose to resign from their engagements. Nevertheless, depending on the type and the level of seriousness of the issues in conflicts, auditors in accordance with laws may have legal obligation to report to regulators. In the US, in certain situations, like detecting illegal acts that would have a direct and material effect on the determination of financial statement amounts, auditors are required to report to management, the audit committee, the board of directors or lastly to the SEC, unless the illegal act is clearly inconsequential.[101] In the UK, auditors are also required by law to provide information to the FSA who also has powers to make rules imposing duties on auditors to make reports to the regulator about aspects of firms' business.[102] Nevertheless, it is found that auditors seldom report cases in violation of laws to regulators. After the financial crisis, it is found that, in the UK, if any events exist that may trigger the legal obligation to report, the auditor, instead directly reporting the potential breach, persuades bank itself to notify the regulator of the potential breach.[103] It appears that auditors may emphasis on maintaining the auditor-client-relationship and keeping client confidentiality in preference to disclosing information to a regulator in the public interests, regardless the reporting duties of auditors to regulator as stipulated in regulations and auditing standards.[104]

To protect public interest, the EU recently requires the duty of report by auditor to the

regulator / supervisor information concerning the public-interest entity in case of some irregularities.[105] The role of auditor is expected beyond only exercising reasonable care and skills in his engagement. Rather, in case of suspicion, auditor should be more vigilant, exercise professional skeptism and investigate more. In compliance with relevant regulations, auditor is also expected to be a whistle blower and intitiate timely communication with regulator on cases in violation of laws or regulations to protect investors and public interest.

In addition to the reporting obligation by auditors to regulators, after the financial crisis, the requirement for regular communication (1) between supervisors and auditors; and (2) between the auditor and the audit committee of the audited companies are reinforced. In the UK, Financial Services Authority (FSA), the then regulator of the financial market in the UK, issued a guidance for the relationship between the external auditor and the supervisor in 2011 which encourages bilateral and trilateral formal meetings as well as informal communications between auditors and supervisors.[106] Meanwhile, information provided by auditor to supervisor will not contravene the duty of auditor if he is acting in good faith and he reasonably believes that the information or opinion is relevant to any functions of the supervisor.[107] In addition to the above, Financial Services Bill extends the power of regulator to impose various sanctions for violation by auditors, like censure, financial penalties.[108] Further, communication between auditor and audit committee of audited company is important as it facilitates audit committees' financial reporting oversight, fostering improved financial reporting and result in benefitting investors.[109] In the US, PCAOB completed a new audit standard on communication between auditor and audit committee which provides list of matters, like information related to significant unusual transaction, etc. for auditor to be discussed with audit committee before the issuance of the audit report.[110] In the UK, the FRC also revised the Guidance on Audit Committees in 2012 which provides guidance on the roles and responsibilities of audit committee, including the detailed works of overseeing external auditor.[111] In the EU, the new statutory audit framework also stipulates the communication between auditors and audit committees.[112] The duties of auditors are expected to be more onerous requiring more communication and coordination with various related parties.

In China, similar to its counterparts, there is not sufficient communication between auditors and regulators and report by auditors to regulators is also uncommon in China. Usually, the accounting scandals in China have been committed by the senior level of management for a long period of time without exposure to the public and their exposures are usually discovered like by media, not the regulators nor the auditors.[113]

[113] Ma Qiaozhen, *Zhong guo jin rong gao guan fu bai wen ti yan jiu ji dui ce qian xi [Brief Analysis Regarding*

Communication among audited companies, auditor and regulator is not sufficient possibly partly due to the unclear legal provisions or standards. For instance, in the banking sector, there is in lack of clear and unambiguous guidance regarding reporting obligation by auditor to regulator. Pursuant to CAS No.1613, it provides guidance on issues to be discussed or reported to regulator.[114] However, according to the above standard, communication with regulator still largely relies on the discretion of auditors and generally auditors are required to inform the management of banks or request their presence.[115] Though CBRC issued a guideline stipulated that banks cannot intervene the report by auditors to regulators on five situations, i.e. (1) serious violation of law, regulation or industry rules; (2) matters seriously affecting the on-going operations; (3) issuance of non-standard audit report; (4) fraudulent behaviors by management; and (5) serious conflict in decision making unit and key functional person resigns suddenly,[116] these Guidelines only state that banks cannot intervene the report of matters relating to the above five situations and there is no requirement for a mandatory report. The report to regulators is subject to the discretion of the auditors. Moreover, the above Guidelines also stipulate the holding of meetings between auditors and the CBRC.[117] However, there is no details regarding when the meeting to be held, how the meeting is held and what to be discussed in the meeting.

There is also a lack of clear guidance regarding the communication between audit committee and auditor, except as stipulated in the Codes on Corporate Governance for Listed Companies which state the responsibilities of audit committee, including (1) proposing the appointment or replacement of external auditors; (2) overseeing the company's internal audit system and its implementation; (3) communicating between the internal and external auditors; (4) inspecting company’s financial information and its disclosure; and (5) reviewing company's internal control system.[118] To enhance the independence of the audit committee, the Codes also stipulate that the majority members in the audit committee should be independent directors who should also be the convener and at least one should be accounting professional.[119] However, the above communication between audit committee and auditor is general in nature and does not specify the details of communications, e.g. the discussion of problems encountered during the audit process.

In accordance with regulations, if auditor could take a more proactive role in reporting cases, like illegal acts as stipulated in regulations, in advance to the attention of regulators instead of the comparatively more passive role of resignation at the very late stage of the scandals, regulators may be able to take more appropriate action earlier to protect the public interests. Regulators in China may also consider to revise their regulations in stipulating clear

and practical guidelines for bilateral and trilateral formal meetings among audited companies, auditors and regulators.

5. Limited liability risks to audit firms / auditors

Liability regime could be one of the factors which drive audit efforts.[120] Under joint and several liability, the auditor may deliver a higher audit effort as auditor has to compensate plaintiffs by damage payments if the company and/or the manager (as the co-defendant) be insolvent.[121] However, if the liability of auditor is limited, an auditor may have a reduced incentive to deliver high audit efforts given a relatively small threat of expected liability losses.[122]

Currently, in China, the possible legal liabilities on auditors and/or audit firms are mainly administrative punishment, which are rather lenient and lack of deterrent effect. MOF can only impose rather mild sanctions like warning.[123] Both criminal liabilities and civil liabilities are available for false reports or serious omission cases. Nevertheless, for civil claims, the compensation is limited to the untrue amounts, except in civil cases relating to false reports for listed companies in the securities market pursuance to the Securities Law. However, civil cases under Securities Law require a numbers of hurdles to be overcome before the cases to be lodged. Moreover, the courts prefer mediation over court proceedings. More importantly, civil liabilities mainly apply to audit firms not auditors. With most of the audit firms in China being limited liability companies, which bear legal liabilities with only their total assets, shareholders are shielded from any claims for compensation from companies, leading to the losses of creditors or investors in vain. Without proper deterrent measures from regulators and courts, compliance with relevant laws or rules may not be effective. Nevertheless, in China, audit firm in the form of limited liability company is now excluded from auditing of banks and listed companies. In recent years, there is a new requirement for the change of the form of audit firms to special general partnership in which a partner or several partners may bear unlimited liabilities or unlimited joint and several liabilities for his (their) intentional or serious wrongful act(s), and that this also the form of establishment for audit firms to be qualified to audit listed companies and banks,[124] that may help drive audit efforts.

The way forward and concluding remarks

A well-functioned disclosure system in financial reporting is important to protect the interests of stakeholders and for the stability of the financial system. Auditor plays an important role in

the disclosure system in enhancing the credibility and reliability of information disclosed. After the financial crisis, the duties of auditor are expected to be more onerous. With professional knowledge and knowledge of client's business and operation, for public interest, auditor is expected to communicate more with regulator and act as a whistle blower beyond just exercising reasonable care and skills as expected in the past. Auditor could also perform as a conduit for information exchange between audit committee of audited company and regulator, especially in communicating, clarifying and ascertaining some significant accounting information, like accounting estimates and valuation of financial products. Moreover, auditors in China need to focus more on the accuracy and the timeliness of information disclosed in the financial reports, in addtion to the sufficiency and relevance of information disclosed in line with international trend.

To synchronize the revised roles of auditors and for the substainable and healthy development of the financial system, the Chinese government should take a firm and determined step forward to improve the legal and regulatory regime regulating auditors. In particular, there should be clear provisions to ensure the independence of auditors to enhance the quality of audit work. Legal liabilities of auditors and audit firms could be reviewed again to provide effective, proportionate and deterrent sanctions. To foster effective and efficient communication, from the legal perspective, there should be specific rules or guidance providing details regarding situations how, what and when auditors should report to the regulators without violating confidentiality between auditors and audited companies. There should also be guidelines regarding areas for communication among audit committees, auditors and regulators. In particular, it is important to provide guidelines on communication between audit committees and auditors and the report of the above communication to regulators and the users of financial reports.

A Premier on the Shanghai-Hong Kong Stock Connect

Raymond W. So
School of Business

Siu Lek Yuen, Hong Kong, P.R. China
rayso@hsmc.edu.hk

In this paper, some premier findings on the Shanghai-Hong Kong Stock Connect are presented. The Shanghai-Hong Kong Stock Connect is a major step in the liberalization of China's capital markets. The Shanghai-Hong Kong Stock Connect is considered as a pioneer and a testing ground for the relaxation over the control of China's capital accounts. Findings in this paper provide some early evidence on the liberalization of China's capital markets. Some issues are suggested for further research.

Keywords: Shanghai-Hong Kong Stock Connect, Capital Market Liberalization, China.

JEL Classifications: F21, G15, O16

1. Introduction

Liberalization of capital market is an important policy decision. To emerging markets, the major advantage of a liberalized capital market is that it can attract more foreign investment and this will lead to greater potential for economic development. From a theoretical point of view, it depicts that liberalization of emerging capital markets can also enhance the efficiency of financial market by allowing its cost of equity capital to decrease (e.g., Stapleton and Subrahmanyan, 1977; Eun and Janakiramanan, 1986; and Stulz, 1999, etc.). Empirically, Henry (2000) provides international evidence to support this view. It is extensively documented in the literature that liberalization of capital market can bring a lower cost of equity capital which can lead to greater investment, hence higher growth potential of the economy.

Though it is well established that capital market liberalization is beneficial to emerging markets, the opening up of capital markets is not a simple consideration. For emerging markets, their infant capital markets are fragile to attacks by overseas speculative capital and financial security is always a major concern. Many emerging markets still recall the painful experience of the 1997 financial crises in which many emerging Asian capital markets were badly hit during the processes of liberalization of their capital markets. Therefore, it is not surprising to observe the opening of capital markets, in particular those of Asia, is occurring in a slow pace.

The issue of opening up capital markets is particularly crucial to China. China is the second largest economy in the world. In 2014, China's GDP reached US$9,240 billion, and is ranked second after the US, which has a GDP of US$16,800 billion. Despite of China's contribution to worldwide GDP, the Chinese capital markets remain underdeveloped. For example, China's capital account is not open and the Chinese currency, the Reminbi (RMB), is not freely convertible. As a result of this underdevelopment, China's capital account only accounts for less than three percent of global holdings of cross-border assets and liabilities. As mentioned in China's 12th Five-Year Plan, ambitious attempts will be made to liberalize its capital markets. Therefore, liberalization of the Chinese capital markets is an important topic, both in terms of policy and in terms of market impact. Academically, the opening of capital markets in China also provides a new testing ground on the benefits of capital market liberalization. The opening of capital markets in China is therefore an important area that deserves closer examination.

Nevertheless, a lot of controversial issues still remain in the debate of liberalization of China’s capital markets. The cause for financial security is often cited by government officials, think tanks and academics in the Mainland as the major source for taking a prudent step in the liberalization of China’s capital markets. The pace of liberalization of China’s capital accounts is not rapid.

The Shanghai-Hong Kong Stock Connect (SHSC) is the latest attempt of China’s efforts in the liberalization of its capital accounts. Through the SHSC, investors in Mainland China can invest directly in selected stocks in Hong Kong, and vice versa. Effectively, this can be considered as opening up China’s capital accounts in a small and well controlled scale. Needless to say, the launch of the SHSC was a major milestone of the liberalization of China’s capital markets.

To ascertain the successful launch of the SHSC, numerous seminars are organized in Shanghai and Hong Kong. For example, more than 100 conferences and workshops were organized in Mainland China to promote the SHSC. As the initial stage of the SHSC targets for the high net worth investors, more than 12,500 institutional and high new worth investors participated in these conferences and workshops. Similar approach was also adopted in Hong Kong. More than 140 seminars were organized in Hong Kong and more than 14,000 investors, including retail, institutional and sales executives participated in these seminars. Apart from Mainland China and Hong Kong, international roadshow activities were also organized. The Hong Kong Stock Exchange has organized roadshows in cities in the US, the UK, Canada, Europe, Middle East, Japan, Taiwan, Korea, Singapore and Australia. These international efforts have reached over 1,500 institutional investors. All these activities demonstrate that the Chinese Government and the Stock Exchange of Hong Kong are serious in making the SHSC a success.

The major implication of the SHSC is that it marked a major breakthrough of capital inflow and outflow of China. Before the SHSC, Chinese investors can only invest in the highly restricted Qualified Domestic Institutional Investors (QDII) scheme. The QDII can hardly be considered as a successful scheme in terms of opening up China’s capital accounts. QDII’s many constraints have, in practice, discouraged Chinese capital investment overseas. The SHSC can be considered as a major breakthrough in the process of opening up China’s capital accounts.

In this paper, some premier findings of the SHSC are contained. The objective of this paper is to document some preliminary findings of this important step of opening up China’s capital markets. The SHSC has in place since November 2014, but the trading was not active in the initial months. The short trading period, together with the problems of non-synchronous trading and availability of data, make it not feasible to draw meaningful conclusions from performing statistical analysis on the trading data. Hence, this paper is mainly descriptive in nature so as to document the development of the SHSC and to report some initial statistics of the SHSC.

Remainder of the paper is organized as follows. Section 2 describes the stock markets in China and Hong Kong, which aims to give readers a background on the development of the SHSC and the institutional issues faced by the SHSC. Section 3 explains the operation of the SHSC, the trading mechanism, as well as some technical details. Section 4 contains the preliminary statistics of the SHSC and offers some discussion of the findings. The final section concludes the paper.Methodology

2. Capital Markets in China and Hong Kong

The Chinese stock markets were established in 1990 in Shanghai and Shenzhen. Initially only domestic investors were allowed, which is known as the "A-share" market. Like any other typical emerging markets, the Chinese stock markets were characterized by strong government influence, insufficient protection to investors, low market transparency, and speculative in nature.

Later development of the Chinese stock markets called for more involvement from overseas capital. To attract overseas capital, a "B-share" market was created in 1992, which only overseas investors could participate. Since overseas investors were allowed, the establishment of the "B-share" market can be viewed as the first step to liberalize China's stock markets. Hence, there exist two segments in China's stock markets: the "A-share" market for domestic investors and the "B-share" market for overseas investors. The "A-share" market is traded in the Reminbi (RMB), while "B-share" market in Shanghai is traded in US dollar and that in Shenzhen is traded in Hong Kong dollar. Despite the establishment of the "B-share" market, this segment was inactive relative to the "A-share" market. The capitalization of the "B-share" market is small. Stocks that issued "A-shares" and "B-shares" typically exhibit discounts in the "B-share" markets. The average discount in the "B-share" market reached a record high of 86% in 2001 (He et. al., 2014).

Apart from the “B-share” market, Chinese firms are also listed in overseas stock markets. Hong Kong and New York are the most common stock markets for the Chinese firms to get listed overseas. The Chinese firms listed in Hong Kong are also known as the “H-shares.” For some big Chinese firms, they have strong links with the Chinese Government and these companies are known as “Red Chips.”

The Stock Exchange of Hong Kong (SEHK) is the only organised stock exchange in Hong Kong. At the end of 2014, more than 1,500 firms were listed on the SEHK. According to the International Finance Corporation (IFC), the Hong Kong stock market is classified into the upper income group, and Hong Kong has been considered a developed market by the IFC since 1993. The importance of the Hong Kong market can be revealed from the fact that Hong Kong is a major international financial centre in channelling investment funds to China. A lot of Chinese firms, the “red chips” and the “H-shares,” are listed on the SEHK (Neoh, 1998). Red chips are companies incorporated and listed in Hong Kong but whose controlling shareholders are China entities. Examples include CITIC Pacific, Guangdong Investment, China Travel and China Telecom. Large red chips are diversified conglomerates which have grown rapidly by injecting assets from their parent companies and raising funds from the public. Indeed, CITIC Pacific and Guangdong Investment were added to the Hang Seng Index, the most known and representative stock index of the Hong Kong market, in 1992 and 1994 respectively.

In 1993, Chinese state-owned enterprises (SOEs) started to issue shares in Hong Kong. These are called H-shares as the “H” denotes Hong Kong, the place in which the companies raise funds. Similarly, shares issued in London are called “L-shares,” and shares issued in Tokyo are called “T-shares.” Examples of H-shares include Tsingtao Brewery Company and Shanghai Petrochemical. Unlike the red chips, H-share companies tend to specialize in a single activity, usually heavy industry or a major infrastructure project. Not every Chinese SOE can issue H-shares on the SEHK. The SOEs are selected by the Chinese Government for their economic importance, management quality, technology, profitability and international significance. At the time of writing, there are around forty H-shares listed on the SEHK.

The listing of red chips and H-shares on the SEHK has been one of the most important events in the development of the Hong Kong stock market in recent years. By signalling to the international financial community that the SEHK is a gateway to China, Hong Kong has established itself as China’s primary source of external capital. Red chips and H-shares have become a small but stable component of the portfolios of many large institutional funds.

Table 1 shows the turnover of China-related stocks on the Hong Kong stock. As evinced by the figures in Table 1, turnover of China-related stocks constitute more than 50% of total turnover on the Stock Exchange of Hong Kong in recent years. This also demonstrates the importance of China related stocks in the investment community.

One particular thing to note is that there are many stocks which are dually listed in China and in Hong Kong. Many “A-shares” stocks also have Hong Kong listings, and it is not uncommon to observe price discrepancies among the “A-shares” and the “H-shares.” Simple finance theory posits that such price differences should lead to arbitrage activities. Limitations to arbitrage opportunities arise because China’s capital accounts are not open. Investors simply cannot buy and sell the same stock in China and Hong Kong to benefit from the price difference. The lack of effective capital flows effectively prohibits arbitrage actions.

The market is well aware of this issue. Indeed, there is a Hang Seng China AH Premium Index which tracks the average price difference of A-shares over H-shares for Chinese companies with both A-share and H-share listings. If the index is below (above) 100, that means the A-shares are traded at a discount (premium) relative to that of H-shares. When the index hits 100, the A-shares and H-shares are trading at par.

3. The Shanghai-Hong Kong Stock Connect

The SHSC was launched on November 17, 2014, which allows cross market investment between Shanghai and Hong Kong stock markets, subject to restrictions in the number of stocks and daily limit. For funds originating from Hong Kong and to be invested in the Shanghai Stock Exchange, the trading is known as the Northbound trading. For funds originating from China and to be invested in the Hong Kong Stock Exchange, this is known as the Southbound trading. The terms “Northbound” and “Southbound” vividly describe the geographical locations of the Shanghai and the Hong Kong stock exchanges.

There are separate daily trading limits for both the Northbound and the Southbound trading. The current daily limit for Northbound trading is set at RMB 13 billion, while that of the Southbound trading is set at RMB 10.5 billion. The trading limits are on a “net buy” basis. This means that the actual trading volumes can be larger than those of the trading limits, as long as the “net buy” positions are still within the prescribed daily limits. In addition to the daily trading limits, there are aggregate quotas for both Northbound and Southbound trading. The current aggregate quota for Northbound trading is RMB300 billion, while the aggregate quota of Southbound trading is RMB 250 billion. Utilization of the daily quota will be disseminated by the Hong Kong Stock Exchange on a 1-minute interval.

Not every stock listed on the Shanghai and Hong Kong stock markets can be included in the SHSC. For the Northbound trading, only 56 stocks are covered in the SHSC. Out of the 56 eligible stocks, 29 of them are qualified for buy and sell activities, while 27 stocks are for sold only. When compared with the Northbound trading, the number of stocks available for Southbound trading is 284, and all of them are eligible for both buy and sell. There are reasons for this difference. For the stocks covered in the Northbound trading, they are to be in the Shanghai Stock Exchange 180 Index or Shanghai Stock Exchange 300 Index, and they are to have both A and H shares. In addition, certain restrictions also apply. For the stocks that are covered in the Southbound trading, apart from certain restrictions, they are not necessary to be index constituent stocks. Hence, the number of stocks available for the Southbound trading exceeds that of Northbound trading by a large margin. In fact, many of the stocks available for the Southbound trading are relatively small and illiquid. The list of stocks available in the SHSC is contained in Table 2.

Trading is done via respective subsidiaries of the Shanghai and Hong Kong Stock Exchanges. Eligible investors are able to place their orders through conventional channels. The trading, however, needs to go through both Shanghai and Hong Kong stock exchanges instead of having one stock exchange to handle the logistics. Details of the trading mechanism are depicted in Figure 1. As seen from Figure 1, Mainland and Hong Kong investors can place their orders through their respective brokers. The orders, however, will go through the respective stock exchange first. Take the Northbound trading as an example. A Hong Kong investor will place his / her order through the broker. The broker will then direct the order to the Stock Exchange of Hong Kong, which will route the order to subsidiary of the Stock Exchange of Hong Kong, and the final order execution is done by the Shanghai Stock Exchange. The settlement of the trading is done by the ChinaClear. Similarly, a Mainland investor can place his / her order through his / her broker. The actual processing is done through the Shanghai Stock Exchange and then directed to the Stock Exchange of Hong Kong. The Hong Kong Securities Clearing will handle the clearing process in Hong Kong. Both the China Securities Regulation Commission in China and the Securities and Future Commission in Hong Kong will perform the roles of macro regulations of the securities, as well as that for the SHSC trading.

Some important points are to be noted. Hong Kong is an international financial market in which dividends and capital gains are exempted from taxes. On contrary, there are taxes on capital gain and dividend in China. Through the SHSC, investors can trade Chinese securities listed on the Shanghai Stock Exchange, hence they are subject to Chinese taxes. For cash and stock dividends, a standard tax rate of 10% will be withheld and paid to Chinese authorities by the respective listed companies. For capital gain taxes, it was resolved to be exempted from paying taxes. This represent a substantial difference between Chinese and overseas investors.

Also, short selling is regulated under the SHSC. Naked short selling is prohibited for both the Northbound and Southbound trading. Stock Borrowing and short selling, however, is allowed for the Northbound trading.

It is expected that many of the above mentioned regulations and limitations will be relaxed in the future. As mentioned by the officials of the Hong Kong Exchange, there are negotiations with the Chinese government on the relaxations on the daily trading limits in the future. At the time of writing, there is also a discussion of a similar initiative called “Shenzhen-Hong Kong Stock Connect,” which is to be modelled after the SHSC to allow cross border trading between the Shenzhen and Hong Kong stock exchanges. It is expected that the success of the SHSC will lead to greater flexibility in the design of the Shenzhen-Hong Kong Stock Connect

4. Preliminary Statistics and Discussion

In this section, some preliminary data and statistics on the SHSC are reported. Panels A and B of Table 3 report, respectively, the summary statistics of the Northbound and Southbound trading. From Panel A, the monthly turnover of the Northbound trading reached the highest level of RMB 137.5 billion in March 2015. When we look at the difference in the buy and sell trade, the net buy trade were RMB 40.6 billion, RMB 28 billion, RMB 11.3 billion, RMB 15.7 billion and RMB 9.8 billion, respectively, for the five months starting in November 2014. Given the fact that the daily limit on “net buy” basis for the Northbound trading is RMB 13 billion, the monthly net buy trades for the Northbound trading clearly did not utilize fully the allowable daily limit. Many people conjecture that the Northbound trading is not welcome by the investors. When compared with the trading volume of the Shanghai stock exchange, the trading activity of the Northbound trading can be considered as minimal. Further, the average daily buy trade is usually larger than the average daily sell trade. It can be viewed as the market's willingness to use the SHSC to enter the Shanghai stock market. Given the fact that the Shanghai stock index is on the upward trend during the sample period, it is conceivable to have more buy trades than sell trades originating from the Northbound trading. When one is to examine the impacts of the Southbound trading, a similar picture also exists. There are more buy trades, in terms of total volume, than sell trades.

This point can be further illustrated by the statistics in Table 4. Panel A shows the percentage of buy trades in total turnover for the Northbound trading. As evidenced by the numbers, buy trade constitute more than 50% of the total turnover in the first five months of the operation of the SHSC. There were only ten trading days for the first month of operation of the SHSC, which is not appropriate to use this as a demonstrable example. In the following four months, the buy trades typically occupy around 60% of total trading volume. When the same metric is examined for the Southbound trading, the buy trades even constitute higher percentages in total turnover. This simple statistic shows that the SHSC allows investors in both markets to invest through the SHSC. The initial stage suggests that investors are more inclined to buy stocks from the respective markets.

Also, the number of buy trades over the number of sell trades also suggests a similar conclusion. If we exclude the first month of operation of the SHSC, for the Northbound trading, the times of buy over sell trades range from 1.60 to 1.05, which indicate that there are more buy trades than sell trades. The numbers for Southbound trading range from 2.70 to 1.69, again consistent with that of the Northbound. Nevertheless, the higher times of buy over sell trades for the Southbound trading suggest that investors in the Mainland are more keen to buy Hong Kong stocks than selling their holdings.

The average size of the buy and sell trades also suggest some interesting findings. For the Northbound trading, the average trade size is smaller than that of the Southbound trading. However, the trading volume of Northbound trading is higher than the trading volume of Southbound trading. This means that despite the fact there are more trading activities in Northbound trading than in the Southbound trading, investors from Hong Kong typically conduct smaller trade than the Mainland investors doing the Southbound trading. This can be an indication that the Mainland investors are typically high net worth investors and their trading sizes are larger, while investors doing the Northbound trade are not as big as those in the Mainland.

Table 5 looks at the growth rate of the utilization of the SHSC over the first months of operation of the scheme. The results are mixed. For the Northbound trading, the growth in total turnover is substantial. The arithmetic monthly growth rate is 53.37%, while the geometric monthly growth rate is 35.26%. The overall growth rate during the sample period is 195.20%, which is a very encouraging finding. For the Southbound trading, the growth rate in total turnover is even more spectacular. The arithmetic monthly growth rate is 97.77%, while that of the geometric monthly growth rate is 56.11%. The overall growth rate during the sample period is 368.84%. Though the growth rates are encouraging, one must be cautious in reading these numbers as both the Northbound and Southbound trading are still in the early period of operations. The trading intensities are still yet to be established. The high growth rate figures may well be an indication that the bases for calculation of growth are still small.

Other growth measurements also suggest a very high growth period for the SHSC. Apart from the average size of daily buy trade and the average daily number of buy trades for the Northbound trading, all measurements exhibit remarkable growth rates. When a closer look is made to the Northbound trading, it can be seen that more drastic growth rates exist. The overall growth rate for sell trade turnover is 2,016.85%; but the average daily buy trade turnover has an overall growth rate of -23.16%. The corresponding numbers for the Southbound trading are not as drastic as those of the Northbound trading. It can be inferred from the growth rates that investors in the Northbound trading exhibit different trading behaviors than those of the Southbound trading.

The above discussion illustrates that the operating of the SHSC gives investors in Mainland and Hong Kong a good opportunity to invest in the other markets. The growth is rapid in early months, though the trading volumes do not match those of the respective home markets. In other words, if one is to judge the effectiveness of the SHSC in terms of flow of funds and trading volumes, the SHSC does not seem to be effective. However, as mentioned in Section 3, the SHSC has a bigger goal of providing a testing ground for the opening of China’s capital markets, as well as leading to the internationalization of the Reminbi. The smooth and orderly operation and execution of the SHSC can be considered as a success.

This finding contributes to one important element in the liberalization of China’s capital markets. To policy makers, the worry over interdependence of financial markets may lead to contagion effect of financial crises. However, this worry does not mean that China should not open up its capital markets. Forbes and Rigobon (2002) show that it is market interdependence and not contagion effect that exists in capital markets. When the Chinese capital markets are having greater interdependence with other capital markets (e.g., Johansson and Ljungwall, 2009; Lin et al., 2009; and Glick and Hutchison, 2013, etc.), the concern over contagion effect should not be over-emphasized.

As suggested by Rejeb and Boughrara (2013), liberalization of capital markets not only improves the degree of market efficiency, but it also reduces the chances of financial crises. Given the SHSC is able to achieve its objective, liberalization of capital markets can be carried out at a faster pace. It is recommended that the SHSC can relax some of its restrictions and put the SHSC to a greater scope of the testing ground in opening China's capital markets.

5. Conclusions

In this paper, some preliminary findings on the SHSC are presented. It is suggested that the SHSC has made some early successes in the opening up of China's capital markets. The statistics provided in this paper are mainly descriptive in nature, given the sample period is too short and the trading of the Northbound and Southbound are not active enough at the current moment to make any meaningful analyses. Nevertheless, findings in this paper suggest that the SHSC helps to speed up China's opening of capital markets. From a theoretical point of view, greater market efficiency will occur. A future research direction can be on the price discovery process of the SHSC. A recent paper by Chan and Kwok (2014) has some exploratory findings of the impacts of the SHSC before the launch of the scheme. Future research along the path of Chan and Kwok (2014) can be made by incorporating more updated data. This will also shed light into the questions of market efficiency and the relative roles of the stock exchanges in Shanghai and Hong Kong in the price discovery process. I leave this to future research.

Table 1: Turnover of Chinese Related Stocks on the Mainboard of Hong Kong Stock Market

Year	H-share		Red Chips		Total	
	HK$ (Billion)	% of equity Turnover	HK$ (Billion)	% of equity Turnover	HK$ (Billion)	% of equity Turnover

□ □ □ □ □ □ Beyond Sustainability / Corporate Social Responsibility (CSR) – Innovative Individuals with Innovations in Operating Environment for Sustainable Impacts

YEUNG, Shirley Mo-Ching
Division of Economics,
Nanyang Technological University,
Singapore
email@com.edu

Riding on the key findings of Yeung (2014) for the key factors in the Model of Creativity Development in Learning Organization:

1) Internal – Individuality and External – Tasks
2) Operating Environment and Activities and
3) Methods to Develop Creativity, this paper has reviewed 16 research papers on innovative model and Corporate Social Responsibility (CSR) innovation from 2010 to 2014 via qualitative and quantitative analysis of N' vivo to design a checklist to evaluate the innovative capacity of organizations for corporate sustainability. Three main dimensions are identified for corporate innovations:

   (1) Individual Innovation (from 0.24 to 1.26% references) – supply chain value management (from 0.45 – 1.26% references) and supply chain risk management (from 0.38 to 0.43% references);

   (2) Organizational Innovation – co-production value (from 0.11 to 2.19% references) and social responsiveness (from 0.03 to 1.39% references); and

   (3) Innovative Operating Environment (from 0.57 to 3.64% references) – interlinked standards (from 0.08 to 1.57% references), sustained environment (from 0.21 to 1.42% references), holistic process (from 0.07 to 1.12% references) and community value (from 0.18 to 1.07% references).

□ □ □ □ □ □ Innovation in the Application of GRI to Visualize Strategic Goals for Sustainable Development – The Case of Tertiary Institution, Hong Kong

Shirley Mo-ching, Yeung
Supply Chain Management Department
Hang Seng Management College
Hong Kong
shirleyyeung@hsmc.edu.hk

This paper explores innovation in how educators use GRI sustainability (CSR) related guidelines to engage different stakeholders and respond to the trend of sustainable development in higher education mentioned by UNESCO. Through the case of a tertiary educational institution in Hong Kong, examples of innovative KPIs are devised to align with the strategic goals of the case institution with implications to the institutional level and the community level. The case institution measures its performance, identifies its risks with priority and reports under three main headings – Responsible Business Management, Responsible Curriculum Design, and Responsible Partnership through stakeholder mapping with action plans for measurement (2015 –2017), the risk level with KPIs of activities with Social Return of Investment (SROI), and benchmarking with self-financed institutions offering business and management related degree programmes and CSR-related activities with impacts created from media reporting. This paper thus lies at the nexus of GRI sustainability (CSR) guidelines, innovative Key Performance Indicators (KPIs) and Strategic Goals to integrate environmental, social and economic impacts and the encouragement of good governance practices throughout the lifecycles of goods and services produced for sustainability.

Keywords: Sustainable Development (SD), Innovation, Responsible, Key Performance Indicators (KPIs).

1. Introduction

In line with the UN Decade 2005-2014 on sustainability, many researcher papers have been found on the sustainable development (SD) in the higher education sector. Different institutions have their own interpretations of sustainable development. In general, sustainable development is related to economic, social and environmental impacts with responsible decision making of allocating resources to meet the present and future needs of a society. This links up to the way of management in defining and interpreting sustainability when setting and implementing their short and long term strategic goals with total involvement of academic and administrative staff. Buying in the concept of sustainable development is the first and the most significant step in implementing sustainability related actions in an institution as the perception of staff on SD well relates to their understanding and exposure on sustainability.

According to the definition of Brundtland Commission (1992) of the United Nations, "sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs." The basic element of sustainability is the economic aspect to support the business in short term, and support the new products, services, processes and people in the long term. In global initiatives of the "United Nations (UN) Decade of Education for Sustainable Development" (DESD) 2005-2015, the mission of DESD outlined by United Nations United Nations Educational, Scientific, Cultural Organization (UNESCO) is to meet the needs of the present without compromising those of future generations. Education is to learn how to learn, un-learn and re-learn through on-going helping people develop values, skills, attitudes, and knowledge with the principles, values and practices of sustainable development; and this kind of proactive thinking has to be integrated into all aspects of education and training to people in all nations at different ages to develop economic, social, environmental and cultural awareness and to seek solutions for these problems. Hence, ESD is relevant to all nations and all higher institutions. Management in higher educational institutions need to keep on practicing the rationale of ESD beyond 2015 through integrating ESD in their institutional operational level in setting strategic goals and performance indicators; and school / programme level in re-visiting the curriculum for the benefit of learners and the community.

As mentioned by UNDESD, quantitative and qualitative ESD indicators are needed to be incorporated into different aspects of education for regular monitoring and reviewing purposes. This paper is going to adopt the rationale of ESD with the principles of Global Reporting Initiatives (GRI) to present a case with organizational values and strategic goals to align with relevant performance indicators on four key areas - economic, social, environmental and governance for demonstrating the linkage between stakeholder mapping and risk identification; the linkage between strategy and sustainability. The job of developing, monitoring and reviewing these ESD related performance indicators can be treated as co-production outputs of management, academic and administrative staff working in an institution. In fact, academics also need to work closely with industry practitioners to better understand the growing importance of sustainable development in higher education and in industries so as to generate meaningful economic, social, environmental, governance and cultural impacts.

2. Objectives and Contributions

In recent years, the higher educational sector has started to address the issues of sustainable development in their operations and curriculum design. This has created a dramatic need of educators, especially curriculum designers, with a mindset of sustainability and social responsibility; and the skills of writing sustainability related reports to communicate with stakeholders for accountability and transparency. This triggers the author to study the steps of setting sustainability related performance indicators to align with institutional strategic goals and to prepare sustainability report with economic, social and environmental impacts.

The purpose of this paper is to explore the application of GRI reporting principles with the seven dimensions of ISO 26000 Corporate Social Responsibility (CSR) Guidelines to identify the steps of designing relevant sustainability-related goals for continuous improvement in management level, programme level and partnership level to fulfill the gaps between academics and industries in terms of developing talents with relevant knowledge, skills, attitudes and values for the future. It is expected that ESD goals can help measure performance from different perspectives for organizational improvement and for partnership and community development.

3. Sustainable Development and Knowledge-based Economy

The concepts of sustainable development have been most debated subjects and of great importance in the future, especially in higher education sector where leaners are educated to prepare how to face the challenges for the future and how to develop themselves personally and professionally in a sustainable manner. Szitar (2014) mentioned that community development was related to sustainability which needed to have stakeholder collaboration, linking up changes with sustainability, adopting interdisciplinary and multidisciplinary approach in teaching in architectural education, for example case study and PAPSA (Presentation, Analysis, Production, Selection and Application) methods and providing solutions in a holistic manner. Pinho et al. (2015) also university not only enabled professional growth, but also in the personal level (p. 162). Besides, they highlighted that contextualization in crucial in university education, including creating a variety of contexts for leaners learning how to perceive the world, how to handle adverse situation, how to develop belonging to the syllabus, how to experience practical contents, and how to create professional network via opportunities in extracurricular activities that are complementary to their studies.

In fact, Gedzune (2013), Gedzune and Gedzune (2012) and Pohl et al. (2010) also mentioned that teacher training and engagement with reflection, action research and co-production of sustainability-related research were needed to understand the importance of a broader and inter-relating perspective on issues related to sustainable development for the future. Back to 2005, Kitagawa pointed out that the role of universities in the knowledge society was examined in light of the emergence of new research and learning systems, conditioned by forces of both globalisation and regionalization with impacts of these new relationships perceived in four principal dimensions: economy, human resources, governance and community.

As we know, the economic development of most countries is now turning from manufacturing into service production which calls for talents with professional knowledge, skills, attitude and values. Kivunja (2015) brought up that the economies had been increasingly globalised with digital technologies assuming ubiquitous presence and functional utility in peoples' lives outside educational contexts. He mentioned that educationalists needed to prepare learners for the Digital Economy, requiring the teaching of new skills rather than the traditional core subjects. Kivunja (2015) named this realization as a New Learning Paradigm, teaching students with skills most demanded in the 21st century. He put forwarded the 4Cs super skills, that is, critical thinking skill, communication skill, collaboration skill and creative skill. If learners are taught with these four super skills with sustainability contents and community development mentioned by Szitar (2014) and contexts for development mentioned by Pinho et al. (2015), it is assumed that the community will be a better one under knowledge-based economy within a digital technology environment.

4. Sustainable Development and Corporate Social Responsibility (CSR) in Higher Education

Under keen competition for resources and unexpected risks from natural and human-made disasters, people are aware of the importance of sustainability in education. In fact, the concept of sustainability can be traced back to the thirteenth century but in more recent times it appeared in the environmental literature in the 1870s (Kamara et al., 2006 quoted in Jones et al., 2011). Jones et al (2011) suggested that sustainability was about human survival and the avoidance of ecological disaster' with complex and technical meaning from a professional perspective. They argued that sustainability could be seen as the goal or endpoint of a process called sustainable development. They also mentioned that a number of attempts had been made from scholars in interpreting sustainability that theoretical frameworks of connecting the nature and society were needed to recognize social and economic development could not be viewed in isolation from the natural environment. (Amsler, 2009, p.123 quoted in Jones et al. p.258)

In 2011, Djordevic and Cotton realized that there had been a growing awareness in national and international policies to integrate sustainability into both business and educational arenas. They emphasized that education for sustainability development (ESD) was an issue of increasing importance in higher education, including the campus, curriculum, community and culture of institutions. They quoted the ideas of UNESCO that ESD was "a process of learning how to make decisions that consider the long-term future of the economy, ecology and equity of all communities". From an institutional perspective, policy and strategy related to sustainable development in higher educational institutions have to be driven from the management, for example, curriculum design and development policy, teaching and learning policy, research policy, campus design and maintenance policy. Two years later, Ryan and Tilbury (2013, p.272) mentioned that though the need to embed Education for Sustainable Development (ESD) in the higher education curriculum was well recognized in international sustainable development dialogues, substantial obstacles were encountered which called for systemic education change. They uncovered that educators needed to re-think the purpose of education with a new angle of visiting existing pedagogy practices to extend learning opportunities for learners who could contribute more for the future. They concluded a deeper reflection on teaching and learning was needed to make ESD a viable education proposition for transferring skills. They also put forward that engaging learners with experiences on sustainable development was significant as this would lead learners to further develop their critical thinking, provocative questioning skills and devising new ways of living.

Besides, Yeung (2014) also highlighted that responsible corporations needed to adopt the seven dimensions of Corporate Social Responsibility (CSR) guidelines of ISO 26000 in their operations: labor practices, consumer issues, fair operating practices, human rights, organizational governance, community involvement and development and the environment.She mentioned that the priority of the seven dimensions was subject to the strategic planning of the management and the expectations of their stakeholders. According to Cajazeira (2008 quoted in Yeung, 2014), the major principles for ISO 26000 are: accountability, transparency, ethical behavior, consideration for the stakeholders, legality, international standards, and human rights. It is the responsibility of organizations to consider the needs of the stakeholders in these seven aspects when designing work processes or executing business-related activities. In fact, ISO 26000 CSR guidelines convey a message that non-economic inputs and soft side of outcomes are the trend of quality management system (QMS).

In order to fulfill the needs of UNESCO and the gaps uncovered by scholars, this paper focuses on exploring ways to link institutional vision and strategic goals with social reporting principles and ISO 26000 CSR guidelines to define steps of engaging stakeholders, identifying possible risks and setting sustainability / CSR related goals for making the institution becoming a more sustainable one. Yeung (2014) mentioned that building quality into products and services were not sufficed for continual improvement. She called for new ways of integrating sustainability and CSR into organizational strategy for sustainable business. In fact, Mootee (2013, p. 59) brought up a similar viewpoint of Yeung (2014) that “More than 80 percent of our management tools, systems, and techniques are for value-capture efforts, not for value creation; this includes techniques such as total quality management (TQM), enterprise resource planning (ERP), Six Sigma, Lean Startup, and Agile Systems. These tools are valuable for keeping an enterprise running smoothly. But we should be focusing on value creation rather than value capture alone. This is where design thinking comes into play. Companies such as Apple, Amazon.com, Netflix, Samsung, Burberry, and BMW are winning by design and the thinking behind that design.” He mentioned that solving problems needed to have a multi-functional and multi-perspective approach that influenced many of the principles inherent in design thinking, that is, core values, identities, expectations, and views of the world. He emphasized that ‘responsibility to shape the future’ was critical and actions had to be humanized, meaningful and connective. When applying the concepts of design thinking in setting sustainability – related goals for educational institutions, it is recommended to embed the principles of empathy, an approach to collective problem solving, and a framework to balance needs and feasibility.

5. Design Thinking for Sustainable Institution

Problems that we come across may not be the same as those in the past. Hence, a new perspective for problem-solving is needed for sustainable development. Mootee (2013, p.39) put forward the idea of design thinking, a natural and inherent thinking, which was an approach to inquiry and expression that complemented and enhanced existing skills, behaviors, and techniques. He mentioned that design thinking was a date-driven analytical thinking with its own mode of analysis – one that focused on forms, relationships, behavior, and real human interactions and emotions. He recommended that design thinking could be applied in the following ways of which they were relevant for sustainable development in higher education:

“1) How a product, service, system, or business currently lives in an ecosystem;

2) How people interact with the above and the nature, frequency, and attributes of that interaction;

3) How the different elements in the ecosystem relate to one another and if any systems-level impact exists;

4) What other ecosystems exist adjacent to your ecosystem;

5) How new insights may be gained by looking broadly at communicative events within these ecosystems and how they fit together from a systems perspective;

6) What the key characteristics and patterns of behavior of new relationships are when viewed from a system level; and

7) What the patterns of people’s information behviors are and how to map them visually to make sense of them” (Mootee, 2013, p. 39)

From the above, design thinking can empower organizations and individuals to better understand their competitive and operational environment for perceiving and solving problems with realization of behavioral patterns, values attached to systems-level and processes of meeting challenges.

Apart from a system level, a process of level in programme / module design with sustainable development and social responsibility are also needed to be addressed. In the 17th International Conference on Teaching and Learning organized by UNESCO-APEID, Bajunid (2014) mentioned that any radical turning points in professional policy shifts required mid-set changes in teachers regarding their beliefs, assumptions, out the box thinking, time management, creativity, edupreneurship and wethanschaaung. “The emerging of basic literacies and new literacies demand continuous learning by teacher as perennial leaner.” Bajunid (2014) also quoted the code of practice for quality assurance in public universities in Malaysia developed by the QA Department of the Malaysian Ministry of Higher Education (2008) that the key foci of programme quality were: conceptual framework, knowledge, skills, content knowledge, pedagogical content knowledge, pedagogical and professional knowledge and skills, professional disposition and assumption system with evaluation, field experience and clinical practice, diversity, faculty qualifications, performance and development, unit governance and resources (p.6) Moreover, he highlighted that all programmes objectives should align with the following learning outcomes:

1) Knowledge;
2) Practical Skills;
3) Social Skills and Responsibilities;
4) Communication, Leadership and Team Skills;
5) Problem-solving and Scientific Skills;
6) Information Management and Life-long Learning Skills; and
7) Management and Entrepreneurship Skills.

Yeung (2014) echoed the ideas of Bajunid (2014) that the following four characteristics were desirable for a social responsible teacher in the future teaching under the digital age. Teachers need to develop techniques to cater a diversified group of students through traditional and non-traditional classroom setting, for example, blending learning and virtual learning environment to motivate students as co-producers for meaningful and relevant curriculum. The eight characteristics are:

1) Knowledge and Intellectual Skills –
   Multi-disciplinary knowledge and multi-thinking with a mindset of change

2) Processes –
   Value creation and waste reduction via curriculum review and revision

3) Autonomy, Accountability and Application –
   Acceptance of professional responsibility with people respect and continual improvement

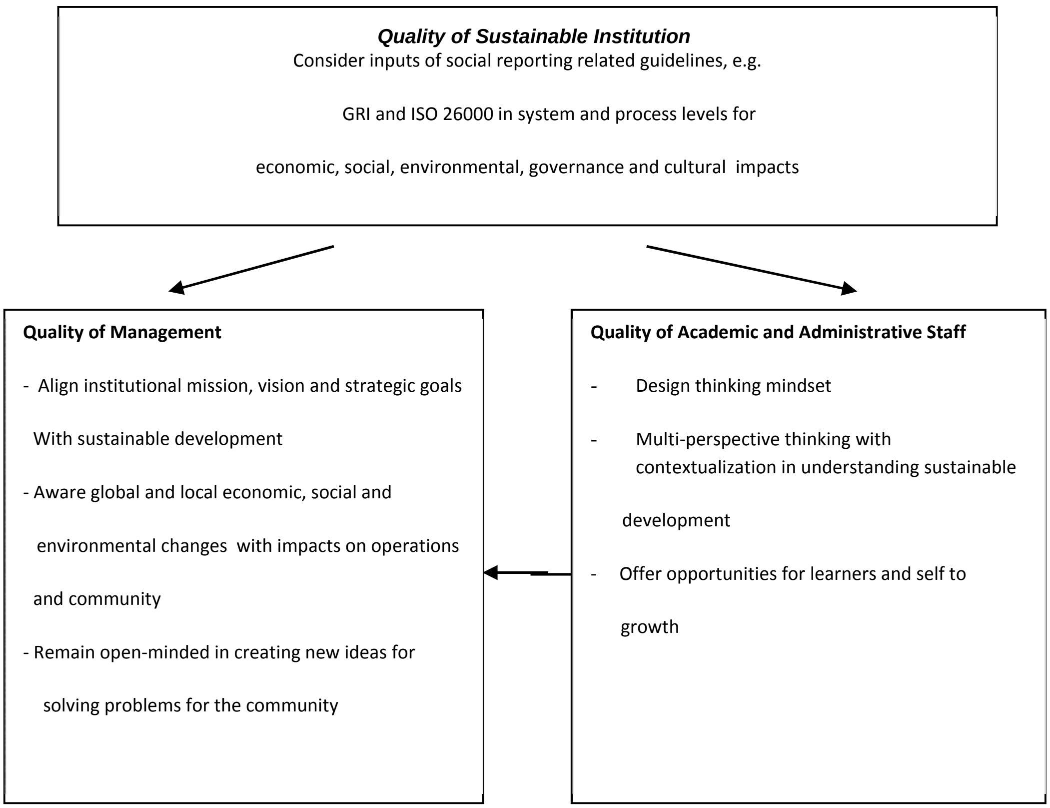
4) IT, Numeracy and Communication –
   Using technology and information with environmental concerns in teaching
   and curriculum design

In 2010, Fisher realised that corporate sustainability/ social responsibility was of utmost importance for the survival of organizations and their future generations of employees. "Organizations' product/ service offerings and vendor networks are interconnected globally and are being recognized on a global scale" (P. 29) If educators can visualise the sustainable development goals of UNESCO, crystallize the manpower projection into curriculum design, can realise the ways of implementing 4Cs into designing community development related programmes, the institution is working towards a sustainable organization for the benefit of learners, the industries, and the community as they can develop awareness of sustainability and social responsibility to their peers and influence students to learn in a sustainable way. Based on the literature of the above, the author has generated a model of sustainable institution (see Figure 1.0).

6. Methodology – Action Research Learning Approach

The paper was conducted with the rationale of action learning approach. Through the years of quality assurance, CSR assessment, curriculum design and teaching experiences gained in the case organization, the author has adopted an approach of action research to organize ongoing inquiry with conceptualization of quality, CSR

Figure 1.0 – Model of Sustainable Institution with Quality Management and Quality Staff



and sustainability raised in higher education in general and methods of advancing the institution from system and process levels with stakeholder mapping and risk identification for defining sustainability-related performance indicators. The author is expected that adopting action research approach could help to solving real problems from a holistic view and can benefit the case organization and the community as a whole. In fact, action research is a way of learning, un-learning and re-learning through a process of inquiry with the experience of not knowing 'what to do next' to finding answers from experience, expertise and reflection.

Research Questions:

1) What are the steps to cover the key dimensions to monitor the performance of a tertiary educational institution?
2) How can a tertiary educational institution turn to be a more sustainable one?

Background of Case Institution in Hong Kong

The case institution has been developing over time from a sixth-form school into a post-secondary / higher education institution offering business related mainly Bachelor's degree programmes. This section is to provide an overview of its development in the past 10 years. The management of case institution decided in early 2001 that from 2003 to around 2007, the institution should run its Associate Degree (AD) Programme in parallel with its their senior years of secondary education, in preparation for becoming a full post-secondary/higher education institution operating at the AD level when A Level courses are finally phased out. In line with Government requirements for non self-accrediting institutions, the case organization has requested the Hong Kong Council for Academic Accreditation and Vocational Qualifications (HKCAAVQ) to conduct an Institutional Review and a Programme Validation of its first AD Programme, which was accredited and ready to offer an Associate in Business Administration Programme in September 2003. From 2003 up till 2014, altogether there are 10 undergraduate degree programmes and one AD Programme with a total of student number of over 4,600 in 2014/15.

Vision

The vision of the case institution is to be a leading private university, recognized for excellence in teaching, learning and research, especially in the areas of business and management. With the following 10 strategic goals (SG 1- SG 10) in place, value can be created to our stakeholders - students, academic and non-academic staff and the community via complying the institutional requirements and programme accreditation requirements of HKCAAVQ, meeting the labor manpower projections of the Hong Kong government, and fulfilling the expectations of our potential employers in different industries.

Strategic Goals (SG) of the Case Institution

1. To afford a modern and stimulating campus environment (SG 1) to facilitate and support teaching and learning activities.
2. To develop and offer innovative academic programmes (SG 2) which respond to changing community needs.
3. To provide a holistic and challenging educational experience for students (SG 3).
4. To cultivate students' global perspective (SG 4) through internationalisation.
5. To develop strategic partnerships (SG 5) with industries and businesses.
6. To create internship opportunities (SG 6) for students to gain practical experience in the workplace.

7. To encourage and support dynamic research (SG 7) initially focusing on regional relevance and gradually broadening to more extensive horizons.
8. To strengthen governance structure (SG 8).
9. To enhance quality control (SG 9) through internal and external monitoring.
10. To explore new ways and sources of funding (SG 10) to augment the financial base of the College.

Turning Vision into Sustainability (CSR) Vision

To the case institution, CSR is the responsibility of the College for creating impacts to the community, the environment, the marketplace and the workplace through continuing commitment in educating our students, influencing our staff and doing business ethically with economic, social and environmental contributions to the community while improving the quality of life to our staff and their families as well as the local community and society at large. The Sustainability (CSR) strategy is to support the case organization vision of becoming a private university through providing quality business and management related programmes to teenagers to meet the job market needs with business and management related knowledge, skills, attitudes with social responsibility and an ethical mindset.

7. Findings

Research Questions:

1) What are the steps to cover the key dimensions to monitor the performance of a tertiary educational institution?

   The followings are the steps of visualizing sustainability (CSR) vision for the case institution:

Step 1) Setting up a CSR Working Group:

Engaging teaching, administrative staff and students of various programmes to discuss ways of maintaining quality in programmes/ students / graduates/ campus with impacts in the workplace, the marketplace, the environment and the community.

Step 2) Arranging Awareness Training for Involved Academic and Administrative Staff:

- Providing on-going (e.g. quarterly) training to primary and secondary stakeholders about the relevant sustainability / CSR practices in higher education, expecting to have actions agreed with members of the CSR working group
- Updating the progress of the 10 strategic goals aligned with the risk level identified and action plans during the on-going training
- Inviting external parties for comments on improvements in programmes/ students/ graduates/ campus when training opportunities come up
- Engaging the community of Shatin area in New Territories, Hong Kong and the society as a whole when training is relevant to their needs

Step 3) Defining Sustainability related Goals and Strategy

Table 3 demonstrates explicitly the above-mentioned 10 strategic goals of the case institution (SG 1-10) and strategy used.

Step 4) Meeting Sustainability related Reporting Guidelines to Engage Stakeholders

Based on GRI 4 criteria to identify relevant action plans (see Table 1) to prepare a sustainability report with 3rd party endorsement for recognition, for identifying rooms of improvement, and for assessing the level of responsibility in the workplace / the marketplace / the environment/ and the society.

The identification of primary and secondary stakeholders, the understanding of their needs and expectations, and the linkage between stakeholders and vision / strategic goals are the critical points in the success of visualization the sustainability (CSR) vision of the case institution. Table 1 shows clearly the linkage among stakeholders, risks, impacts and action plans for sustainability (CSR) vision.

For example:

Maximizing graduates' employment opportunities; increasing student exposure on green movements, anti-corruption, worker right protection, work-family balance, public education efforts; promoting business ethics, community services & engagement, implementing actions against global poverty, and other social innovations, etc.

Step 5) Communicating with Stakeholders for Sustainability / CSR related Achievements for Engagement and Team Spirit Enhancement

On-going and effective internal and external communication plays an important role in the College’s overall performance, student and teacher performance and reputation. Regular communication with factual information drives our staff to make continual contributions to the strategic goals and the sustainability (CSR) vision of the workplace, the marketplace, the environment and the society.

Through adopting the Hong Kong CSR Advocate Index (ISO 26000 CSR guidelines) held by Hong Kong Quality Assurance Agency (HKQAA) since 2009, the commitment in the 10 strategic goals embedding sustainability (CSR) vision covering key and supporting processes to meet the expectations of the stakeholders has been shown with continual improvement. In the past two years (2013 and 2014), the case institution obtained a full score of “5” through the professional and third party on-site verification visit of HKQAA. This is the first comprehensive Index in Hong Kong with participants coming from diversified industries, for example, educational institutions, governmental department manufacturing, and service sectors. And, the case institution is the only participant from the tertiary education sector with 6 years’ promising track record in the advocate CSR Index with ISO 9001: 2008 system in place to support process management, with comprehensive College-wide Quality Assurance (QA) mechanism to measure and improve the performance of programmes, students and teachers, and with innovative green building assessment from third party to increase the awareness of the environmental related issues in the campus.

Through participating the CSR Index, the concerns of stakeholders have been addressed. The case organization believes the CSR Index assessment is not only a self-check exercise to look for opportunities of improvements under the changing external environment for the benefit of our stakeholders, but also a good learning platform to understand that sustainable organizational development is closely related to engaging stakeholders, implementing relevant policies, measuring performances, reviewing the polices for advancing further planning for reaching the strategic goals of the College, for example:

- Students, academic and non-academic staff, programme accreditation body, the potential employers, the strategic partners, the local community and the government have been identified for continual improvements with policies, action plans and measurements;
- Governance structure enhanced;
- External and internal control strengthened;
- Innovative programmes offered to meet the needs and expectations of the community; and
- Modern campus with environmental impacts for learning offered.

To quote an example, UNESCO mentioned that the entrepreneurship education needed to be strengthened to reduce the teenage unemployment issue in 2013. The case organization has supported the Entrepreneurship Project organised by an NGO – Ocean Junior Chamber (OJC) to publish a book written by our students of different degree programmes after interviewing entrepreneurs from different industries in 2014. Recently, the project details of the book and learning outcomes of students have been shared with UNESCO international entrepreneurship education members as a good practice. Through this project, active involvement with the local community has been demonstrated through sharing project experience, conducting research, developing skills for learners to meet the challenges in the future. All but not least, CSR is both a functional and an integrative tool to visualize the mission of the case institution to develop talents for the business and management area as the future managers are expected to be socially responsible for their business from different perspectives.

Step 6) Conducting Sustainability Assessment and Benchmarking

The case institution measures its performance, identifies its risks with priority and reports under three mean headings – Responsible Business Management, Economic Impacts/ Social Impacts and Building Relationship. The stakeholder mapping with action plans for measurement (2015 –2017) and the risk level with KPIs of activities with Social Return of Investment (SROI) has been illustrated clearly in Table 1. For example:

Responsible Business Management
- Harmonized employment with stable teaching staff
- Green building assessment of the campus

Economic and Social Impacts
- New programmes offered, e.g. Asian studies and Cultural and Creative Industries undergraduate degree programmes in coming years

Building Relationship

- Building strong relationships with stakeholders, e.g. ministry of education in different countries and overseas universities for achieving the strategic goals and sustainability (CSR) vision and the vision of the case institution.

Research Questions:

2) How can a tertiary educational institution turn to be a more sustainable one?
The following Table demonstrates actionable items to align with the sustainability goals defined.

Table 1 Stakeholder Assessment and Future Measurable Goals

Stakeholder	Risk	Impact	Probably	Priority	Future Measurable Goals for Areas of Improvement in 4 Sustainability Pillars of Workplace, Marketplace, Environment, Society (2015 to 2017)
Primary Students (SG 2 - 5)	Low employability rate Student dissatisfaction	5 Reputation ruined without creating value to students and without developing talents to meet the labour market	3	5 x 3 = 15	Marketplace Sustainability Goal ISO 26000 CSR – Consumer Issues KPI – e.g. 4 meetings / year with increasing total number of strategic local/ overseas partners in internship offer from developing and developed countries with international exposure to let the students understand cultural diversity and skills of accommodation (GRI 4 – market presence/economic / social impacts) e.g. On-going meetings (formal and informal) with students, teachers, programme accreditation bodies and potential employers to review performance of SG2-5 through engaging more relevant and external stakeholders along with the market change to review

					the quality of programmes / students/ interns/ graduates/ teachers and the College as a whole Example: Develop students with skills of 4Cs (critical thinking skill for solving problems, communication skill for understanding and communicating ideas, collaborating skill for working with others, and creating skill for producing high quality work) mentioned by Kivunja (2015) to face the future challenges and to handle the sustainability related matters for community development. **Other activities can be considered to widen students' perspectives are: - green movements, - anti-corruption, - worker right protection, - work-family balance, - public education efforts, - promoting business ethics, - community services &

					- engaging concerns/actions again global poverty, and social innovations which can be integrated with in-class and beyond-class activities (Diarise the progress of identified KPIs with actions plans for improvement after meetings)
Teaching staff (SG7)	Pressure of research and heavy teaching assignments affecting the well being of teachers Dissatisfaction leading to high turnover	3 High staff turnover and unfair teaching assignment affecting programme quality and low student intake	3	3 x 3 = 9	Workplace Sustainability Goal ISO 26000 CSR – Human Rights and Staff Issues KPI e.g. Add a new strategic goal of improving the well-being of academic and non-academic staff for improving quality of life e.g. Organise large scale activities / year with participation of staff from different industries and professional counselors to identify the source of pressure and methods of releasing them with methods passed over to students when appropriate to help release their study pressure. e.g. Invite experts in mindfulness and emotional quotient for maintaining quality of workplace and quality of family life to teaching staff and non-teaching staff

					e.g. Regularly review the fairness in research, teaching assignment and administrative duties for utilize the skills of staff to increase job satisfaction ** Other on-going activities can be considered as staff development are: - green movements, - anti-corruption, - worker right protection, - work-family balance, - public education efforts, - promoting business ethics, - community services & - engaging concerns/actions again global poverty, and social innovations which can be integrated with student activities, if appropriate (GRI 4 – labor/ management relations/ equal remuneration/ labor practices grievances mechanism) (Diarize the progress of identified KPIs with actions

					plans for improvement after meetings)
College management (SG 1-10)	Programme quality not recognised Skills not relevant to employers required or expected Insufficient funding	3 Gap appeared between what offered in the College and applied/ expected in the workplace/ College Council/ Board	3	3 x 3 = 9	Society Sustainability Goal Marketplace Sustainability Goal Economic Sustainability Goal (GRI 4 – Product responsibility) ISO 26000 CSR – fair operations/ community involvement / consumer issues KPI- e.g. Fixing a certain number of meetings/ year with College management, teachers, students and relevant external parties for identifying the change in workforce structure and best practice in higher educational sector or industry to improve programme quality with 2 innovative improvements in programmes and 2 new sources of funding opportunities e.g. inviting research scholars and curriculum designers from Israel institutions (Diarise the progress of identified KPIs with actions plans for improvement after meetings)

Programme accreditation body (SG1-4/ 8-9)	Student attributes programme quality and College infrastructure not consistently meeting the requirements under the fast development of case institution	5 Risk of losing confidence from HKCAAVQ and the public	3	5 x 3=15	Marketplace Sustainability Goal (GRI 4 – Product responsibility/ Marketing communication) ISO 26000 CSR – fair operations, community involvement/ consumer issues e.g. On-going communication with a fixed number of announcements / year to staff and students for agreed outcomes / actions) with local and overseas programme accreditation bodies, psychologists and NGOs to understand the development of teenagers' emotional, mental, psychological, physical changes and let them have more opportunities to work with CEOs and blue collar to realize personal potential, skills intended to develop and career to be pursued; and these experience will be embedded into programme design or college activities to fulfil the programme accreditation bodies, if appropriate, for the changes in requirements to align with the performance/ development of the College (Diarize the progress of identified KPIs with actions plans for improvement after meetings)

Government (Education Bureau EDB) (SG 2/ 8)	Not gaining recognition and subsidy of programmes for the benefit of students	3	3	3 x 3 =9	Society Sustainability Goal (GRI 4 – Product responsibility) ISO 26000 CSR – fair operations/ community involvement KPI- e.g. On-going collection of feedback/ media reporting (10 relevant reports / year to staff and students on programmes/ students/ staff / infrastructure) e.g. Collecting updated and relevant information from government in areas of research, programmes, teaching and students…etc. for funding application or opportunities of seeking support (Diarize the progress of identified KPIs with actions plans for improvement after meetings)
Potential Employers (SG 2-6)	Not developing talents with appropriate knowledge, skills, attitude, values for potential employers	5	3	5 x 3 =15	Market Sustainability Goal Society Sustainability Goal (GRI 4 – Product responsibility) ISO 26000 CSR – fair operations /community involvement / consumer issues

	leading low employability and ruined reputation				KPI- e.g. On-going communication with a fixed number of announcements / year to staff and students for expected outcomes / actions and achievements of the College) with identified potential employers in targeted industries e.g. Inviting existing (from internship and job fairs) and potential employers to discuss the change of labor market, job structure and skills required to review the programmes (Diarize the progress of identified KPIs with actions plans for improvement after meetings)
Secondary Parents Related Government Dept. e.g. Labor Dept. Professional bodies for module	Dissatisfaction about study environment and treatment to students Minimal recognition from professional	3	3	3 x 3 = 9	Marketplace Sustainability Goal Society Sustainability Goal Environmental Sustainability Goal Workplace Sustainability Goal ISO 26000 CSR – involvement of community / environmental issues

exemption and programme recognition Suppliers of e-journals and research materials Strategic partners on programme matters, e.g.Exchange Partners/ Funding or Sponsorship Parties/ Employers	body for articulation and employability Irrelevancy and obsolete journals (mismatched with programmes and teachers' research interest) Lack of communication				KPI- e.g. On-going communication with a fixed number of announcements / year to internal and external stakeholders on all mutual concerned areas with communication of environmental issues to neighboring community, e.g. secondary schools) e.g. Organizing different kinds of activities with external secondary stakeholders for analyze potential risks and impacts of mutual concerned matters to maintain or enhance brand name (GRI 4 – Product responsibility/ Market presence/ Economic Performance / Supplier assessment on impacts on society/ Local communities/ Environmental compliance) (Diarise the progress of identified KPIs with actions plans for improvement after meetings)

8. Conclusion and Discussion

Based on the GRI social reporting principles and ISO 26000 CSR guidelines, environmental, social and economic impacts and the encouragement of good governance practices throughout the lifecycles of goods and services produced by the case institution have been integrated for sustainable development. The case organization has achieved the objective of SC sustainability to create new and relevant programmes to meet the needs of the market, protect the rights of students and staff, and grow with long-term environmental, social and economic value for all stakeholders involved in bringing a diversity of business and management programmes and services to the community of Hong Kong.

The case institution measures its performance, identifies its risks with priority and reports under three main headings – Responsible Business Management, Responsible Curriculum Design, and Responsible Partnership through stakeholder mapping with action plans for measurement (2015 –2017), the risk level with KPIs of activities with Social Return of Investment (SROI), and benchmarking with self-financed institutions offering business and management related degree programmes and CSR-related activities with impacts created from media reporting.

Examples on Responsible Business Management for Economic and Environmental Impacts are:

- Harmonised employment with stable teaching staff
- Green building assessment of the campus

Example on Responsible Curriculum Design for Economic and Social Impacts is:

- New undergraduate degree programmes will be offered in coming years

Example on Responsible Partnership for Economic and Social impacts is:

- Building strong relationships with stakeholders, e.g. ministry of education in different countries and overseas universities for achieving the strategic goals and sustainability (CSR) vision and the vision of the College

Based on the steps 1 – 6 and Table 3 of stakeholder mapping and future sustainability goals, the learning processes of applying 4Cs in sustainability - critical thinking skill, communication skill, collaboration skill and creative skill of Kivunja (2015) and the design thinking concept of Moore (2013) with ecosystem and multi-disciplinary interaction for problem-solving can be shown with the case institution. It is found that “Critical Thinking” process requires a full understanding of SD in higher education and the organizational culture of the institution in implementing SD related strategic goals. For “Communication and Collaboration”, stakeholders in academics and industries need to be engaged with actionable items for creating new and diversified learning experiences to learners and the institution itself for economic, social and environmental impacts. For “Creative Thinking”, educators need to attempt the use of design thinking when defining sustainability related goals for the benefit of the learners, the staff, the management and the community.

Though the methodology of this study is action research approach, quantitative data on implementing SD actions is recommended to be collected in the future for a better understanding of how to implement SD into different perspectives for enhancing multidisciplinary knowledge and for collaborating academic partners and industry practitioners to realize the definition of Brundtland Commission (1992) of the United Nations, “sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs.”

This paper analyzes the informational role of institutional investors' trading using the dynamic intraday measure of the probability of informed trading (hereafter DPIN). Using a unique account-level dataset of institutional investors from the Taiwan index futures market, we show that the DPINs of foreign institutional buy trades are significantly positively related to future market returns. Moreover, compared to using trading imbalance as the informed trading measure, we find that the DPIN provides consistent predictive power for the market volatility, particularly during intense trading periods. Overall, our results also provide support for the notion that foreign intuitional traders are better informed than domestic institutional traders in the emerging markets.

Keywords: Institutional investors; Probability of informed trading; Emerging markets.

1. Introduction

The informed trading of institutional investors has been studied for more than 40 years in the literature (e.g., Kraus and Stoll, 1972; Chakravarty, 2001; Saar, 2001; Chiyachantana et al., 2004; Yan and Zhang, 2009; Dasgupta, Prat and Verardo, 2011; Puckett and Yan, 2011).[1] If institutional investors are informed with regard to undervalued or overvalued stocks, their trading will speed up the adjustment of fundamental values for stock prices. As such, institutional investors' trading behavior would be likely to stabilize the stock market and improve market efficiency. On the other hand, institutions may not fully take advantage of their information in investments and thus provide only little evidence of stock-picking skill because of the limits of arbitrage (Cohen, Gompers and Vuolteenaho, 2002; Lewellen, 2011).

The study of how institutional investors employ their information is of continual interest to both practitioners and academics; however, measuring the information of transactions for institutional investors is not an easy task. One of the most common and widely accepted methods is the probability of informed trading (PIN), successively developed by Easley, Kiefer, O'Hara and Paperman (1996), Easley, Kiefer and O'Hara (1997a, b) and Easley, Hvidkjaer and O'Hara (2002).[2] Although the PIN has been widely accepted in previous studies, it is also well-known for its difficulty in capturing short-lived information.[3] Recently, Chang, Chang and Wang (2014) have extended the ACG (Avramov, Chordia and Goyal, 2006) model to construct a dynamic intraday version of the PIN (hereafter DPIN) and allow researchers to estimate the probability of informed trading at much finer frequencies.[4] Chang et al.'s (2014) DPIN is a newly developed measure that provides intuitive explanation and friendly application. These advantages make the DPIN an attractive alternative for directly determining the information content of all kinds of transactions in the market. To date, the DPIN has received little examination in the literature, and thus this paper seeks to examine different types of institutional trading using the DPIN and provide further evidence for its application.

We select an emerging market, the Taiwan futures exchange (TAIFEX), as our target to conduct the examination. Using a unique dataset from the TAIFEX, we can precisely classify domestic institutional transactions and foreign institutional transactions. Given the

---

[1] Kraus and Stoll (1972) find that block trades can affect market efficiency. Chakravarty (2001) confirms the influenced of informed trading on medium-size trades in favor of the stealth-trading hypothesis. Saar (2001) and Chiyachantana et al. (2004) both investigate the information content of institutional trades. Dasgupta, Prat and Verardo (2011) provide a theoretical equilibrium model to confirm the association between institutional herd behavior and both short- and long-term returns.

[2] The PIN measure is generally used in many fields of corporate finance, investment, and market microstructure, for example, in the studies of Easley et al. (1996), Brown et al. (2004), Vega (2006), Zhao and Chung (2006), Chan et al. (2008), Duarte and Young (2008), and Brockman and Yan (2009).

[3] In order to estimate the PIN measure, one must aggregate very fine intraday data, which occur at approximately five-minute intervals within the trading day across multiple days (Easley et al., 1997a, b). The resulting estimate measures informed trading over a very long horizon from one month to one quarter. In addition, over such long horizons it is likely that the actual impact of short-lived private information may become diluted or masked by other factors.

[4] Specifically, at 15-minute intervals throughout the trading day, such frequencies being more in line with the speed at which traders react to and digest information in modern financial markets. Our dynamic DPIN measure may be better suited to capturing information based on trading activity at higher frequencies, even within the trading day.

general viewpoint that foreign institutional traders may enjoy an information advantage over domestic institutional traders in a local market such as the TAIFEX,[5] the advantage of our dataset is relevant for our analyses. Comparing different types of institutional trading using the DPIN, we can test whether it captures informed trading well, and also investigate the information content of foreign and domestic institutional trades.

As a comparison to the DPIN, we also use the trade imbalance (TIB) to examine the information content of different institutional trading.[6] Some previous studies have examined the information content of trading by testing the price impact of trading activities. Of these, many use TIB to measure trading activity as this measure can proxy for both of the direction and magnitude of price changes (see, e.g., Chordia, Roll and Subrahmanyam, 2008; Easley, Engle, O'Hara and Wu, 2008; Subrahmanyam, 2008; Barber, Odean and Zhu, 2009; O'Hara, Yao and Ye, 2011).[7] Therefore, in addition to providing further empirical evidence on the application of the DPIN, this study also compares the difference (if any) between the newly developed measure (DPIN) and the conventional measure (TIB). By doing so, we believe we can enhance our understanding of the proxy of informed trading.

To study the validity of the DPIN and the TIB for both domestic and foreign institutional investors, we test return impact and volatility impact for each measure. Chang, Hsieh and Wang (2009) show that foreign institutional traders are better informed concerning price movements and variations than domestic traders in the local market; in the same vein, we consider both return and volatility in our analyses.

Our empirical findings are summarized as follows. First, we show that the DPIN of foreign institutional buying trades is significantly positively related to the market return. This finding suggests that the DPIN is able to capture informed trading on the buying side of foreign institutional traders. Second, we show that the DPIN as the informed measure provides more stable performance than the TIB for volatility predictability, particularly during an intense trading interval within a day. The overall results indicate that the DPIN is more suitable for measuring the informed trading of foreign institution investors than the TIB.

For domestic institutional traders, we find weak prediction of returns, revealing that the DPIN does not fully measure the informed trading of domestic institutional traders. Return predictability for the domestic institutional DPIN can be found only during intense trading

[5] For example, several prior studies (Grinblatt and Keloharju, 2000; Huang and Shiu, 2009) show that foreign institutional investors are more likely to select winners in the markets than domestic investors, implying that foreign institutional traders are better informed than their local competitors.

[6] Kyle (1985) and Admati and Pfleiderer (1988) focus on order imbalance as a signal of informed trades. It is assumed in these models that market makers will adjust prices upwards (downwards) when there are excess buy (sell) orders.

[7] Chordia, Roll and Subrahmanyam (2002, p.112) describe a simple and clear case: "Consider, for example, a reported volume of one million shares. At one extreme, this might be a million shares sold to the market maker while at the other extreme it could be a million shares purchased. Perhaps more typically, it would be roughly split, about 500,000 shares sold to and 500,000 shares bought from the market maker. Each scenario has its own specific implications for price movement or liquidity changes."

intervals, when the same cannot be seen using the TIB. On the other hand, the TIB and the DPIN of domestic institutional traders perform indifferently in relation to volatility impact. To sum up the findings regarding domestic institutional trading, the DPIN appears to have slightly better ability in measuring the informed trading of domestic institutional traders than the TIB.

Our investigation provides support not only for the information role of foreign institutional traders in the emerging market, but also contributes to the discussion regarding the validity of the DPIN in capturing short-lived information. Earlier studies usually report that foreign institution investors are better informed than other types of investors based on analysis using the PIN or the TIB. Our paper shows that the DPIN may be able to capture the information content of foreign institutional trading more accurately at higher frequencies. In the spirit of the definition of the DPIN given by Chang et al. (2014), the results also imply that foreign institutions are more likely to be contrarian traders, which is consistent with the argument of Barber and Odean (2011).

The remainder of this paper is organized as follows. Section 2 describes the data and methodology. Section 3 presents the empirical results for foreign institutional investors and domestic institutional investors. Section 4 concludes.

2. Data and methedology

2.1. *Data and variable definition*

We obtain the transaction data for TXF contracts from the Taiwan Futures Exchange (TAIFEX).[8] TXF is the major and most actively traded index futures product on the TAIFEX. Our dataset covers the period from January 1, 2003 to December 31, 2007. The dataset contains the date and time of the transactions, the indicator of opening or closing position, the indicator of trading direction (buy or sell),[9] and the quantity demanded or offered. Most importantly, it provides the identification of traders, which enables us to categorize the type of trader as foreign institutions or domestic institutions. As our analysis focuses on intraday horizons, we divide a single trading day into twenty 15-minute trading intervals, with each buy or sell trade being assigned to one of these intervals, depending on when the trade occurred during the day.

As mentioned, we use two measures of institutional informed trading, the DPIN and the TIB, to investigate the trading behavior of foreign institutional investors. The DPIN is defined according to the model of Chang et al. (2014), whereas the TIB follows the general definition in the literature. All measures are calculated on the basis of 15-minute intervals. The return of index futures is computed by the first difference of the natural log of the mid-

---

[8] At the end of 2007, TAIFEX was ranked 21 among 54 derivatives exchanges reported to the Futures Industries Association. The TAIFEX is ranked eighth among emerging markets. Trading on the TAIFEX is conducted from 8:45 AM to 1:45 PM Monday to Friday (excluding public holidays).

[9] Compared to Lee and Ready (1991), determining the method of trade direction allows us to measure the trading activities of the investors more accurately, eliminating the measurement errors of trading volume

price of the bid–ask spread at the end of each intraday interval.[10] Our estimation for the volatility of index futures is consistent with the method of Kuo, Chung and Chang (2014).[11]

2.1.1. *DPIN measure*

Following Chang et al. (2014), the DPIN is constructed by extending the ACG model. The buy (sell) trades in the presence of negative (positive) unexpected returns are classified as informed trades, whereas buy (sell) trades in the presence of positive (negative) unexpected returns are classified as uninformed trades. To calculate the unexpected component of returns, we extract the residuals from the following regression:

$$R_t = \delta_0 + \sum_{k=1}^{4} \delta_{1,k} D_{kt}^{day} + \sum_{k=1}^{20} \delta_{2,k} D_{kt}^{Interval} + \sum_{k=1}^{6} \delta_{3,k} R_{t-k} + \varepsilon_t \,, \tag{1}$$

Where R_t is the index futures returns at intraday interval t, D_{kt}^{day} represents day-of-week dummy variables for Tuesday through Friday, and $D^{interval}$ represents dummy variables corresponding to the particular 15-minute interval at which returns are measured. Thus, the residual ε_t captures the variation in returns left over after day-of-week effects, intraday time effects, and the effect of past returns have been accounted for, and therefore serves as a proxy for unexpected returns.

Let NB_t, NS_t, and NT_t represent the number of buy, sell, and total trades, respectively, for index futures returns at interval t. Then, the DPIN is constructed as follows:

$$DPIN_{base_t} = \frac{NB_t}{NT_t}(\varepsilon_t < 0) + \frac{NS_t}{NT_t}(\varepsilon_t > 0) \,, \tag{2}$$

As can be seen, the DPIN represents the proportion of contrarian trades taking place during the 15-minute interval, which is based on the interpretation of Chang et al. (2014) regarding the trading behavior of informed investors.

2.1.2. *TIB measure*

---

[10] The return of index futures is defined as the first difference of the natural log of the TAIFEX (S_t) in each trading interval: $R_t = 100*(\ln S_t - \ln S_{t-1})$, the annualized rate of return multiplied by (20 × 252).

[11] We refer to Kuo et al. (2014) to construct the measure of volatility. We estimate a GARCH(1, 1) model to obtain the volatility of futures:

$$R_t = \alpha_0 + \varepsilon_t \quad \varepsilon_t \mid \Omega_{t-1} \sim N(0, h_t)$$

$$h_t = \eta_0 + \eta_1 \varepsilon_{t-1}^2 + \eta_2 h_{t-1} + \theta_3 TA_t$$

where R_t is the return of index futures at intraday interval t; TA_t is futures trading activity by total volume at interval t; Ω_{t-1} denotes the information set available up to time t; h_t is the conditional futures variance term at interval t; ε_{t-1}^2 are the lagged squared residuals from the return equation.

Based on the general definition in the literature, e.g., Chordia and Subrahmanyan (2004), the trading imbalance (TIB) is defined as:

$$TIB_t = \frac{B_t - S_t}{B_t + S_t}, \tag{3}$$

where B_t and S_t are the buying volume and selling volume of foreign institutional traders at interval t, respectively.

2.2. *Regression specifications*

2.2.1. *The relation between returns and trading activities*

First, we use the DPIN and the TIB as proxies of trading activities and examine their association with market returns. However, we would like to note that the DPIN measures the likelihood of informed trading and presents no signs, whereas the index future returns are signed in the positive (buy) or negative (sell) direction. Therefore, when we examine the relation between index future returns and DPINs, we separate the DPIN into $DPIN_{buy}$ and the $DPIN_{sell}$ accordingly. We perform the following time series regressions with Newey–West robust standard errors for institutional trading activities:

$$R_t = \alpha_0 + \sum_{k=1}^{4} \delta_k DPIN^i_{buy_{t-k}} + \sum_{k=1}^{4} \eta_k DPIN^i_{sell_{t-k}} + \sum_{k=1}^{4} \beta_k R_{t,k} + \varepsilon_t \tag{4}$$

$$R_t = \alpha_0 + \sum_{k=1}^{4} \gamma_k TIB^i_{t-k} + \sum_{k=1}^{4} \beta_k R_{t-k} + \varepsilon_t , \tag{5}$$

where R_t denotes the index futures return for the t interval. $DPIN^i_{buy_t}$ is the buying component, defined as the number of buy transactions divided by the total number of trades for group i in interval t, written as $DPIN^i_{buy_t} = \left[NB^i_t / NT^i_t \right](\varepsilon_t < 0)$, and $DPIN^i_{sell_t}$ is the selling component, defined as the number of sell transactions divided by the total number of trades of trades for group i in interval t, written as $DPIN^i_{sell_t} = \left[NS^i_t / NT^i_t \right](\varepsilon_t > 0)$. The TIB measure is computed using buy and sell trades for group i in interval t, written as $TIB^i = (B^i - S^i)/(B^i + S^i)$.

2.2.2. *The relation between volatility and trading activity*

Next, our paper examines the association between volatility and trading activity. A natural question is whether volatility is significantly affected by the DPIN or the TIB. We regress the volatility on the DPIN and absolute of the TIB, and see whether the trading activities of foreign institutional investors and domestic institutional investors have an impact on market volatility. The regression models are shown as follows.

$$Vol_t = \alpha_0 + \sum_{k=1}^{4} \theta_k DPIN_{t-k}^{i} + \sum_{k=1}^{4} \lambda_k Vol_{t-k} + \varepsilon_t \,, \tag{6}$$

$$Vol_t = \alpha_0 + \sum_{k=1}^{4} \rho_k \left| TIB_{t-k}^{i} \right| + \sum_{k=1}^{4} \lambda_k Vol_{t-k} + \varepsilon_t \,, \tag{7}$$

where Vol_t denotes the volatility of index futures for the t interval. The $DPIN_t^i$ and the TIB_t^i are defined as in Equation (2) and Equation (3), respectively.

2.3. *DPIN and TIB statistics*

Table 1 reports the intraday DPIN and TIB of foreign institutional investors and domestic institutional investors from 2003 to 2007 in Panel A and Panel B, respectively. The DPIN is also displayed as the buy side DPIN ($DPIN_{buy}$) and the sell side DPIN ($DPIN_{sell}$). Statistics for all the measures are calculated as the daily average of all 15-minute intervals. As reported in Panel A, the means of DPIN, $DPIN_{buy}$, $DPIN_{sell}$, and TIB for foreign institutional investors are 0.4979, 0.2432, 0.2547, and -0.0085, respectively, while the statistics for domestic institutional investors in Panel B are 0.4993, 0.2435, 0.2557, and -0.0119, respectively. The results present no significant differences between the two types of institutional investors.

We further report the correlation coefficients among variables for foreign institutional investors and domestic institutional investors in Panel C and Panel D, respectively. For foreign institutional investors, $DPIN_{buy}$ is significantly negatively correlated with returns (-0.68%), whereas $DPIN_{sell}$ is significantly positively correlated with returns (0.65%). For domestic institutional investors, $DPIN_{buy}$ is significantly negatively correlated with returns (-0.78%), whereas $DPIN_{sell}$ is significantly positively correlated with returns (0.78%). Overall, the correlation among variables is consistent with the theoretical presumption that DPIN captures buy (sell) trades in the presence of negative (positive) unexpected returns. In addition, the TIB is negatively correlated with returns for foreign institutions and positively correlated with returns for domestic institutions; the TIB is also negatively correlated with volatility for foreign institutions and positively correlated with volatility for domestic institutions. However, none of the coefficients are significant (weak to minimal). In sum, the DPIN rather than the TIB presents a much stronger association with market prices, which may imply that the DPIN is a superior proxy for price information.

[Insert Table 1 about here]

3. Empirical results

3.1. *Trading activity of foreign institutional investors*

Further to earlier findings, we examine the trading activity of foreign institutional investors using the DPIN and the TIB in this section. First, we study the return predictability of foreign institutional trades. The results are presented in Table 2. As reported, the coefficient of $DPIN_{buy_{t-1}}$ is significantly positive in Model (1), and remains significantly positive when controlling for other lagged DPINs. In contrast, although TIB_{t-1} is significantly positively related to market returns, it loses its significance when other lagged TIBs are included in the regression. In sum, the results indicate that the DPIN seems to be a better measure of the trading activity of foreign institutional investors than the TIB in terms of capturing their price information. This finding is consistent with Barber and Odean’s (2011) argument that informed institutional investors tend to be contrarians.

[Insert Table 2 about here]

Similar to Table 2, Table 3 studies the volatility information of foreign institutional trades. We find that both $DPIN_{t-1}$ and $|TIB_{t-1}|$ are significantly related to current market volatility regardless of whether or not the other lagged DPINs and TIBs are included. In addition, all model specifications present very similar regression power, which suggests that the DPIN of foreign institutions provide information content no different to that obtained from the TIB in predicting market volatility. Interestingly, as the coefficient of $DPIN_{t-1}$ is negative, the result is consistent with Brennan and Cao (1996), which suggests that investors who adopt contrarian strategies are likely to be informed. Similarly, Avramov et al. (2006) show that informed traders generally reduce volatility by contrarian trading.

[Insert Table 3 about here]

3.2. *Trading activity of foreign institutional investors during intense trading intervals*

A central prediction of traditional microstructure theory is that trading takes place because investors have different beliefs or because of differences in information. The role of the number of trades in price formation is also highlighted by Easley and O’Hara (1992), who show that the presence or absence of trades may provide information to market participants. Specifically, the larger the number of trades, the higher the probability that new information has been obtained. Therefore, we also test whether the foreign institutional trades provide different information on returns during intense trading intervals. We impose additional dummies on Equations (4) and (5) to account for intense trading intervals within a day. The regression model is as follows:

$$R_t = \alpha_0 + \sum_{k=1}^{4} \delta_k DPIN^i_{buy_{t-k}}(LT_t^{i,buy}) + \sum_{k=1}^{4} \eta_k DPIN^i_{sell_{t-k}}(LT_t^{i,sell}) + \sum_{k=1}^{4} \beta_k R_{t,k} + \varepsilon_t\,, \tag{8}$$

$$R_t = \alpha_0 + \sum_{k=1}^{4} \gamma_k TIB^i_{t-k}(LT_t^i) + \sum_{k=1}^{4} \beta_k R_{t-k} + \varepsilon_t\,, \tag{9}$$

where $LT_t^{i,buy}(LT_t^{i,sell})$ is the "intense trading" indicator, equal to 1 if the value of $DPIN_{buy_t}^{i}(DPIN_{sell_t}^{i})$ and TIB_t^i are ranked as the top 10% on that day, and zero otherwise. Table 4 reports the regression results for Equations (8) and (9). Again, we find that the coefficient of $DPIN_{buy_{t-1}}$ is significantly positive for Models (1) and (2), which is consistent with the findings reported in Table 2. However, for two models we find no evidence that *TIBs* during intense intervals are able to predict current returns. In sum, regarding the prediction of returns, the results in Table 4 show that DPINs rather than TIBs are more likely to be superior as measurements in capturing information advantageous to foreign institutional investors when trades are clustered.

[Insert Table 4 about here]

Similarly, we further estimate the following modified regression models for market volatility based on Equations (6) and (7):

$$Vol_t = \alpha_0 + \sum_{k=1}^{4} \theta_k DPIN_{t-k}^{i}(LT_t^i) + \sum_{k=1}^{4} \lambda_k Vol_{t-k} + \varepsilon_t , \tag{10}$$

$$Vol_t = \alpha_0 + \sum_{k=1}^{4} \rho_k \left| TIB_{t-k}^{i} \right| (LT_t^i) + \sum_{k=1}^{4} \lambda_k Vol_{t-k} + \varepsilon_t , \tag{11}$$

where all variables are defined as in previous equations. Table 5 presents the results.

Consistent with the results reported in Table 3, both $DPIN_{t-1}$ and $|TIB_{t-1}|$ significantly related to current market volatility during intense trading sessions regardless of whether or not the other lagged DPINs and TIBs are included. In addition, $DPIN_{t-2}$ also has a significant impact on volatilities, whereas $|TIB_{t-2}|$ presents insignificant impact. However, comparing the explanatory power, there is little difference between DPINs and TIBs. Interestingly, while the results in Table 3 show that both DPIN and TIB have a negative impact on market volatility, the results of Table 5 are the opposite. Both $DPIN_{t-1}$ and $|TIB_{t-1}|$ have a positive impact on volatility.

Extensive evidence indicates that trading volume and return volatility are positively correlated (Karpoff, 1987; Gallant, Rossi and Tauchen, 1992).[12] Jones, Kaul and Lipson (1994) find that only trade frequency affects price volatility. On the other hand, the larger the number of trades, the higher the probability that new information has been acquired (Kyle 1985). French and Roll's (1986) price formation theory also points out that price variation is caused by the provision of information. Therefore, the positive association between

[12] Gallant et al. (1992) find a positive correlation between conditional volatility and volume, wherein large price movements are followed by high volumes.

volatility and the DPIN or the TIB during intense trading intervals shown in Table 5 might be evidence that informed trading causes price volatility. As our earlier findings have shown, informed trading can also reduce volatility, and thus it is likely that the informed trading of foreign institutional investors has a twofold impact on volatility, and appears as an asymmetric influence for normal trading intervals and intense trading intervals.

[Insert Table 5 about here]

Overall, the examination of intense trading intervals using the DPIN and the TIB provides support for our earlier findings. Measuring the trading activity of foreign institutional investors through the DPIN offers a better ability to capture their information advantage regarding market returns.

3.3. *Trading activity of domestic institutional investors*

So far, our analyses have focused on the trading activity of foreign institutional investors, and the findings show that the DPIN performs better than the TIB in representing informed trading. For comparison, we extend the tests to domestic institutional investors. We examine their trading activity using the DPIN and the TIB as in the analyses completed in Sections 3.1 and 3.2.

Table 6 presents the relation between returns and trading activity for domestic institutional investors. Unlike the results reported in Table 2, we find that the DPIN for domestic institutional investors does not have a significant impact on market returns, whereas the TIB has a significant impact on returns in each model specification. The findings in Table 6 are not consistent with those in Table 2, indicating that the TIB is more suited to measuring return information for domestic institutional trades than the DPIN. The finding also implies that domestic institutional investors are less likely to behave as contrarian traders compared to foreign institutional traders.

[Insert Table 6 about here]

Table 7 presents the relation between volatility and trading activity for domestic institutional investors. Consistent with the findings for foreign institutional investors in Table 3, the result shows that both the DPIN and the TIB have a significant negative impact on volatility in each model specification. Again, the results confirm that the DPIN and the TIB are no different in measuring the volatility information of institutional investors.

[Insert Table 7 about here]

3.4. *Trading activity of domestic institutional investors during intense trading intervals*

The analyses using trades during intense trading intervals are also applied for domestic institutional investors. We rerun the regression models (Equations (8) to (11)) for the DPIN and the TIB of domestic institutional investors. First, Table 8 reports the results of the impact on returns. Interestingly, in contrast to the finding in Table 6 showing that the DPIN of domestic institutional investors has inferior ability in showing the impact on returns, the coefficient of $DPIN_{buy_{t-1}}$ for domestic institutional investors in Table 8 is significant, whereas that of TIBt-1 is insignificant. Therefore, Table 8 shows that the DPIN is still a more suitable measure for capturing the trading activity of domestic institutional investors during intense trading intervals, as shown also for foreign institutional investors.

[Insert Table 8 about here]

Finally, Table 9 reports the results of regressing volatility with the trading activity of domestic institutional investors during intense trading intervals. It is no surprise that the findings show that both the DPIN and the TIB have significant impacts on market volatility. However, in contrast to what we have shown for the DPIN and the TIB in relation to foreign institutional investors, the DPIN and the TIB for domestic institutional investors have the opposite effects. The DPIN has a positive impact on volatility, whereas the TIB has a negative impact on volatility. The results are not altered by including other lagged DPINs or TIBs.

[Insert Table 9 about here]

3.5. *Discussion*

Although there is slight divergence in our findings regarding the validity of the DPIN for foreign institutional investors and domestic institutional investors, it still appears that the DPIN performs considerably better in capturing informed trades in a range of situations than the TIB. The DPINs of foreign institutional investors have more significant impact on returns than TIBs in all trading sessions and intense trading intervals, and the DPINs of domestic institutional investors also have more significant impact on returns than TIBs in intense trading sessions. For volatility information, it seems that the DPIN and the TIB present no distinct difference in terms of the volatility effect. However, it is still apparent that the DPIN has more consistent impact on market volatility than the TIB. Overall, the findings indicate the suitability of the DPIN as a measure to proxy for informed trading, especially when we are interested in foreign institutional traders. In addition, the results imply that informed foreign institutional traders generally behave as contrarians, as in the setting of Chang et al. (2014) and as argued by Barber and Odean (2011).

4. Conclusions

This study examines the validity of the DPIN developed by Chang et al. (2014). Using the trades of foreign institutional investors and domestic institutional investors on the TAIFEX, we study the impact of the DPIN on market returns and volatilities and compare its effect to that of the TIB. We show that the DPIN carries more return information than the TIB, especially for foreign institutional investors. This finding suggests that the DPIN is able to capture the informed trading of foreign institutional traders. Furthermore, the DPIN as the informed trading measure provides stable performance throughout different trading intervals within a day. Compared to the traditional informed trading measure, i.e., the PIN, Chang et al.'s (2014) DPIN is a newly developed measure that provides intuitive explanation and friendly application without complex estimation. Our findings confirm its feasibility. We also believe that it is a suitable alternative approach to discern directly the intraday information content of transactions.

In addition, according to the assumption underpinning the construction of the DPIN, informed traders are more likely to behave as contrarians; thus, our results also suggest that informed foreign institutional investors generally behave as contrarians. A similar argument can be seen in Barber and Odean (2011), who claim that the informed trader has more incentives to act against price moves.

Table 1 Characteristics of intraday trade volume measure

Panel A and Panel B of Table 1 report interval means and medians for the DPIN and TIB of institutional investors. Panel C and Panel D show correlations among all regression variables. Samples Panel A reports foreign institutional investor values and Panel B the domestic institutional investor values. *Return* denotes the index return, computed from the difference of the natural log of the mid-point of the bid–ask spread at the end of an intraday interval. *Volatility* is the GARCH(1,1) model developed by Bollerslev (1986), incorporating commonly used volatility measures. The DPIN measure is computed as $DPIN^{i}_{buy_t} = \left[NB_t / NT_t\right](\varepsilon_t < 0)$, and $DPIN^{i}_{sell_t} = \left[NS_t / NT_t\right](\varepsilon_t > 0)$. The TIB measure is computed as $TIB^{i}_{t} = (B^{i}_{t} - S^{i}_{t}) / (B^{i}_{t} + S^{i}_{t})$ for interval t. The data are from January 1, 2003 to December 31, 2007, covering 1,238 trading days.

Table 2 Intraday trade volume measure for the influence of foreign institutional investors on returns

This table presents the results with Newey–West corrected *t*-statistics for time-series regressions from January 1, 2003 to December 31, 2007 with index future returns as the dependent variable. R_t denotes the index futures return for the *t* interval $DPIN^i_t$ is the number of buy transactions divided by the total number of trades for group *i* institutional investors in interval *t*. DPIN measure is computed as $DPIN^i_{buy_t} = \left[NB^i_t / NT^i_t \right](\varepsilon_t < 0)$. $DPIN^i_{sell_t}$ is the number of sell transactions divided by the total number of trades for group *i* institutional investors in interval *t*, computed as $DPIN_{sell_t} = \left[NS^i_t / NT^i_t \right](\varepsilon_t > 0)$. The TIB measure is computed as $TIB^i_t = (B^i_t - S^i_t)/(B^i_t + S^i_t)$ for interval *t*. The regression model is as follows:

$$R_t = \alpha_0 + \sum_{k=1}^{4} \delta_k DPIN^i_{buy_{t-k}} + \sum_{k=1}^{4} \eta_k DPIN^i_{sell_{t-k}} + \sum_{k=1}^{4} \beta_k R_{t,k} + \varepsilon_t , \tag{4}$$

$$R_t = \alpha_0 + \sum_{k=1}^{4} \gamma_k TIB^i_{t-k} + \sum_{k=1}^{4} \beta_k R_{t-k} + \varepsilon_t , \tag{5}$$

***indicates significance at the 1% level; **indicates significance at the 5% level; *indicates significance at the 10% level.

Table 3 Intraday trade volume measure for the influence of foreign institutional investors on volatility

This table presents the results of the Newey–West corrected t-statistics for time-series regressions from January 1, 2003 to December 31, 2007 with the volatility of index futures as the dependent variable. Vol_t is the GARCH(1,1) model developed by Bollerslev (1986), incorporating commonly used volatility measures. The DPIN measure is computed as $DPIN^i_{buy_t} = \left[NB^i_t / NT^i_t \right](\varepsilon_t < 0)$, and $DPIN^i_{sell_t} = \left[NS^i_t / NT^i_t \right](\varepsilon_t > 0)$. The TIB measure is computed as $TIB^i_t = (B^i_t - S^i_t)/(B^i_t + S^i_t)$ for interval t. The regression model is as follows:

$$Vol_t = \alpha_0 + \sum_{k=1}^{4} \theta_k DPIN^i_{t-k} + \sum_{k=1}^{4} \lambda_k Vol_{t-k} + \varepsilon_t , \tag{6}$$

$$Vol_t = \alpha_0 + \sum_{k=1}^{4} \rho_k \left| TIB^i_{t-k} \right| + \sum_{k=1}^{4} \lambda_k Vol_{t-k} + \varepsilon_t , \tag{7}$$

Table 4 Intraday trade volume measure for the influence of foreign institutional investors on returns, conditioned on the intense trading interval

This table presents the results of the Newey–West corrected t-statistics for time-series regressions from January 1, 2003 to December 31, 2007 with the returns of index futures as the dependent variable. R_t denotes the index futures return in the t interval. $DPIN_t^i$ is number of buy transactions divided by the total number of trades for group i institutional investors in interval t. The DPIN measure is computed as $DPIN_{buy_t}^i = \left[NB_t^i / NT_t^i\right](\varepsilon_t < 0)$. $DPIN_{sell_t}^i$ is the number of sell transactions divided by the total number of trades for group i institutional investors in interval t, as $DPIN_{sell_t} = \left[NS_t^i / NT_t^i\right](\varepsilon_t > 0)$. The TIB measure is computed as $TIB_t^i = (B_t^i - S_t^i)/(B_t^i + S_t^i)$ for interval t. $LT_t^{i,buy}(LT_t^{i,sell})$ is a "large trades" indicator variable that equals 1 if $DPIN_{buy_t}^i$ ($DPIN_{sell_t}^i$) and TIB_t^i were located in the top 10% of the current day, and zero otherwise. The regression model is as follows:

$$R_t = \alpha_0 + \sum_{k=1}^{4} \delta_k DPIN_{buy_{t-k}}^i (LT_t^{i,buy}) + \sum_{k=1}^{4} \eta_k DPIN_{sell_{t-k}}^i (LT_t^{i,sell}) + \sum_{k=1}^{4} \beta_k R_{t,k} + \varepsilon_t , \tag{8}$$

$$R_t = \alpha_0 + \sum_{k=1}^{4} \gamma_k TIB_{t-k}^i (LT_t^i) + \sum_{k=1}^{4} \beta_k R_{t-k} + \varepsilon_t , \tag{9}$$

Do Foreign Institutional Investors Have Private Information for Market Index Futures? The Natural Experiment on the TAIFEX

When traders trade for the market index futures, usually they act on the same public information set regarding the state of the economy. It is, therefore, less straightforward to claim that specific trader group has inside information on “the whole market”. However, working with six-year market index futures transaction data from the Taiwan Futures Exchange (TAIFEX), this paper shows that foreign institutional investors still have private information for the market. By French and Roll’s (1986) decomposition for price formation, we find that no change occurs for the public information flow during our sample period but that price volatility changes significantly between periods. Excluding the cause of mispricing, we find that the price variation is more likely to be caused by the private information of foreign institutional trading. In addition, information-related intraday patterns of volatility and bid-ask spread react to the changes in order submission behaviors of foreign institutional traders, suggesting that the private information of the index futures market and foreign institutional trading are closely-related. We provide evidence that private information is not irrelevant in the index futures market and that foreign institutional traders in fact carry private information and cause price variation in such a market.

Keywords: Foreign Institutional Investors; Market Index Futures; Private Information; Bid-Ask Spread; Volatility U-shape.

1. Introduction

Foreign institutional investors, particularly in those emerging markets, own private information that has not been revealed to the public, and thus foreign institutional investors are usually viewed as better informed and more sophisticated traders than individual investors (Seasholes (2000); Grinblatt and Keloharju (2000); Froot and Ramadorai (2001); Albuquerque, Bauer, and Schneider (2009); Barber, Lee, Liu, and Odean (2009);). However, the corollary of the information role of foreign institutional investors in the equity market, particularly for individual stocks, may face a challenge in the index futures market. Private information is not necessarily relevant for market index futures trading, for example, if all participants in the market are projecting on the same public information set regarding the state of the market.[1] This study, therefore, provides evidence on price formation to determine the information source using a comprehensive data set of market index futures from the Taiwan Futures Exchange (TAIFEX). Over our sample period from 2003 to 2008, the participation proportion of foreign institutional investors on the TAIFEX increases from 4% to 24%.[2] Different levels of foreign institutional trading across different periods allow us to investigate the influence of foreign institutional investors on the market variation on the TAIFEX. More important, we can directly answer the question of whether foreign institutional investors have private information on such a market.

The notion that trading increases volatility is central to the theory of price formation (French and Roll (1986)). Previous researchers conclude that three dimensions can explain this phenomenon: (i) Public information arrives primarily during trading hours; (ii) private information induces trades that affect price during trading hours; and (iii) errors in pricing are more likely to occur during trading hours. To discriminate among these explanations, French and Roll (1986) show that return volatility continues to decrease during stock market closures even though concurrent public information flow does not change. Given that public information does not appear to be the cause, they further examine the other two alternatives. They find that pricing errors play only a small role and thus conclude that private information is the main source of high trading-time volatility on the NYSE.

French and Roll's (1986) conclusion is widely proposed in the empirical literature regarding price formation in the stock market. We fill a gap in the literature by implementing their argument with regards to the index futures market, which remains unclear. In particular, given the argument that foreign institutional investors trade on private information to their

[1] The seminal work of Chan (1992) studies the intraday lead–lag relation between returns of the major market cash index and returns of the major market futures index; he finds strong evidence that the futures market leads the cash index and weak evidence that the cash index leads the futures market. His work hence suggests that the index futures market is the main source of market-wide information. As previously discussed, when we view the futures index as a market indicator, it is a common assumption that all participates in the index futures market are projecting on the same public information set regarding the state of the economy. Thus, a corollary is that private information is irrelevant in futures market.

[2] The partition proportion is based on the average daily percentage of foreign institutional trades in the overall market.

advantage, do they have this private information for trading in an index futures market?[3]

We perform several stages of analysis. The first stage of our experiment, which is similar in spirit to the analysis of French and Roll (1986), provides a preliminary picture of the role of foreign institutional investors for price formation on the TAIFEX.[4] Because no plausible analog exists to the inside information so common to the stock market, concurrent market variance increases accompanied by the participation of foreign institutional investors in the market implies lasting information production. Because the flow of public information can also change over time, an unchanged flow of public information across different time regimes is clearly relevant to the inference whether foreign institutional traders have private information. In line with Ito, Lyons, and Melvin (1998), we test the flow of public information over our sample period. Specifically, we test whether daily news reports within our sample period increased or revealed any specific pattern. We examine the flow of news reports in the major financial newspaper of Taiwan as a measure of public information flow, as is commonly used in the literature.[5]

Because pubic information flow remains unchanged across our sample period, we eliminate the possibility of public information as the cause of price formation. We therefore focus our analysis on discriminating between the two other alternatives: private information and pricing errors. As mentioned in French and Roll (1986), when we use volatility to make inferences about the information source, consistency with the private-information alternative does not rule out mispricing. Therefore, we estimate mispricing's contribution in price variation. If the mispricing in variance falls or keeps constant as the growth of foreign institutional traders, we can waive the worry that changes in price variance coming wholly from mispricing.

The second stage of our analysis focuses on intraday changes in volatility. Earlier studies have shown empirical evidence of a U-shaped pattern embodied on intraday volatility (Wood, McInbish, and Ord (1985); Harris (1986); Andersen and Bollerslev (1997), among many others).[6] Furthermore, Foster and Viswanathan (1993) track the intraday U-shape to determine whether private information is used in trading to make the volatility smile. Because Easley and O'Hara (1992) also show that information asymmetry declines over the entire trading period, we link U-shaped volatility to private information by comparing the changes in the U-shape over time. Ito et al. (1998) show that the introduction of lunch-hour trading induces greater information revelation in that period, leading to the presence of a volatility U-shape in the Tokyo FX market. They conclude that the results support the predictions of a

---

[3] A range of empirical works have contributed to the discussion about the information content of foreign institutional investors by investigating their trading behavior including return predictability (Nagel (2005); Chang, Hsieh, and Wang (2009)), price impact (Stoll (2000); Chan and Fong (2000)), trading profitability (Barber, Lee, Liu, and Odean (2011)), and volatility predictability (Chang, Hsieh, and Wang (2010)).

[4] Researchers have widely adopted French and Roll's (1986) approach to classify the information source within price changes (e.g., Fama and French (1988); Berry and Howe (1994); Chordia, Roll, and Subrahmanyam (2008, 2011).

[5] In their study of the FX market in Japan, Ito et al. (1998) use the number of news headlines as a measure of public information flow. Goodhart (1989) and Peiers (1997) adopt a similar measure.

[6] Admati and Pfleiderer (1988), Foster and Viswanathan (1990), and Slezak (1994) also address the theory on U-shapes.

private-information model, implying that the information content of trading can be represented in the intraday volatility shape.[7]

In addition to the changes of volatility shape, the bid–ask spread can be another important microstructure measure to examine private information. Stoll (1989) shows that the component of adverse information costs in the quoted spread is as high as 43%, indicating that the bid–ask spread to large extent represents the level of information asymmetry in the market. Because the extent of information asymmetry is associated with private information in the market, the time variation of the quoted spread should reflect the changes in informed trading. For example, Glosten (1994) shows that the market has a positive bid–ask spread arising from the possibility of trading on private information. Accordingly, the third stage of our analysis focuses on changes in bid–ask spread.

In line with the U-shaped feature of intraday volatility, Madhavan, Richardson, and Roomans (1997) suggest that the U-shaped intraday spread is induced by the combined effect of a decline in information asymmetry and an increase in the order process component during the day.[8] While Madhavan et al. point out that informed trading may concentrate in early trading hours in a hybrid market such as the NYSE, some studies extend the interest for pure limit-order market and report comparable results. For example, Brockman and Chung (1999) and Chan (2000) study the bid–ask components on the Stock Exchange of Hong Kong. De Jong, Nijman, and Roell (1996) examine the bid–ask component on the Paris Bourse. Particularly focusing on adverse selection costs, Ahn, Cai, Hamao, and Ho (2002) find that the bid–ask spread of the Tokyo Stock Exchange also exhibit U-shaped pattern. Different from but not contradictory to Madhavan et al., Ahn et al. conclude that the evidence of an increase in information asymmetry around the end of the trading day suggests that transactions around this period convey private information. In sum, consistent with the second stage of our analysis, in the third stage of our analysis we link the uneven pattern of the intraday spread to private information by comparing their changes in shape over time.

As yet, our use of the term *private information* is less explicit. Because our study examines the information source of foreign institutional traders in the index futures market, the accurate definition of private information should be made clear before undertaking our analysis. Ito et al. (1998), who examine the information source in the FX market, suggest an explicit definition of private information. According to Ito et al., the information must satisfy two criteria: (i) It is not common knowledge, and (ii) it is price relevant. To be considered price relevant, private information can incorporate the permanent price impact or, under Ito et al.'s definition, the temporary price effects. The index futures market, as previously mentioned, projects the whole market or the economy; its information source is similar to the FX market. Therefore, we propose the same taxonomy of the definition of private information as that of Ito et al. Appendix A provides a detailed taxonomy on private

[7] Before December 21, 1994, the Tokyo FX exchange was restricted from trading over the lunch break (12:00 PM to 1:30 PM). The restriction was introduced in 1972. However, due to the migration of trading volume to other exchanges, the committee of Tokyo FX exchange removed the restriction on December 21, 1994.

[8] Mclnish and Wood (1992) report a U-shaped pattern in bid–ask spread for NYSE stocks. In addition, Madhavan (1992) considers a model in which information asymmetry is gradually resolved during the trading day. Madhavan's model predicts that the bid–ask spread will decline throughout the day.

information.

The seminal work of French and Roll (1986) on the closure of the NYSE provides us with a starting framework of analysis. Other relevant papers include Barclay, Litzenberger, and Warner (1990), Amihud and Mendelson (1991), Ito and Lin (1992), and Ito et al. (1998). All these studies examine the information flow in the Tokyo Stock Exchange (TSE), a pure limit-order market as is the TAIFEX. By investigating the changes in weekend or lunch volatility in the TSE, these studies link trading to the associated process of information dissemination. The study by Hsieh and Kleidon (1996), who use spread and volatility patterns measured simultaneously across different trading centers to evaluate models of asymmetric information, is also relevant. Another branch of related empirical work is about foreign institutional traders, especially about whether they have an information advantage over their local competitors in the same market. Current empirical findings are not fully conclusive. For instance, Grinblatt and Keloharju (2000), Froot, O'Connell, and Seasholes (2001), Seasholes (2000), and Froot and Ramadorai (2008) find that foreign investors' trades lead price movements, implying that foreign institutional traders have an information advantage. Conversely, Choe, Kho, and Stulz (2005) amd Dvorak (2005) find no evidence of better-informed foreign investors in Korea and Indonesia, respectively. Similarly, at the market level, Griffin, Nardari, and Stulz (2004) show that, after controlling for the contemporaneous relation between flows and returns, foreign investors are generally not able to time the market at the daily frequency. All the preceding findings, however, focus on the stock market, which is essentially projecting complex information sources, including inside information. By focusing on the index futures market, our study sheds new light on the understanding of foreign institutional trading in derivatives markets. The conclusion is particularly important to emerging markets as foreign institutional traders have been participating more deeply in these markets and may play an increasingly influential role in developing markets.

The remainder of this study is divided into following sections. Section 2 describes the data and the analysis approach. Section 3 reports the empirical findings and robustness tests, and Section 4 concludes.

2. Data and analysis approach

2.1 *Data Description*

Our detailed transaction data comprise the detailed history of order flows of TAIEX futures (hereafter, TXF) on the TAIFEX covering the period from January 1, 2003 through December 31, 2008.[9] For each order, the data set reports the date and time of arrival of the order, its direction (buy or sell), the quantity demanded or offered, and, most important for our purposes, the identification of traders. The trader code enables us to categorize foreign institutional trading.[10] TXF is the major index futures contract on the TAIFEX and also the

[9] TAIEX is the abbreviation of Taiwan Stock Exchange Capitalization Weighted Stock Index, which is constructed by the Taiwan Stock Exchange.

[10] In addition to the transaction data set directly obtained from the TAIFEX, we also use the data set of intraday

most actively traded product. Its underlying index, the Taiwan Stock Exchange Capitalization Weighted Index, is a value-weighted index of all individual stocks traded on the Taiwan Stock Exchange.

From 2003 to 2008, daily average trading volume of foreign institutional traders on the TAIFEX grows quickly compared to that of other traders. The increase in foreign institutional trading can be separated into three periods: (i) January 2003 to December 2005, (ii) January 2006 to August 2007, and (iii) September 2007 to December 2008. In the first period, the growth in the overall market is relatively steady, but the volume continues to advance over time. In the second period, the TAIFEX permanently reduced the trading tax rate from 0.025% to 0.01% for index futures trading from January 1, 2006. This 60% fee reduction was designed to stimulate market participants and induce more trading activity. Indeed, the growth of foreign institutional trading is more rapid after 2006. This phenomenon is consistent with Chordia, Roll, and Subrahmanyam (2011), who find that the reduced transaction cost contributed significantly to the trading volume uptrend in the NYSE from 1993 through 2008. The second regime ends in August 2007, which is right before the beginning of the global financial crisis in the following month. The separation is self-evident because the financial crisis affects the market comprehensively and brings structural changes to trading.

Figure 1 shows that from the period 1 to the period 3 foreign institutional trading each day increases from 3,783 to 89,426; the growth is more than twentyfold. Over the same time periods, the growth for domestic institutions and individuals is only around sixfold and twofold from period 1 to period 2 and from period 2 to period 3, respectively. In addition, the percentage of foreign institutional trading in period 1, period 2, and period 3 is 3.74%, 11.22%, and 24.46%, respectively, while the trading percentage for domestic institutions in each period is 18.91%, 33.42%, and 31.66%, respectively, and the trading percentage for individual traders in each period is 77.36%, 55.54%, and 43.88%, respectively. Neither domestic institutional trading nor individual trading present a monotonic uptrend, whereas the uptrend in foreign institutional trading across different periods represents a distinct low, medium, and high regime of foreign institutional trading on the TAIFEX.

[Insert Figure 1 Here]

2.2 *Changes in the public information flow and the price variation*

We first examine the changes in the public information set over the sample period. To this end, we refer to the seminal work of Ito et al. (1998) to perform the comparison. We analyze the impact of public information changes by using news reports about the market in the major financial newspaper of Taiwan across different regimes within our sample period.

To proxy the public information set by the number of news reports, we measure the changes in the public information flow by the standard deviations of the number of daily news. Specifically, the increases (decreases) in the standard deviations of the number of daily news represent a larger (smaller) public information flow; if the standard deviation of the number of daily news keeps constant, the public information flow remains unchanged.

---

futures prices of the Taiwan Economic Journal (TEJ) database.

After examining the changes in public information set, we calculate and examine the price variation in the index futures market. To demonstrate a complete comparison, we adopt different intraday frequency to measure price variation. We calculate realized volatility by 1-minute, 5-minute, 10-minute, and 15-minute returns and estimate daily volatility using a GARCH(1,1) model for additional examination.[11] To avoid biases related to using high-frequency data, we calculate all intraday returns by the mid-point of bid and ask prices in each given time interval and define the return as the log-difference of the mid-price between time intervals. We measure the intraday price volatilities with all available returns within a day and perform the comparison for volatilities across different periods based on daily observations. If the price variation is solely driven by the variation of public information, price volatility should have corresponding changes as those in the variation of public information.

2.3 *Mispricing errors and the private information*

Following the method in section 2.2, we can conclude whether price variation is solely caused by the public information; a negative result implies that increased foreign institutional trading incorporates more private information into market prices. The rejection, however, also includes the possibility of mispricing. Discriminating between private information and mispricing errors requires additional evidence. To this end, two seminal works help us to discriminate between private information and mispricing errors. French and Roll (1986) denote an upper bound for the mispricing error component of the return in a given period *t* as

$$1-\frac{V_l}{V_s}=\frac{V(E_t)}{V(R_t)}' \tag{1}$$

where V_l is the return variance over the long holding period, V_s is the cumulated variance over short subintervals; $V(R_t)$ is the return variance in period *t*; and $V(E_t)$ is the concurrent the fraction of variance from mispricing. Appendix B provides a detailed description of French and Roll’s variance decomposition. Although the French–Roll method is insightful, Ito et al. (1998) argue that their method for distinguishing mispricing from private information has its shortcoming. Specifically, their assumption requires that the private information effects are permanent and mispricing effects are temporary. However, among certain classes of private information price effects are only temporary and mispricing therefore is also persistent. Because interpreting the bound’s level is difficult, they argue that addressing how trading changes the bound can better exploit the information content of trading in the regime shift. Following the spirit of Ito et al. and French and Roll, in the next stage of our analysis we study the impact of mispricing using Equation (1). We carefully adopt several measurements to calculate variance ratios on the daily basis, including 5-minute variance over 1-minue variance, 10-minute variance over 1-minue variance, 15-minute variance over 1-minue variance, and 15-minute variance over 5-minue variance. Then, we perform the comparisons for deviations of variance ratios (i.e., the bound) across different periods. If the deviations of

[11] In our original data, each quote is time stamped to the second. We report results based on data with periodicity of one minute, constructed by taking the price closest to each minute.

variance ratios change accordingly as the changes in price volatilities across different periods, the results suggest that mispricing plays an important role in price formation and is inconsistent with the no-private-information null. [12]Volatility changes in different trading sessions within a day can discriminate further between private information and mispricing. Therefore we separate whole day trading hours into three trading sessions, early morning (8:45 AM to 10:15 AM), late morning (10:15 AM to 12:15 PM), and lunch (12:15 PM to 1:45 PM) and test the volatility shapes among sessions in each day across different periods. The literature reports that information asymmetry within trading hours contributes to the U-shaped intraday pattern of volatility; accordingly, the pattern change is more likely due to the shift in trade submissions of foreign traders if we observe the changes in volatility among different trading sessions. More specifically, we calculate the proportion of trade submission from foreign traders in the session of early morning, late morning, and lunch, respectively. If the distribution is unchanged among the three sessions through time, the intraday volatility U-shapes should be also unchanged because no shift in private information occurs between trading sessions. If the proportion of trades submissions shifts to the late morning session, the U-shape will flatten; conversely, if the proportion of trade submissions shifts to the early morning or lunch session, the U-shape will be deepen. By conducting this exercise, we generate predictions for how intraday volatility responds to different trading regimes. If we can verify the prediction, we can recognize the existence of private information for foreign institutional traders in the index futures market.

Aside from the U-shape pattern, prior studies have stylized that intraday bid–ask spread also has a U-shaped pattern similar to intraday volatility (Mclnish and Wood (1992), among many others). Because the U-shaped pattern in intraday spread can be attributed to the existence of information asymmetry, the additional prediction of private information relates to the changes in U-shaped pattern of bid–ask spread among different regimes.

2.4 *Robustness tests for exogenous controls*

The natural experiment on the TAIFEX is not a pure regime shift with increasing foreign institutional trades, because concurrent growth occurs in the trading volume for domestic institutional traders. To make our preceding tests more powerful, we exclude the possible effect from domestic institutional trading, which may also contain the private information. We therefore identify two periods – 2004 and 2005 – to make additional comparisons. We choose these two years because only the period from 2004 to 2005 has declining trading volume growth in our sample period. Interestingly, in these two years, only foreign institutional trading (daily average volume) grew, from 4,700 contracts to 5,600 contracts, while the trading volume of domestic institutions is relatively unchanged. This difference provides us with an opportunity to test the private information of foreign institutional trader

[12] The variance of the information component in the price return does not change because private information does not exist and the public information is unchanged; therefore trading variance cannot possibly increase with a failing or constant fraction due to error component, because the changes in total variance can only come from mispricing.

by comparing the changes in intraday volatility or bid–ask spread U-shapes between 2004 and 2005 and determine whether our findings are consistent with those in section 2.3.

We also perform a similar comparison between 2006 and 2007. From 2006 to 2007, foreign institutional traders are the only trader group that increases in trading proportion (8.55% to 13.78%) whereas the trading proportion of domestic institutional traders decreases slightly (26.09% to 24.17%). This separation once again provides us with an opportunity to exclude the impact of domestic institutional traders because it is less likely that decreasing domestic institutional trading will carry more private information into the market.

2.5 *Robustness tests using the model of Schlag and Stoll (2005)*

Our analysis directly investigates the information source of price formation in the market by decomposing the causes of price volatility into three parts – public information, private information, and mispricing – to determine whether the production of private information is associated with foreign institutional traders. To also assess the price impacts of foreign institutional trading, we adopt the model of Schlag and Stoll (2005) to estimate a regression of the following form:

$$R_t = \alpha_t + \delta_0 BUY_t + \sum_{i=1}^{4} \delta_i BUY_{t-i} + \eta_0 SELL_t + \sum_{i=1}^{4} \delta_i SELL_{t-i} + \sum_{i=1}^{4} \omega_i R_{t-i} + \varepsilon_t, \qquad (2)$$

where represents index futures return, BUY_t is the buy order of foreign institutions at time *t*, and *t*, and $SELL_t$ is the sell order of foreign institution at time *t*. Without loss of generality, we control four lags for *BUY/SELL* orders and returns. The variables are calculated based on a 15-minute intraday interval.

Note that the coefficients □δ and η are similar to Kyle's (1985) lambda measure of price impact. On the basis of the current lambda and the lambda coefficients for lagged orders, Schlag and Stoll (2005) propose two hypotheses about the relation of price change and signed volume: the information hypothesis and the liquidity hypothesis. The expected signs of the coefficients on current and one-lag *BUY/SELL* orders under the two hypotheses are specified as follows:

Information Hypothesis

For *BUY*: Lag 0 is positive; Lag 1 is zero.

For *SELL*: Lag 0 is negative; Lag 1 is zero.

Liquidity Hypothesis

For *BUY*: Lag 0 is positive; Lag 1 is negative.

For SELL: Lag 0 is negative; Lag 1 is positive.

If the information hypothesis is supported, the price impact is informed; conversely, if the liquidity hypothesis is supported, the liquidity demand rather than private information causes the price impact. We perform the regressions for each period and discern the information content of price impact in different regimes.

3. Empirical findings

3.1 *Are market variations solely caused by the public information?*

We first examine the number of news reports based on one of the major financial newspaper in Taiwan, *Economic Daily News*, across three periods. Our statistics of news reports are hand-collected and compiled by investigating daily news in the whole sample years. We include only the news related to market-wide information. Panel A of Table 1 reports that the average daily number of news about the Taiwan market decreases from period 1 to period 2 and increases in period 3. Because we measure public information by the number of daily news reports, the variation of public information should be represented by the standard deviation of the number of daily news. In Panel A, standard deviation of the number of news increases from period 1 to period 2 but remains unchanged to period 3 because the variance difference tests are statistically insignificant.

[Insert Table 1 Here]

It is well-known that the Taiwan market is affected by the U.S. market; therefore, we also count the number of news about the U.S. market and report the statistics in Panel B of Table 1. Although the pattern of the number of news articles in Panel B is similar to that in Panel A, the variation of public information is slightly different. The standard deviation of the number of news articles decreases in period 2 but increases in period 3. To obtain a comprehensive picture regarding the public information flow, we combine the numbers of news articles related to the Taiwan market and to the U.S. market and report statistics in Panel C. Again, the pattern of the number of news articles in Panel C is similar as those reported in Panels A and B. For the standard deviations, however, it presents a stable pattern through time. No significant change in variation occurs between each period. The results in Panel C indicate that the flow of public information throughout the sample period is unchanged.

As previously mentioned, if price variation in the market is solely driven by public information, the dynamics of price volatility should mimic the pattern of the volatility of public information. Figure 2 draws a brief time-plot for 1-minute and 10-minute realized intraday volatility with trend curves. As the figure shows, the volatility increases in the late sample period, while the mid-sample period has the lowest volatility.

[Insert Figure 2 Here]

We next examine the dynamics of market volatility in the three different regimes. We estimate the volatility by five different realized volatilities and one GARCH model. Table 2 reports the results. All volatility measures, except for 1-minute realized volatility, present very similar patterns. Specifically, volatility slightly decreases from period 1 to period 2 but increases dramatically from period 2 to period 3. No significant change occurs in 1-minute realized volatility from period 1 to period 2. It changes from period 2 to period 3 in a manner similar to the other measures; average 1-minute realized volatility is about 0.442 in period 2, which increases almost twofold to 0.811 in the period 3. Given unchanged public information flow from period 2 to period 3, the results in Table 2 imply that private information on the TAIFEX causes price variation to some extent.

[Insert Table 2 Here]

3.2 *Does the mispricing or the private information cause the variation?*

The findings in Table 2 do not exclude the possibility that price variation may be primarily caused by mispricing rather than the private information. A simple way to discern the causes of price variation is to test the changes in mispricing. If the changes in mispricing are inconsistent with the changes in price volatility, it is less likely that price variation solely results from pricing errors in the market. By Equation (1), we calculate a variance ratio deviation as the bound of mispricing and examine the differences between each period. It is clear from Table 3 that all variance ratio deviations decrease from period 1 to period 2; this decrease pattern is similar to the pattern found in Table 2. The changes between period 2 and period 3, however, are inconsistent with corresponding changes in volatilities. Finally, the deviations of the 5-to-1 variance ratio continues to decrease from period 2 to period 3 whereas the deviations of other variance ratios are generally unchanged during the same time period.

[Insert Table 3 Here]

Given that public information remains unchanged and the volatility increases from period 2 to period 3, the decrease in mispricing in Table 3 rule out the possibility that mispricing causes the increase in volatility. This finding provides evidence of the existence of the private information in the index futures market because the increase in the market volatility from period 2 to period 3 should be caused by private information. However, we still obtain ambiguous results for the comparison between period 1 and period 2 because both the bound of mispricing and price volatility decrease. To access the private information of the market more precisely, we enrich our investigation by adding evidence of intraday dynamics in volatility shapes and bid–ask spread shapes.

3.3 *U-shapes in the intraday volatility and bid–ask spread*

As discussed in section 2.3, our motivation is to examine the order submissions of foreign institutional traders to determine whether any change occurs for the quotes distribution among the three different intraday trading sessions: early morning, the late morning, and lunch. In Table 4, we calculate the daily percentage of quotes submitted by foreign institutional traders in late morning session for each trading day of each period and conduct difference tests between the periods.

[Insert Table 4 Here]

The results in Table 4 show that the order submissions of foreign institutions are relatively more concentrated in the late morning session through time. The average (median) daily percentage of submission is around 30% (30%), 32% (31%), and 33% (32%) in period 1, period 2, and period 3, respectively. A monotonic increase occurs across the periods although only the difference between period 2 and period 3 is statistically significant.[13] Given the findings in Table 4, intraday volatility and bid–ask U-shapes should flatten through time if foreign institutional traders carry more private information into the late morning session compared to the early morning and the lunch session.

To capture intraday volatility and bid–ask spread patterns, we calculate early morning-to-late morning (E/L) volatility and bid–ask spread ratios and lunch-to-late morning (L/L) volatility and bid–ask spread ratios. If the intraday volatility or bid–ask spread has a U-shape, both the E/L ratio and L/L ratio should be greater than 1. We use 1-minute and 5-minute realized volatility for the volatility analysis and quoted spread (QSPR) and percentage spread (PSPR) for the bid–ask spread analysis.[14] Tables 5 and 6 report the results for the intraday volatility and the bid–ask spread, respectively.

[Insert Table 5 Here]

[Insert Table 6 Here]

Table 5 shows that the intraday volatility in period 1 has a distinct U-shape, which is consistent with the findings reported in prior literature. Interestingly, in period 2 and period 3, the volatility U-shape is obviously flattened. At least one of the E/L and L/L ratios decreases between two periods, and the changes are statistically significant. We also plot the U-shapes for each period in Figure 3; the figure provides a clearer picture of the erosion of the U-shape through time.

[Insert Figure 3 Here]

Table 6 shows very similar patterns for QSPR and PSPR. Again, a distinct bid–ask spread U-shape is present in period 1, but the shape flattens in period 2 and period 3. Figure 4 shows graphically this flattening over time.

[Insert Table 6, Figure 4 Here]

In sum, the findings regarding changes in intraday shapes for volatility and bid–ask spread provide evidence of a shift in private information not only between period 2 and period 3 but also between period 1 and period 2. The changes of shapes are associated with the changes in order submissions of foreign institutional traders.

[13] The difference between period 1 and period 2 is statistically significant in the one-way test but only marginally significant in the two-way test.

[14] We also apply 10-minute and 15-minute realized volatility for the volatility analysis. The findings are consistent with those using 1-minute and 5-minute volatility. For brevity, we do not report the results in the table.

3.4 *Excluding the possible effect for domestic institutional trading*

In sections 3.1 to 3.3 we show that private information drives market volatility on the TAIFEX and that the source of the private information is more likely related to foreign institutional traders. Across our sample period, foreign institutional traders carry more private information into the market. However, domestic institutional trading may possibly increase at the same time, although the increase in their trading proportion is less than that of foreign institutional trading. To exclude the possible influence of domestic institutional traders, we make two additional comparisons in Tables 7 and 8.

[Insert Table 7 Here]

[Insert Table 8 Here]

Table 7 presents the comparisons of the intraday volatility U-shape. After controlling for domestic institutional trading, we still observe that the volatility U-shape flattens from 2004 to 2005 and from 2006 to 2007. Table 8, which shows the results of the comparisons of the bid–ask spread, provides evidence of a flattened intraday bid–ask spread U-shape.[15] Overall, from 2004 to 2005 and from 2006 to 2007, domestic intuitional traders are less able to cause market-wide changes because their trading in these periods is relatively unchanged. However, both Tables 7 and 8 show that a shift of the private information in the market and flattening of the intraday U-shape still occurs for either volatility or bid–ask spread.

3.5 *Robustness Tests Using Schlag and Stoll's (2005) Model*

Thus far we provide evidence that the private information of foreign institutional traders cause changes in the index futures market. However the question remains of whether foreign institutions, which are a relatively small trader group that trade only 15% to 25% of the total market, can create a market-wide change. Therefore we conduct a regression analysis using the model of Schlag and Stoll (2005) to specify the price impact from foreign institutional trading.

Table 9 presents the results across the three time periods. The result for period 1 only partially supports the liquidity hypothesis. Although both contemporaneous coefficients and one-lagged coefficients are significant, the sign of coefficients of BUY_t and BUY_{t-1} are inconsistent with the expectation. In addition, the result for period 2 is consistent with the expectation of the liquidity hypothesis. Interestingly, unlike the other periods, the result for period 3 supports the information hypothesis. The information effect in period 3 implies that foreign institutional trading from period 1 to period 3 becomes more informative. Thus, with the accompanied increased trading proportion of foreign institutional traders, the regression

[15] We compare the distribution of order submissions of foreign institutional traders for the same year pairs before the robustness test in Tables 7 and 8. Similar to the findings in Table 4, the percentage of order submissions in the late morning session is relatively higher in 2005 and 2007. For brevity, the results are not reported.

analyses using the model of Schlag and Stoll (2005) support our prior findings.

[Insert Table 9 Here]

4. Conclusions

Our primary aim is to extend the line of research regarding the private information of foreign institutional traders in the index futures market. By dividing our sample period into three subperiods based on different levels of participation of foreign institutional traders, we compare the information content in each regime and then infer whether the participation of foreign institutional investors incorporates the private information into market prices.

Our analyses and findings are summarized as the following. First, we test the relation between the flow of public information and intraday volatilities and show that the public information is not the only cause of price variation in the index futures market. We find that public information flow is quite stable throughout the sample period, whereas the price volatility varies across different periods. This finding suggests that private information or mispricing contribute to price formation. Second, we test the role of mispricing in price volatility and find that the changes in mispricing cannot fully explain the price variation. This result supports the argument that private information affects price formation on the TAIFEX. Third, we test the intraday volatility and bid–ask spread patterns to discern the influence of foreign institutional trades through time. We find that the information-related U-shapes of intraday volatilities and bid–ask spreads flatten as foreign institutional trades increase in the late morning session (10:15 AM to 12:15 PM).

Finally, as robustness checks we reexamine the changes in intraday U-shapes by making comparisons that take the influence of domestic institutional traders into consideration. These findings support our prior results. In addition, we test the information content of the price impact of foreign institutional traders using Schlag and Stoll's (2005) model. The results show that foreign institutional trading is more informative as the proportion of foreign institutional trading in the market increases. The results also indicate that foreign institutional traders carry more private information by trading through time.

Overall our findings are consistent with the commonly held view that foreign institutional investors own private information that is not available to the public. Further, we extend the literature by challenging the common assumption that all participants in the index futures market project the same public information set regarding the state of the economy. We suggest that private information in such a market causes price variance that cannot be accounted for by public information or mispricing. As such, we provide evidence that foreign institutional investors have private information for the index futures trading.

APPENDIX A: The taxonomy of private information

To root the taxonomy in theory, we consider the theoretic setting of Ito et al. (1998). The code of their definition about private information is that superior information about temporary price effects qualifies as private information. We begin by considering a canonical two-period trading model in which trading occurs initially at price P_0 and then again at P_1, and then a terminal payoff F is realized at t=2. In this framework, information on the terminal payoff F can be viewed as *fundamental* private information. In contrast to fundamental private information, information unrelated to the payoff F but relevant to interim prices P_0 and P_1 as *semifundamental* private information. P_0 and P_1 are assumed to be determined by many arguments beyond the expectation of the payoff F, for example, traders' risk aversion, traders' trading constraints, the supply/demand of the risky asset, and other features of the trading environment. All these features affect P_0 and P_1 but do not alter the expectations of F; superior knowledge of them, therefore, qualifies as semifundamental private information in the index futures market.

APPENDIX B: The variance decomposition (French and Roll (1986))

French and Roll (1986) drive the components of return variance from an identifying assumption: Mispricing has temporary effects on price but private information has permanent effects. First, we decompose the return in period t, R_t, into two components, an information component I_t and an error component E_t:

$$R_t = I_t + E_t$$

where the error component can both a pricing error and a measurement error. Because the error component's effect on price is temporary, the variance of returns over long holding periods reflects only the information component, whereas the cumulated variance over short intervals includes both components. Letting V_l denote the long-term return variance and V_s denote the short-term return variance, then $1 - V_l / V_s$ $(=V(E_t)/V(R_t))$ provides an upper bound on the fraction of variance from mispricing. This deviation is the upper bound because $V(E_t)$ includes the effect of bid–ask bounce. This measure essentially assumes that the components are uncorrelated: $V(R_t) = V(I_t) + V(E_t)$.

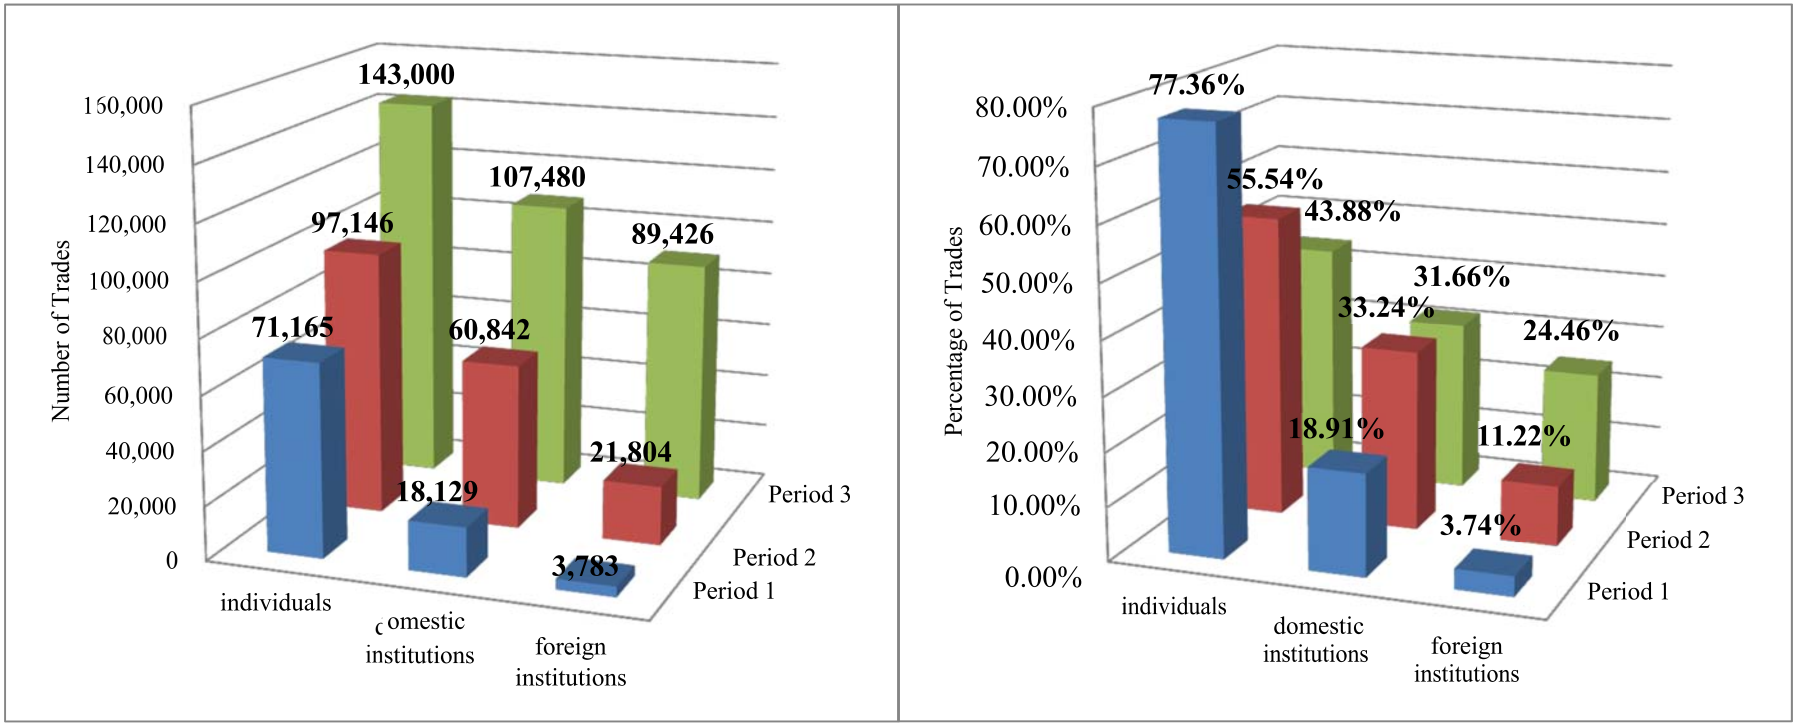

Figure 1: The number and Percentage of Trades for Each Investor in Different Periods. This figure presents the daily average trading volume for foreign institutional investors, domestic institutional investors, and individual investors in different periods. The sample period is from January 2003 to December 2008, which includes 1,484 trading days. Period 1 is from January 2003 to December 2005. Period 2 is from January 2006 to August 2007. Period 3 is from September 2007 to December 2008. The left plot is based on the number of trades (contract), and the right plot is based on the trading percentage.

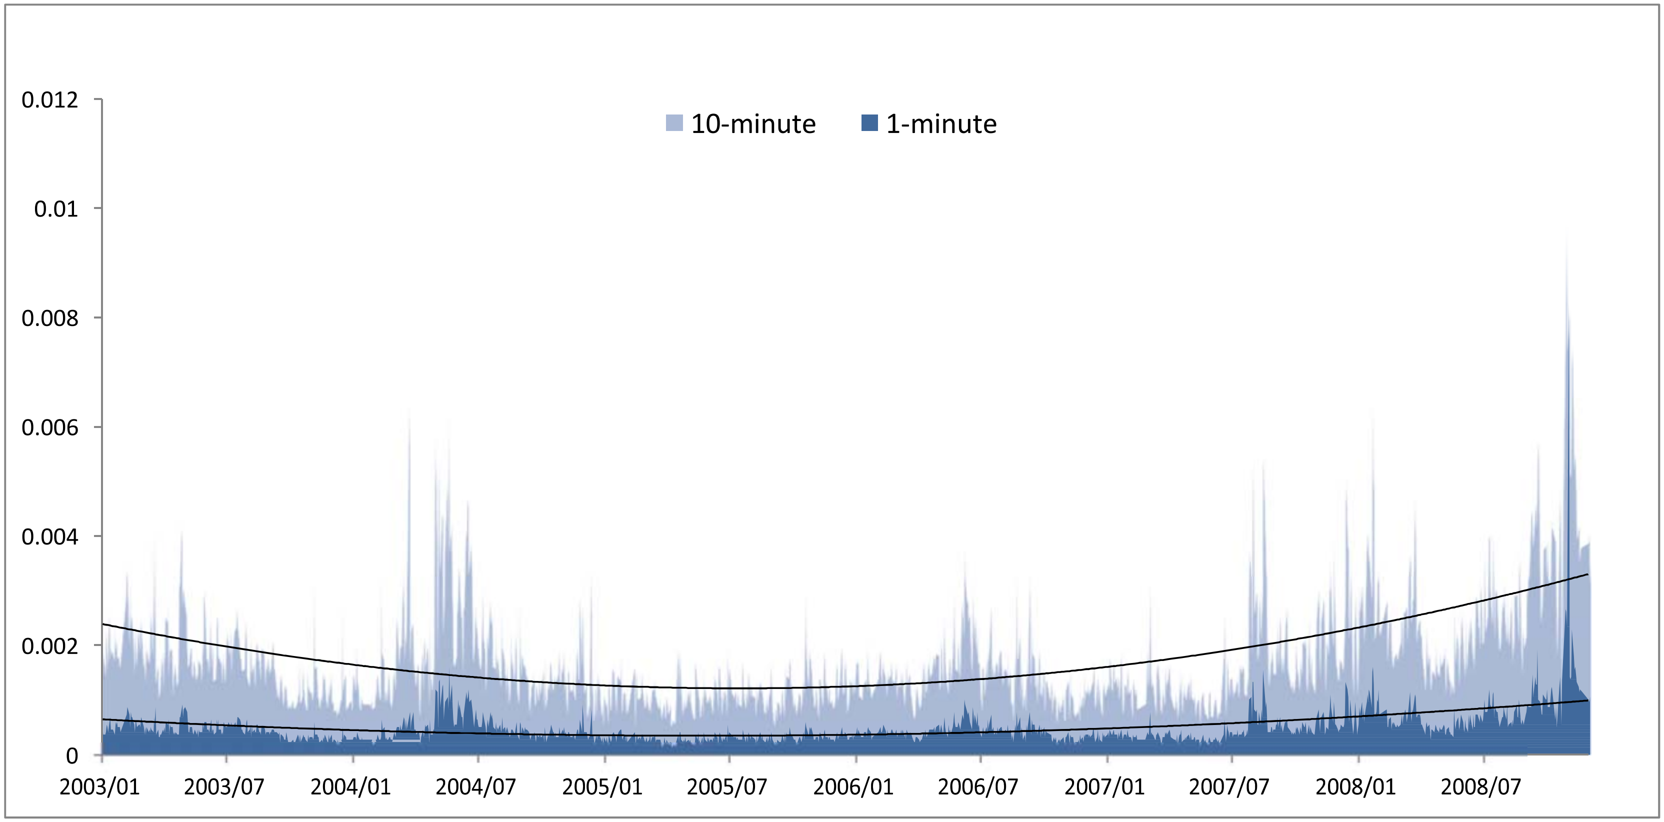

Figure 2: Intraday Volatility through Time. This figure presents the time dynamics of return volatilities of the TXF index by two measures: 1-minute return volatility and 10-minute return volatility. The sample period is from January 2003 to December 2008, which includes 1484 trading days. The volatilities are calculated by corresponding intraday returns for each trading day. The returns are calculated as the changes in the log of the bid–ask midpoint. Two solid cures are nonlinear trend lines for return volatilities.

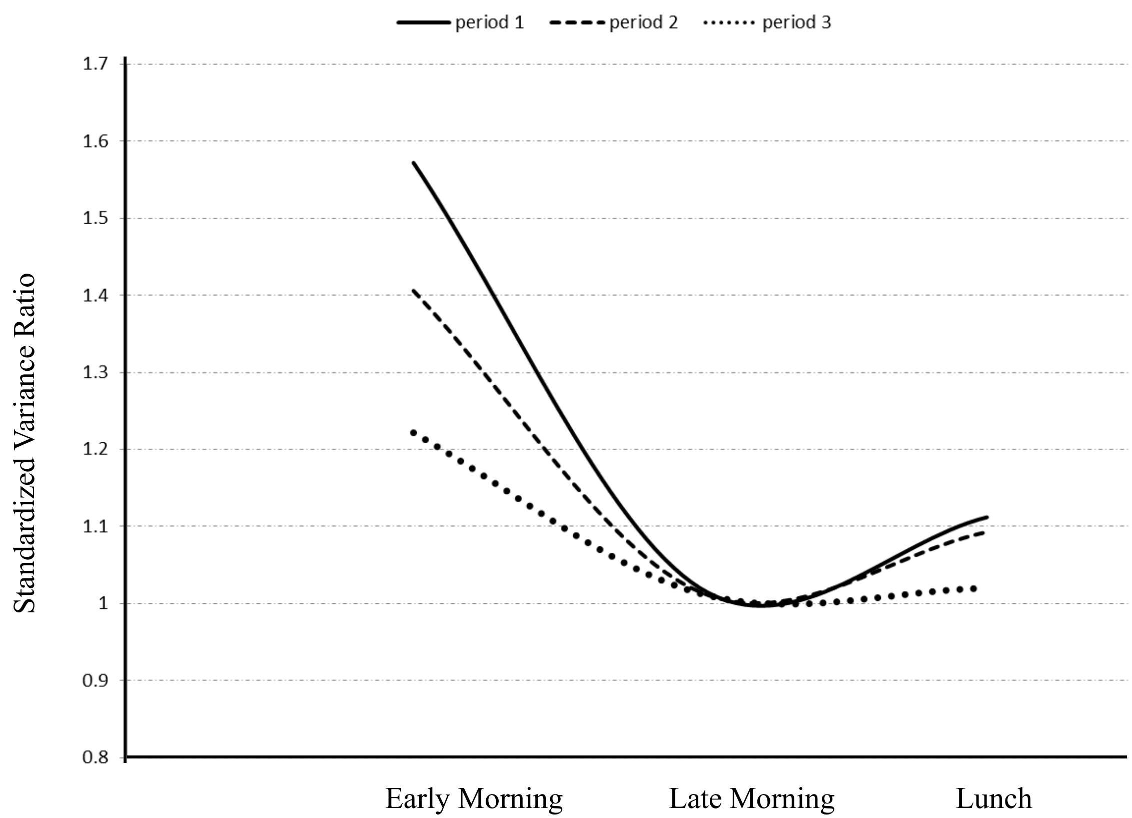

Figure 3: Intraday Volatility U-Shapes by Different Periods. This figure presents the return variance of the TXF index for three intraday trading sessions: early morning (8:45 AM–10:15 AM), late morning (10:15 AM – 12:15 PM), and lunch (12:15 AM–1:45 PM), Taipei time. The sample period is from January 2003 to December 2008, which includes 1,484 trading days. The return variances are calculated by1-minute returns for each session. The returns are calculated as the changes in the log of the bid–ask midpoint. For cross-period comparison, we standardize each variance by the variance of late morning session for each period (the variance of late morning session is hence equals 1). The lines are smoothed interpolations of the three variance estimates.

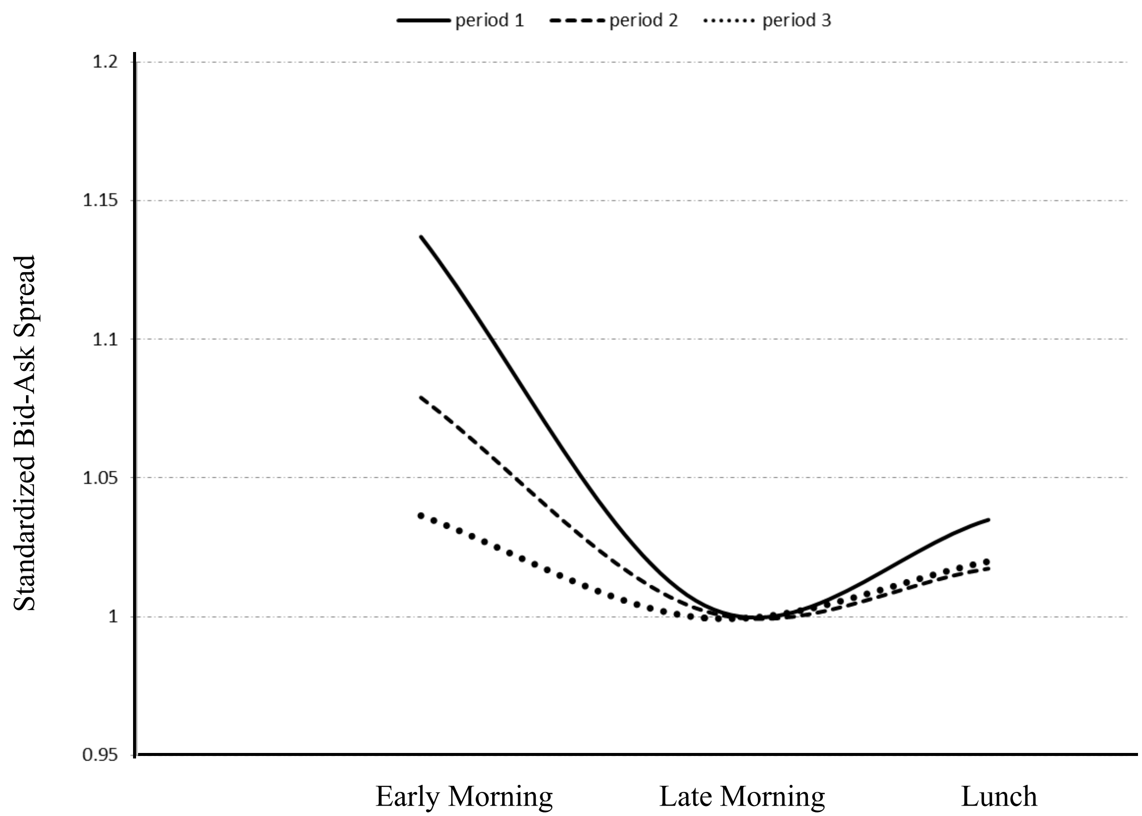

Figure 4: Intraday Bid-Ask Spread U-shapes by Different Period. This figure presents the quoted spread of the TXF index price for three intraday trading sessions: early morning, (8:45 AM–10:15 AM), late morning (10:15 AM – 12:15 PM), and lunch (12:15 AM–1:45 PM), Taipei time. The sample period is from January 2003 to December 2008, which includes 1,484 trading days. The numbers of quoted spreads in this plot are calculated as the mean of all spread value (best ask – best bid) for each session. For cross-period comparison, we standardize the number of spread by the spread of late morning session for each period (the spread of late morning session is hence equals 1). The lines are smoothed interpolations of the three spread estimates.

Table 1: The Public Information Flow: Daily Number of News reports

This table reports the public information flow in term of the number of news reports about the market status by the news database, *Economic Daily News*. Panel A reports the news about the Taiwan market, including the stock market and futures market. Because the Taiwan market is affected by the U.S. market, Panel B reports the news about the U.S. market. Panel C aggregates the number of the Taiwan news and the U.S. news. The *t*-test, Wilcoxon test, and *F*-test are used to test means, medians, and, variances across different periods, respectively. The statistics of tests are reported in the last six columns. ***, **, and * represent a significance level of 1%, 5%, and 10%, respectively.

Table 2: Intraday Volatility across Different Periods

This table reports the statistics of intraday volatility by different frequency and measurements—realized volatility (RV) and GARCH (1,1) estimates. The sample period is from January 2003 to December 2008, which includes 1,484 trading days. Volatilities are estimated by intraday returns or daily returns. The returns are calculated as the changes in the log of the bid–ask midpoint. The units of realized volatilities are multiplied by 10^3. The units of GARCH estimations are multiplied by 10^2. The *t*-test and Wilcoxon test are used to test means and medians across different periods, respectively. The statistics of tests are reported in the last four columns. ***, **, and * represent a significance level of 1%, 5%, and 10%, respectively.

Table 3: Mispricing across Different Periods

This table reports the statistics of mispricing errors by different frequencies. The sample period is from January 2003 to December 2008, which includes 1,484 trading days. The mispricing is defined as

$$1 - \frac{V_l}{V_s},$$

where V_l is the return variance over the long holding period, and V_s is the return variance over short subintervals. The return variances are calculated by corresponding intraday returns for each trading day. The returns are calculated as the changes in the log of the bid–ask midpoint. The *t*-test and Wilcoxon test are used to test means and medians across different periods, respectively. The statistics of tests are reported in the last four columns. ***, **, and * represent a significance level of 1%, 5%, and 10%, respectively.

Table 5: How does the intraday volatility U-Shape change?

This table presents the return variance ratio based on three intraday trading sessions: early morning (8:45 AM–10:15 AM), late morning (10:15 AM – 12:15 PM), and lunch (12:15 AM–1:45 PM), Taipei time. The sample period is from January 2003 to December 2008, which includes 1,484 trading days. The return variances are calculated by 1-minute and 5-minute returns for each session. The returns are calculated as the changes in the log of the bid–ask midpoint. For each period, the left column is the ratio of the variance in the early morning session over the variance in the late morning session (E/L), and the right column is the variance in the lunch session over the variance in the late morning session (L/L). The *t*-test and Wilcoxon test are used to test means and medians across different periods, respectively. The statistics of tests are reported in the last four columns. ***, **, and * represent a significance level of 1%, 5%, and 10%, respectively.

Table 6: How does the intraday bid-ask spread U-Shape change?

This table presents the bid-ask spread ratio based on three intraday trading sessions: early morning (8:45 AM–10:15 AM), late morning (10:15 AM – 12:15 PM), and lunch (12:15 AM–1:45 PM), Taipei time. The sample period is from January 2003 to December 2008, which includes 1,484 trading days. The spreads are defined by quoted spread (QSPR) and percentage spread (PSPR), calculated as (best ask – best bid) and (best ask – best bid)/midpoint price, respectively. For each period, the left column is the ratio of the mean (median) spread in the early morning session over the mean (median) spread in the late morning session (E/L), and the right column is the mean (median) spread in the lunch session over the mean (median) spread in the late morning session (L/L). The *t*-test and Wilcoxon test are applied to test means and medians across different periods, respectively. The statistics of tests are reported in the last four columns. ***, **, and * represent a significance level of 1%, 5%, and 10%, respectively.

Table 7: Paired years comparisons: Intraday volatility U-shape

This table presents the return variance ratio based on three intraday trading sessions: early morning (8:45 AM–10:15 AM), late morning (10:15 AM – 12:15 PM), and lunch (12:15 AM–1:45 PM), Taipei time. Panel A is the comparison of 2004 and 2005. Panel B is the comparison of 2006 and 2007. The return variances are calculated by 1-minute and 5-minute returns for each session. The returns are calculated as the changes in the log of the bid–ask midpoint. For each period, the left column is the ratio of the variance in the early morning session over the variance in the late morning session (E/L), and right column is the variance in the lunch session over the variance in the late morning session (L/L). The *t*-test and Wilcoxon test are used to test means and medians across different periods, respectively. The statistics of tests are reported in the last four columns. ***, **, and * represent a significance level of 1%, 5%, and 10%, respectively.

Panel A: Comparison 1

		2004		2005		H_0: no changes between years

Table 9: Price Impact Test: Schlag and Stoll (2005) Model

This table presents the results of the regression estimates using Schlag and Stoll's (2005) model. The variables are calculated based on 15-minute intraday intervals. The sample period is from January 2003 to December 2008, which includes 29,680 intraday time intervals. The regression model is defined as

$$R_t = \alpha_t + \delta_0 BUY_t + \sum_{i=1}^{4} \delta_i BUY_{t-i} + \eta_0 SELL_t + \sum_{i=1}^{4} \delta_i SELL_{t-i} + \sum_{i=1}^{4} \omega_i R_{t-i} + \varepsilon_t,$$

where R_t is futures index return at time t, BUY_t is the buy order of foreign institutions at time t, and $SELL_t$ is the sell order of foreign institution at time t. For brevity, only the coefficients of current quotes and lagged quotes are reported. The returns are calculated as the changes in the log of the bid–ask midpoint. The *t-test* is applied to test the coefficients; *t*-statistics are in the parentheses. ***, **, and * represent a significance level of 1%, 5%, and 10%, respectively.

How bank capital buffer and insolvency risk vary across European countries: Business cycle, income diversification and bank regulation

Kim Cuong Ly
PhD student, Adam Smith Business School, University of Glasgow, University Avenue, Glasgow

United Kingdom
Email: k.ly.1@research.gla.ac.uk

This paper examines business cycle, income diversification, regulatory and supervisory determinants of capital buffer and insolvency risk by using a panel data of EU27 countries from 2001 to 2011. The results show that capital buffer fluctuates procyclically over the business cycle and diversification benefits exist in encouraging banks to hold higher capital buffers. Banks are more likely to increase probability of failure during economic boom due to engaging excessively in risky activities. Economic downturn in countries with tighter capital regulation diminishes benefits of capital buffer, therefore, increase level of bankruptcy risk. Banks tend to be safer under upturn cycle given that their country has generous deposit insurance. Deposit insurance can be substitutes for income diversification in diminishing capital buffer. Official supervision reduces banks' incentive to hold capital buffers and increase the likelihood of failure. Better private monitoring practice has a clear positive impact on capital buffers and making banks to reduce risk-taking incentives. Business cycle and improved accounting transparency are substitutes in reducing banks' incentive to hold larger capital buffers, thereby increasing banks' risk-taking incentives. Given the condition of tighter restriction on bank activities and business cycle upturn, banks are more stable and might not need to increase capital.

Keywords: Capital buffer, insolvency risk, business cycle, income diversification, bank regulation, supervision

JEL Classification: G200, G210, G380

1. Introduction

The banking industry in general as well as European banking sector in particular has experienced a significant amount of bank failures during the recent financial crisis and economic recession. The experiences from these crises have attracted shareholders, bank themselves as well as regulators about the importance of holding sufficient capital buffers. According to the Basel capital adequacy requirements, banks have to maintain their capital buffers above the minimum requirement of 8 percent as a cushion to absorb negative capital shocks. Banks may also need to hold extra capital as an indication of soundness to the market and please the expectations of rating agencies (Jackson et al., 1999). Therefore, the supervision of capital buffers over the business cycle plays a crucial role in maintaining the financial stability of the banking system.

Under the Basel III (Basel committee, 2013) banks have to build up the excess capital above the minimum requirement by regulators so that capital buffer can be used in financial distress. As building up capital is cheaper and easier in an economic boom than in an economic recession (Ayuso et al.2004). Several authors have found that capital buffer is more likely to decrease in economic expansion and increase during economic recession (i.e. Jokipii and Milne, 2008; Ayuso et al., 2004; Estrella, 2004; Lindquist, 2004). Meanwhile, others argue that capital buffer is more likely to increase in business upturn and decrease in business downturn (i.e. Jokipii and Milne, 2008; Ayuso et al., 2004 and Borio et al; Lindquist, 2003). This paper will examine the question about whether bank's capital buffers behave procyclically or anticyclically over the business cycle.

On the other hand, in order to increase capital buffer, income diversification is considered as a fundamental strategy for the banks' revenue growth. The motivations for diversifying the sources of bank revenue as well as its impacts have attracted lots of interest in the literature (Stiroh and Rumble, 2006; Stiroh, 2004; DeYoung and Roland, 2001). Diversifying may lead to be better bank performance, hence increase capital buffer (Perold, 2011; Demirgüc-Kunt and Huizinga, 2010 and Elsas et al., 2010; Chiorazzo et al., 2008; Stiroh and Rumble, 2006; Stiroh, 2004a; Gallo et al., 1996) or it might result in reducing banks' revenue, hence decrease capital buffer (Berger and Ofek,1995; Jensen, 1986). However, Stiroh (2004b) argues that a greater dependence on non-interest income, especially trading revenue, is correlated to higher risk and lower risk-adjusted profits across commercial banks. This research will therefore investigate whether the increase in income diversification is connected with changes in banks' capital buffer and insolvency risk and whether income diversification contributes to lessen the possibility of bank default and helps banks build up their capital buffer.

This paper examines business cycle, income diversification, regulatory and supervisory determinants of capital buffer and insolvency risk by using a panel data of EU27 countries from 2001 to 2011. According to the author's knowledge, this research is the first study to look at the interrelated relationship among business cycle, income diversification, capital buffer and insolvency risk as Shim (2013) examine on portfolio risk rather than insolvency risk. The results show that capital buffer fluctuates procyclically over the business cycle and diversification benefits exist in encouraging banks to hold higher capital buffers. Banks are more likely to increase probability of failure during economic boom due to engaging excessively in risky activities.

On the other hand, the regulation and supervision in the context of capital buffer and insolvency risk is largely unexplored. This paper aims to fill the gap by bringing a range of the regulatory and supervisory practices as determinants of capital buffer and insolvency risk. Furthermore, this study significantly contributes to our understanding about the influence of business cycle and income diversification on capital buffer and insolvency risk given the condition on regulation and supervision, therefore, offers effective implications for regulatory policy. Economic downturn in countries with tighter capital regulation diminishes benefits of capital buffer, therefore, increase level of bankruptcy risk. Banks tend to be safer under upturn cycle given that their country has generous deposit insurance. Deposit insurance can be substitutes for income diversification in diminishing capital buffer. Official supervision reduces banks' incentive to hold capital buffers and increase the likelihood of failure. Better private monitoring practice has a clear positive impact on capital buffers and making banks to reduce risk-taking incentives. Business cycle and improved accounting transparency are substitutes in reducing banks' incentive to hold larger capital buffers, thereby increasing banks' risk-taking incentives. Given the condition of tighter restriction on bank activities and business cycle upturn, banks are more stable and might not need to increase capital.

The remainder of the paper is organized as follows. Section 2 reviews literature. Section 3 describes data and methodology. The empirical results are presented in Section 4. Section 5 concludes.

2. Brief literature review

2.1. Business cycle determinant

Lindquist (2003) finds a positive impact of the business cycle on the capital buffer of Norwegian banks. Ayuso et al. (2004) suggest that banks should build up their capital buffers in an economic boom as it is easier to build up the capital in an economic upturn than in an economic downturn. If banks expanding their loan portfolio in an economic upturn without building up their capital buffers accordingly then, banks' capital buffers cannot absorb the materializing of credit risk when the recession sets in. Hence, banks are forced to increase their capital buffers through a cutback in lending. Moreover, Ayuso et al. (2004) and Borio et al. (2001) debate that given a countercyclical materialization of credit risk, a countercyclical fluctuation of capital buffers may be indication for banks' short-sightedness. The capital buffers co-move positively with the business cycle, dropping in recessions for co-operative banks and small banks (Jokipii and Milne, 2008).

Turning to insolvency risk, Jiménez and Saurina (2006) find that riskier borrowers can access bank lending in economic boom, hence, banks' capital cushions tend to be eroded during this period. Another strand of literature argues that insolvent banks may bet themselves by taking riskier credit policies with higher returns but also higher risk (Salas and Saurina, 2002). Furthermore, Rajan (1994) argues that banks tend to relax credit standards to hide loss on non-performing loans and protect their own reputation during upturn. It is predicted that banks tend to be more financial distressed in economic boom. Since a borrower's default may transfer information about an increasing likelihood of other firms' constraint in the same industry (Dahiya et al., 2003), banks may lose their reputational values due to this poor signal of loan management. Whenever reputational considerations diminish because of negative shock, banks are motivated to tighten credit polices (Rajan, 1994). Hence, Jiménez and Saurina (2006) find that banks become conservative in lending activities during economic downturn. Granting loans to fewer but well-performed firms helps banks to have enough capital cushion in order to withstand through economic-wide recession (Dell's Ariccia and Marquez, 2006). Since Zscore is a measure of insolvency risk in this study, lower Zscore indicates increased probability of failure.

Taken together, this study hypothesizes as follows:

H.1a. *Business cycle is positively related to capital buffer, i.e. capital buffer increases in economic expansion and decreases during economic recession.*

H.2a. *Business cycle is negatively associated with insolvency risk, i.e. insolvency risk increases in expansion and decreases in recession.*

One contradictory set of theories suggest that, when examining the relationship between the most advantageous forward looking capital buffers and deterministic cycles of loan losses, Estrella (2004) finds that banks will build up capital buffers in anticipation of loan losses because loan losses themselves tend to drop behind the business cycle. This implies that actual capital buffers will increase during cyclical down turns, i.e. negative cyclical co- movement. Other theory finds that, the cyclical behavior of European bank capital buffers changes in accordance to type and size of bank (Jokipii and Milne, 2008). Capital buffers increase in recession for savings banks, commercial banks and large banks. Lindquist (2004) also finds a negative impact of the business cycle on the capital buffer of Norwegian banks.

Earlier literature (Dell's Ariccia and Marquez, 2006; Goodhart et al., 2005) offers a link of business cycle and crisis to the quality of bank's investment portfolio. Crockett (2001) finds that banks are expected to build up excess capital in economic boom because there may be an increase in portfolio risk during this period. While banks use bankruptcy prediction model to monitor credit risk, prior literature (Hol, 2007; Chen, 2006; Westgaard and Van der Wijst, 2001) suggests that weak firms are more likely to be insolvent during recession period, however, business upturn tends to favor weak firm a temporary extension. As a result, Van den Heuvel (2002) content that banks with strong capital buffers tend to over-lend during business upturn.

However, Dell's Ariccia and Marquez (2006) argue that the trend of financial turmoil tends to occur after the strong credit expansion since lending boom raises sensitivity of banks' profitability to aggregate shocks, hence, higher failure exposure in economy-wide recession. Insofar the expansion in credit moves toward the end, acceleration in riskier lending erodes banks' capital buffers (Van den Heuvel, 2002). Nevertheless, Kim and Santomero (1988) claim that banks are required to hold enough capital to absorb larger losses to prevent bankruptcy. As larger shift toward riskier assets offsets the capital buffers, banks are more likely to fail (Koehn and Santomero, 1980). It seems that banks may be financial distressed in economic downturn rather than upturn. Therefore, the following hypothesis is posited:

H.1b. *Business cycle is negatively related to capital buffer, i.e. capital buffer decreases in business upturn and increases in business downturn.*

H.2b. *Business cycle is positively associated with insolvency risk, i.e. insolvency risk decreases in expansion and increases in recession.*

2.2. Income diversification determinant

The motivations for diversifying the sources of bank revenue have received extensively interest in the literature (Stiroh and Rumble, 2006; Stiroh, 2004 and DeYoung and Roland, 2001). Banks are probably to increase the production and sale of fee-based financial services to take the advantage cost scope of economies by sharing inputs in joint production. Gallo et al. (1996) argue that banks might exploit revenue scope economies by providing cross-selling chances to customers who are keen to pay for the extra convenience of financial supermarkets. A substantial body of literature (Demirgüc-Kunt and Huizinga (2010); Elsas et al. (2010); Chiorazzo et al. (2008) and Stiroh and Rumble (2006)) concludes that banking performance could be improved through a diversity of revenues, therefore, capital buffer tends to increase by holding more retained earnings.

However, Stiroh and Rumble (2006) argue that there is the deteriorating correlation of the risk return trade-off for US banks. They state that the earnings profit from diversification produced by expansion in non-interest income is outweighed by the volatility rising, resulting in a non-commensurate arising in stock returns. Furthermore, Stiroh (2004b) accomplishes that a greater dependence on non-interest income, especially trading revenue, is related with higher risk and lower risk-adjusted profits across commercial banks. Baele et al. (2007) study European banks over the time from 1989–2004 to suggest that banks which have higher non-interest income tend to have higher market betas and hence higher systematic risk. Similarly, Lepetit et al. (2008a) find that banks which tend to expand into non-interest income activities face higher insolvency risk.

In a recently study during the financial crisis, DeYoung and Torna (2013) analyse the contribution of income diversification on bank failure. They find that the movement toward non-traditional banking activities has importantly effected on the possibility of bank failure depending on the bank's financial conditions. Engagement in these activities increases the likelihood of failure for financially concerned banks. Hence, the hypothesis is formalised as below:

H.3a. *Income diversification is more likely to increase capital buffer.*

H.4a. *Income diversification is more likely to increase insolvency risk.*

Countervailing arguments, however, challenge the view that if increasing the share of non-interest income in the bank's revenue portfolio diminishes overall earnings volatility then banks may have to reduce their capital requirements (Demirguc-Kunt and Huizinga, 2010). Furthermore, Sinkey and Nash (1993) report a higher and more volatile returns as well as higher likelihood of insolvency than for banks with traditional product mixes when examining commercial banks which specializing in credit card lending. Stiroh (2004b) also emphasizes rising volatility of bank earnings arise from shifting into non-interest activities such as trading activities. In a study of Italian banks, Acharya et al. (2002) find that diversification of bank assets does not assure to produce exceptional performance to guarantee a higher retained earnings for capital cushion.

Enriching the diversification of assets and liabilities permits banks to enhance their risk and return trade-off. In other words, at any given level of risk, return is increased or evenly at any given rate of return, insolvency risk is decreased. Stiroh (2004) examines the potential diversifying repayments from the movement into non-interest income sources of bank revenue. He suggests that the rising in non-interest revenue in the US commercial banks has contributed to higher levels of bank income over time and has also reduced the volatility of bank profits, hence, reducing the possibility of insolvency risk. Pennathur et al. (2012) study the effect of ownership structure of Indian banks on the income diversification and risk relationship and they find that higher fee-based income is correlated with lower default risk for private domestic banks as well as public sector banks. These results are consistent with a cross-country study of Sanya and Wolfe (2011) who examined a sample of listed banks in 11 emerging countries. The authors find that by expansion into non-banking activities result in arising profitability and decrease bank insolvency risk. Nguyen et al. (2012) also find the benefits from diversification revenues in South Asian countries. Their results give that banks with greater market power tend to decrease their default risk when banks shift into non-interest activities. Then, the contradictory hypothesis is postulated:

***H.3b.** Income diversification is more likely to decrease capital buffer.*

***H.4b.** Income diversification is more likely to decrease insolvency risk.*

2.3. Regulatory and supervisory determinant

It is postulated that the influence of business cycle and income diversification on capital buffers and insolvency risk varies across countries, depending on bank regulation and supervision. Hence, this section analyze the impact of capital requirement, deposit insurance, official supervisor power, private monitoring practices and restriction on bank activities.

2.3.1. Capital requirement

The traditional approaches to bank regulation highlight the positive features of capital requirement (Dewatripont and Tirole, 1994). Furlong and Keeley (1989) demonstrate that capital requirements reduce risk-taking. They argue that capital serves as a buffer against loss and failure and banks are required to hold a minimum capital requirement. Hence, it can postulate as follows:

H.5. Capital requirement tends to increase capital buffer, therefore, lower probability of financial distress

2.3.2. Deposit insurance

There is a general agreement that more deposit insurance encourages banks to take greater risks (Hovakimian, 2003; Hovakimian and Kane, 2000; Merton, 1977). Demirguc-Kunt and Detragiache (2002) find a negative relationship between deposit insurance and banking stability and emphasize the destabilizing effect of guarantees in the increased likelihood of banking crises. Fonseca and González (2010) suggest that more generous deposit insurance diminishes market discipline but increase bank charter value, negatively influence on capital buffer. Hence, the sixth hypothesis is:

***H.6.** More deposit insurance makes capital buffer less important in reducing the cost of financial distress, therefore, increase probability of bank failure.*

2.3.3. Official supervisor power

Fonseca and González (2010) document that if official bank supervision is a stand-in for private supervision, it may negatively influence on capital buffer. Any official practice that curbs investors' incentives in monitoring banks would make the cost of funding less sensitive to bank risk. In a similar line, Shehazad et al. (2009) find that official supervision eliminates benefits of bank ownership concentration in reducing bank risk-taking. There it is expected as follows:

***H.7.** More official supervisory power constrains banks' capital buffer and higher excessive risk-taking.*

2.3.4. Private monitoring practices

Investor monitoring of banks requires the information disclosure mechanisms to provide information on the value of banks' claims (Nier and Baumann, 2006). Fonseca and González (2010) find that banks in countries with stricter accounting standards have higher capital buffers. On the other hand, the quality of firms' information disclosure is negatively related to credit spreads. Reduction in spreads may raise bank valuations, and eliminate banks' risk-taking incentives, therefore, encouraging greater capital buffers (Yu, 2005). Based on this argument, the following hypothesis is:

***H.8.** Stricter private monitoring practices encourage banks to hold larger capital buffer and reduce the cost of financial distress.*

2.3.5. Restriction on bank activities

Tighter restriction on bank activities limit the ability of banks' managers to involve in risky investments (Fonseca and González , 2010), reducing retained earnings, therefore, limited resources for capital buffer. The last hypothesis is:

H.9. *Tighter restriction on bank activities constrains banks' risk-taking incentives and fewer resources for capital buffer.*

3. Methodology and data

3.1. Data

Since Basel III is expected to be broadly implemented by all active banks at EU-wide level (BCBS, 2014), this study will examine the enlarged EU27 countries covers time series of 11 years from 2001 to 2011, including commercial banks, saving banks, cooperative banks, real estate and mortgage banks, investment banks and bank holding companies. Malta has no banks relative to this requirement, so Malta is omitted. In May 2004, the EU experienced the largest enlargement as 10 countries joined the EU, including Cyprus, Czech Republic, Estonia, Hungary, Latvia, Lithuania, Malta, Poland, Slovakia and Slovenia. Bulgaria and Romania then entered the EU in January 2007. Because those countries have joined the EU, the structure of their banking industries have not been in line yet, so they could create outliers to the sample. Hence, extreme outliers are dropped. There is a point which Estonia, Latvia, Slovakia are removed from this outlier process. The sample then includes 23 EU countries with exception of Estonia, Latvia, Malta and Slovakia and 4,114 banks.

Bank-specific variables are obtained from Bankscope. The information on the regulatory and supervisory variables is obtained from World Bank database by Barth et al. (2004) relative to updated version in 2008. The country-specific controls obtained from the World Bank.

3.2. Econometric model

Earlier literature on bank's capital adjustments (Jokipii and Milne, 2011; Shim, 2010; Flannery and Rangan, 2006) uses partial adjustment framework to estimate the adjustment speed toward its desired level. Following Shim (2013), this research aims to build a partial adjustment framework to investigate whether banks establish capital buffers during economic upturn to reduce the probability of insolvency risk in economic downturns or whether they keep their capital buffers at a certain level by reducing their risky non-interest income activities in recession. The banks' capital buffer and insolvency risk adjustment models, which observe changes in capital buffer and insolvency risk in period t are a function of the target capital buffer and insolvency risk, the one-year lagged buffer and risk level and exogenous shocks as follows:

$$\Delta\, CAP_{i,k,t} = \alpha\left(CAP^{*}_{i,k,t} - CAP_{i,k,t-1}\right) + \varepsilon_{i,k,t} \tag{1}$$

$$\Delta\, RISK_{i,k,t} = \beta\left(RISK^{*}_{i,k,t} - RISK_{i,k,t-1}\right) + \delta_{i,k,t} \tag{2}$$

Where $\Delta\, CAP_{i,k,t}(CAP_{i,k,t} - CAP_{i,k,t-1})$ and $\Delta\, RISK_{i,k,t}(RISK_{i,k,t} - RISK_{i,k,t-1})$ capture the observed changes in capital buffer and insolvency risk of bank i in country k between two periods. α and β indicate the speeds of adjustments. The actual and target capital buffers (insolvency risk) of bank i in country k at year t are denoted by $CAP_{i,k,t}\,(RISK_{i,k,t})$ and$CAP^{*}_{i,k,t}\,(RISK^{*}_{i,k,t})$, respectively. $CAP_{i,k,t-1}\,(RISK_{i,k,t-1})$ represents the actual capital buffer (risk) in the previous year. $\varepsilon_{i,k,t}$ and $\delta_{i,k,t}$ are the error terms.

However, Flannery and Rangan (2006) argue that the target capital buffer (insolvency risk), i.e. $CAP^{*}_{i,k,t}\,(RISK^{*}_{i,k,t})$, respectively are not observable. As indicated in the above literature, they depend on the business cycle, income diversification and the heterogeneity in the banks' risk-behaviors. Therefore, the impact of business cycle and diversification on the changes of banks' capital buffer and insolvency risk is primary interest of this research. The empirical models including business cycle, diversification variables and financial characteristics can be written as:

$$\begin{aligned}\Delta CAP_{i,k,t} = {} & \alpha_0 + \alpha_1 CYCLE_{k,t} + \alpha_2 INCDIV_{i,k,t} + \alpha_3 \Delta RISK_{i,k,t} - \alpha_4 CAP_{i,k,t-1} + \alpha_5 B_{i,k,t} \\ & + \alpha_6 C_{k,t} + \alpha_7 REGSUP_k + T_t + \varepsilon_{i,k,t}\end{aligned} \tag{3}$$

$$\begin{aligned}\Delta RISK_{i,k,t} = {} & \beta_0 + \beta_1 CYCLE_{k,t} + \beta_2 INCDIV_{i,k,t} + \beta_3 \Delta CAP_{i,k,t} - \alpha_4 RISK_{i,k,t-1} + \beta_5 B_{i,k,t} \\ & + \beta_6 C_{k,t} + \alpha_7 REGSUP_k + T_t + \delta_{i,k,t}\end{aligned} \tag{4}$$

Where $CYCLE_{k,t}$ denotes for business cycle of country k at year t. $INCDIV_{i,k,t}$ is a measure of non-interest income diversification of bank i in country k at year t. According to (Rime, 2001; Shrieves and Dahl, 1992), banks' capital and risk choices are interdependent as banks manage capital relative to the level of risk-taking incentives. Hence, in order to capture simultaneous relationship between capital buffer and risk adjustments, equation (3) and (4) include $\Delta RISK_{i,k,t}$ and $\Delta CAP_{i,k,t}$ as explanatory variables, respectively. To examine whether the speed of adjustments are relevant, this study also consists of $CAP_{i,k,t-1}\, a$ and $RISK_{i,k,t-1}$ in equation (3) and (4), respectively. To control for heterogeneity of banks' risk behaviors and country-specific condition, $B_{i,k,t}$ is included as a vector of bank financial characteristics for bank i of country k in year t whereas $C_{k,t}$ indicates a vector of country-specific control variables for country k in year t. $REGSUP_k$ is a set of regulatory and supervisory variables in country k. T_t represents time fixed-effect and $\varepsilon_{i,k,t}$ ($\delta_{i,k,t}$) are the error terms.

Since equation (3) and (4) may deal with endogeneity problem because there are one-year lagged endogenous variables. Therefore, this research will follow earlier studies (Shim, 2013; Rime, 2001; Wickens, 1982) to employ three-stage least squares (3SLS) estimation in order to take into consideration the cross-equation correlations.

Table 1 presents description of variables and sources.

Capital buffer (CAP): Banks are required to hold more capital than the regulatory minimum to withstand a distressed period. Similar to Shim (2013), bank's capital buffer equals to the difference between the actual total risk-weighted capital ratio and the minimum total required capital ratio of 8%.

Insolvency risk (ZSCORE): Following the recent literature on bank risk (Demirgüc-Kunt and Huizinga 2010, Laeven and Levine 2009), Z-score is used in this research as a main indicator of insolvency risk. It is denoted by the sum of return on assets and the capital ratio, which is then divided by the standard deviation of ROA. Standard deviation of ROA is calculated on a four, five and six-year rolling time frame to show consistency results. Furthermore, non-performing loans to total loans ratio is used in robustness test since it is evident that non-performing loan significantly deteriorates before the actual banks' bankruptcy happens (Reinhart and Rogoff, 2011).

Business cycle (CYCLE): the real GDP growth is a proxy for business cycle and its data is obtained on World Development Indicator. Based on the above hypothesis development, the influence of business cycle on capital buffer and insolvency risk is undetermined.

Income diversification (INCDIV): non-interest income to operating income is a proxy for income diversification. As mentioned by DeYoung and Roland (2001), the growing share of non-interest income directly influences volatility of bank's net operating revenue growth and higher degree of total leverage. However, the above hypotheses show that the expected sign for coefficient of income diversification on capital buffer and insolvency risk is ambiguous.

Bank-specific variables are bank size, net interest margin, deposit, loan and cost-to-income ratio.

Bank size (SIZE): Bank size, which is defined as the natural logarithm of total assets, is a common proxy in researches on bank (Curry et al., 2008; Goodard et al., 2004; Molyneux and Thornton, 1992). According to Francis and Osborne (2012), larger banks tend to hold smaller capital buffer above the minimum required capital ratio. Additionally, based on too-big-to-fail hypothesis, if bank is sufficiently large, the regulator will bail out the bank in case of financial distress (Acharya and Yorulmazer, 2007). Therefore, bank size is expected to negatively associated capital buffer and insolvency risk.

Net interest margin (NIM): Chortareas et al. (2011) define that NIM measures the gap between what bank earns from borrowers and what bank pays depositors regarding to bank's function of asset transformation. The higher NIM is, the higher the margin bank is commanding, or the cheaper the funding bank is acquiring. Therefore, NIM is expected to be positively associated with capital buffer.

Deposit (DEPOSIT): refers to ratio of deposit to total assets. When money markets work poorly and interbank lending is difficult, deposit financing helps banks more stable in financing (Beltratti and Stultz, 2009).

Loan (LOAN): characterizes the asset side of the banks by using loans to total assets.

Efficiency in expense management (COST): is defined as the operating costs divided by the gross income.

Country-specific variables are inflation and financial development.

Concentration indicator (CONC): is the Hirschman-Herfindahl index, which is computed by the sum of squared market shares in terms of total assets for each country in the sample, is common indicator for market concentration. According to traditional Structure-Conduct-

Restriction on bank activities (RESTRICT): Bank activity regulatory variable is defined to measure the degree to which banks may engage in the following three fee-based activities such as securities, insurance and real estate activities. Barth et al. (2004) assess each country's regulations concerning these activities and rated the degree of regulatory restrictiveness for each activity from 1 to 4, with larger numbers representing greater restrictiveness, including unrestricted, permitted, restricted and prohibited.

Table 2 summarizes statistics of all regression variables and Table 3 reports mean values of bank variables by country. Table 4 displays correlation matrix. In general, there is no high correlation among variables.

4. Empirical results

4.1. Business cycle and income diversification determinants

Table 5 reports the results for business cycle and income diversification determinants on capital buffer and insolvency risk. In model I, Zscore with the standard deviation of ROA rolling four-year time is used as a main results and the five-year time is employed in the model II as a robustness test to show consistency in the results. In buffer model (3), positive and significant coefficient of CYCLE (0.019) on capital buffer implies that capital buffer fluctuates procyclically over the business cycle and positively significant coefficient of INCDIV (-0.002) shows that banks with higher risky non-interest income portfolio are able to increase their capital buffer, i.e. diversification benefits exist, consistent with hypothesis H.1a. and and H.3a.

In risk equation (4), negative coefficient of CYCLE (-0.546) and negative sign for INCDIV (-0.069) suggest that banks are more likely to increase probability of failure during economic boom due to engaging excessively in risky activities, consistent with H.2a. and H.4a. In other words, potential risks increase due to increasing non-interest income activities during boom cause banks to raise their capital buffers in order to take into account their increased probability of failure. Therefore, when risks materialize in the period of economic busts, banks can draw on these higher capital cushions. The impact of $\Delta CAP_{i,k,t}$ and $\Delta RISK_{i,k,t}$ in both capital buffer and insolvency risk equations (3) and (4) is not statistically significant. Both lagged dependent variable $CAP_{i,k,t-1}$ and $RISK_{i,k,t-1}$ exhibit negatively significant coefficients, confirming that due to the presence of adjustment costs, the speed of capital buffer adjustment is relatively slow, therefore, incompletely adjustment to the higher stability in the period.

The estimated coefficient of bank size is negative and significant at 1% level in buffer equation (3) but insignificant in risk equation (4). Large banks tend to hold less capital buffers possibly because of greater diversification or government's support in case of financial distress (Shim, 2013). The profitability measured by NIM has a positive impact on capital buffer but negative influence on insolvency risk, implying that more profitable banks have higher buffers, however, increasing capital buffers incur banks to involve in risky activities and to be vulnerable to financial constrain. Deposit is negatively associated with capital buffer, confirming that deposit is regarded to be stable funding, so greater deposit portion may reduce capital buffer. The estimated coefficient of deposit in risk model is significant and positive, suggesting that such a stable funding might decrease bank failure.

To examine whether the different macro-economy level across countries may change the results, country-control variables are included for further analysis. Fortunately, the coefficient of CYCLE and INCDIV in both capital buffer and insolvency risk model are unchanged. Economically, the business cycle and income diversification have considerable impact on capital buffer and insolvency risk.

4.2. Regulatory and supervisory determinants

To analyze how the regulation and supervision across countries influence on capital buffer and insolvency risk, five regulatory and supervisory variables are included. Additionally, CYCLE and INCDIV are interacted with these five regulatory measures to examine if they are substitutes. If banks in countries with well-functioning banking system, basically in better regulatory and supervisory practices, it may not need to increase capital when banks' risk profiles increase. In this case, the positive relation is expected in all the specifications. In contrast, a negative coefficient of interactive term suggests that they are substitutes in favoring higher capital buffers and lower level of insolvency risk.

Table 6 reports the results of regulatory and supervisory determinants on capital buffer and insolvency risk. Capital regulation is found to be positively associated with insolvency risk in column (2) but insignificant in column (1). Banks tend to be more stable in countries with tighter capital regulation. The negative coefficients of CAPITAL* CYCLE in column (1) and (2) confirm that capital regulation and business cycle are substitute in capital buffer and insolvency risk. Economic downturn in countries with tighter capital regulation diminishes benefits of capital buffer, therefore, increase level of bankruptcy risk. The negative coefficient of CAPITAL*INCDIV in column (1) and its positive sign in column (2) shows that the capital regulation dampens the banks' ability in risky activities and leads banks to hold smaller capital buffers.

Turning to deposit insurance, diminished benefit of capital buffer due to more deposit insurance is not found in column (3). However, the negative and significant of DEPINS in column (4) shows that deposit insurance increase the likelihood of bank failure, consistent with prior literature (Hovakimian, 2003; Demirguc-Kunt and Detragiache, 2002; Hovakimian and Kane, 2000; Merton, 1977). The significantly positive coefficient of DEPINS*CYCLE in column (4) indicates that banks may not need to increase capital during economic boom in order to reduce insolvency risk because banks tend to be safer under upturn cycle given that their country has generous deposit insurance. As indicated by negative coefficient of DEPINS*INCDIV in column (3), deposit insurance can be substitutes for income diversification in diminishing capital buffer.

Consistent with hypothesis H.7., the results in column (5) and (6) indicate that more official supervisor power reduces banks' capital buffer, however, increases banks' probability of financial distress. The results of interactive terms are not significant in these specifications.

Regarding private monitoring practice, the results in column (7) and (8) are consistent with an expectation in hypothesis H.8. that the quality of private monitoring practice has positive impact on capital buffer and insolvency risk. The negative coefficient of PRIVATE*CYCLE confirm that business cycle and improved accounting transparency are substitutes in reducing banks' incentive to hold larger capital buffers, thereby increasing banks' risk-taking incentives.

The negative coefficient of RESTRICT in column (9) indicates that banks' capital buffer decrease in countries with tighter restrictions on bank activities. Both positive coefficients of RESTRICT*CYCLE in column (9) and (10) suggest that given the condition of tighter restriction on bank activities and business cycle upturn, banks are more stable and might not need to increase capital.

5. Conclusion

This paper examines business cycle, income diversification, regulatory and supervisory determinants of capital buffer and insolvency risk by using a panel data of EU27 countries from 2001 to 2011. Partial adjustment framework and 3SLS are employed in this study. The results show that capital buffer fluctuates procyclically over the business cycle and diversification benefits exist in encouraging banks to hold higher capital buffers. Banks are more likely to increase probability of failure during economic boom due to engaging excessively in risky activities.

Economic downturn in countries with tighter capital regulation diminishes benefits of capital buffer, therefore, increase level of bankruptcy risk. Banks tend to be safer under upturn cycle given that their country has generous deposit insurance. Deposit insurance can be substitutes for income diversification in diminishing capital buffer. Official supervision reduces banks' incentive to hold capital buffers and increase the likelihood of failure. Better private monitoring practice has a clear positive impact on capital buffers and making banks to reduce risk-taking incentives. Business cycle and improved accounting transparency are substitutes in reducing banks' incentive to hold larger capital buffers, thereby increasing banks' risk-taking incentives. Given the condition of tighter restriction on bank activities and business cycle upturn, banks are more stable and might not need to increase capital.

This paper suggests basic implications for regulatory policy. First, the regulators should take into account business cycle in a number of regulation and supervision as instruments of inducing banks to hold capital and increasing financial stability. Second, regulators and supervisors should realize that the effectiveness of tighter capital regulation varies across countries and economic downturn will diminish benefit of capital requirement. Third, deposit insurance should be clearly revisited since it tends to be a substitute in diminishing banks' incentives to hold capital buffer.

Table 1

Variable description

Variables	Description	Source
Bank-specific control variables		
CAP	Capital buffer: the difference between total regulatory variable ratio and minimum required capital ratio of 8%	Calculated using the data from Bankscope
△CAP	Change in capital buffer	Calculation
ZSCORE	Insolvency risk measured by the return on assets (ROA) plus capital to asset ratio divided by the standard deviation of ROA rolling 4-year time	Calculated using the data from Bankscope
△ZSCORE	Change in insolvency risk	Caculation
INCDIV	Non-interest income to gross revenues	Bankscope
SIZE	Logarithm of bank' total assets	Bankscope
NIM	Net interest margin	Bankscope
DEPOSIT	Deposit to total assets	Bankscope
LOAN	Loan to total assets	Bankscope
COST	Cost to income ratio	Bankscope
Country-specific control variables		
CYCLE	Annual growth rate of GDP	World Bank
CONC	Market concentration, computed by the sum of squared market shares in terms of total assets for each country	Calculated using the data from Bankscope
MACGDP	Market capitalisation to GDP	World Bank
ASSGDP	Total assets of banks to GDP	Calculated using the data from Bankscope, World Bank
Regulatory variables		
CAPITAL	Capital regulatory index	Barth et al. (2004)
DEPOSIT	Deposit insurer power	Barth et al. (2004)
OFFICIAL	Official supervisory power	Barth et al. (2004)
PRIVATE	Private monitoring	Barth et al. (2004)
RESTRICT	Restrictions on bank activities	Barth et al. (2004)

Note: This table reports summary statistics of variables for the whole sample. N is number of observations. CAP is capital buffer equal to the difference between total risk-weighted capital ratio and minimum required capital ratio of 8%. △CAP is changes in capital buffer. ZSCORE is insolvency risk measured by the return on assets (ROA) plus capital to asset ratio divided by the standard deviation of ROA rolling 4-year time. △ZSCORE is change in insolvency risk. INCDIV is non-interest income to gross revenues. SIZE is bank size. NIM is net interest margin. DEPOSIT is deposit to total assets. LOAN is loan to total assets ratio. COST is cost to income ratio. CYCLE is annual growth rate of GDP. CONC is market concentration. MACGDP is market capitalization to GDP. ASSGDP is total assets of banks to GDP. CAPITAL is capital regulatory index. DEPOSIT is deposit insurer power. OFFICIAL is official supervisory power. PRIVATE is private monitoring. RESTRICT is restriction on bank activities.

Note: This table reports correlation matrix. CAP is capital buffer equal to the difference between total risk-weighted capital ratio and minimum required capital ratio of 8%. △CAP is changes in capital buffer. ZSCORE is insolvency risk measured by the return on assets (ROA) plus capital to asset ratio divided by the standard deviation of ROA rolling 4-year time. △ZSCORE is change in insolvency risk. INCDIV is non-interest income to gross revenues. SIZE is bank size. NIM is net interest margin. DEPOSIT is deposit to total assets. LOAN is loan to total assets ratio. COST is cost to income ratio. CYCLE is annual growth rate of GDP. CONC is market concentration. MACGDP is market capitalization to GDP. ASSGDP is total assets of banks to GDP. CAPITAL is capital regulatory index. DEPOSIT is deposit insurer power. OFFICIAL is official supervisory power. PRIVATE is private monitoring. RESTRICT is restriction on bank activities. * denotes 1% significant level.

Note: This table reports the results for the 3SLS estimation. In model (1): dependent variables are rCAP calculated by changes in capital buffer and rZSCORE as change in insolvency risk measured by the return on assets (ROA) plus capital to asset ratio divided by the standard deviation of ROA rolling four-year time. In model (2): dependent variables are rCAP calculated by changes in capital buffer and rZSCORE as change in insolvency risk measured by ROA plus capital to asset ratio divided by the standard deviation of ROA rolling five-year time. CAP(t-1) is the lagged capital buffer equal to the difference between total risk-weighted capital ratio and minimum required capital ratio of 8%. ZSCORE(t-1) is the lagged insolvency risk. CYCLE is annual growth rate of GDP. INCDIV is non-interest income to gross revenues. SIZE is bank size. NIM is net interest margin. DEPOSIT is deposit to total assets. LOAN is loan to total assets ratio. COST is cost to income ratio. CONC is market concentration. MACGDP is market capitalization to GDP. ASSGDP is total assets of banks to GDP. ***, ** and * denote significant at 10%, 5% and 1% level.

Note: This table reports the results for the 3SLS estimation. The dependent variables are △CAP calculated by changes in capital buffer and △ZSCORE as change in insolvency risk measured by the return on assets (ROA) plus capital to asset ratio divided by the standard deviation of ROA rolling 4-year time. Explanatory variables are: CYCLE is annual growth rate of GDP. INCDIV is non-interest income to gross revenues. CAP(t-1) is the lagged capital buffer. ZSCORE(t-1) is the lagged insolvency risk. SIZE is bank size. NIM is net interest margin. DEPOSIT is deposit to total assets. LOAN is loan to total assets ratio. COST is cost to income ratio. Country-control variables are market concentration CONC , market capitalization to GDP MACGDP and total assets of banks to GDP ASSGDP. Regulatory variables include capital regulatory index CAPITAL, deposit insurer power DEPINS, official supervisory power OFFICIAL, private monitoring PRIVATE, restriction on bank activities RESTRICT. There are interactive terms between regulatory variables and CYCLE and between regulatory variables and INCDIV. Year and country dummy variables are included but not reported. ***, ** and * denote significant at 10%, 5% and 1% level.

Abstract
Starting in 2010, the US regulators have taken a series of actions against accounting fraud at some US-listed Chinese reverse merger companies. Recent studies have documented spillover effects against Chinese reverse mergers not accused of accounting fraud as well as Chinese IPOs but not against US-based reverse mergers. There seems to be a perception that accounting fraud is widespread among the Chinese firms. This study documents spillover effects against the Chinese firms listed in China. We also find that the financial reporting quality of the Chinese firms is no worse than that of the U.S. firms. In fact overall results suggest that the Chinese firms may even have better financial reporting quality than the U.S. firms. This study is important to academics, regulators and investors given the increasing prominence of the Chinese firms on the global capital markets and the concerns about the financial reporting quality among the Chinese firms..
Keywords: Chinese reverse mergers, Chinese listed firms, financial reporting quality, accounting fraud, earnings quality, conditional conservatism, spillover effects, accrual anomaly.

JEL: M41, M48, N25, G14, G18

1. Introduction

Reverse mergers provide a legitimate avenue for private and foreign firms to list on a US exchange, while circumventing the costly and time-consuming requirements of an initial public offering (IPO). [1] Recently, however, reverse mergers have drawn intense scrutiny from regulators because several firms, mainly from China, were accused of accounting fraud. On July 12, 2010, the Public Company Accounting Oversight Board (PCOAB), in issuing an alert about practices not in accordance with PCAOB standards, used the example of a U.S. audit firm retaining an accounting firm in the China region to perform audit procedures (PCAOB, 2010). On June 9, 2011, the Securities and Exchange Commission (SEC) cautioned against investment in reverse mergers because of the potential for fraud and other abuses (SEC, 2011). These events, among others, have resulted in Chinese reverse mergers (CRMs) facing stock price crashes, delistings, auditor resignations, and lawsuits (Bikard, 2011; Darrough et al., 2012).[2] The backlash has spilled over to CRMs not accused of fraud, and Chinese firms that entered the US market through the IPO process, but not against U.S. reverse merger companies (Ang et al. 2012). It is therefore possible that the SEC's warning, while not specifically targeting Chinese firms, coupled with concurrent alerts from the PCAOB, gave investors the perception that accounting fraud is more widespread in Chinese firms than in comparable US firms. Against this backdrop of concerns about accounting irregularities at Chinese reverse merger firms, an intriguing question, and the focus of this study, is whether there are spillover effects against Chinese firms listed in China.

In our initial tests, we re-examine market reactions to a series of regulatory actions, between July 12, 2010 and November 9, 2012, for samples of Chinese reverse merger firms, Chinese IPO firms and US reverse merger firms. We choose these three samples for the

---

[1] In a reverse merger, a shell company with negligible assets and operations acquires a private or foreign company by issuing shell shares to the owners of the private or foreign company, who then become the controlling shareholders of the merged company.

[2] See Appendix A for a timeline of major regulatory actions against the Chinese reverse mergers.

following reasons. First of all, given that the SEC cautioned investors against investing in reverse mergers in general, we would expect no difference in the market reactions between Chinese and U.S. reverse merger firms. Consistent with Ang et al. (2012), we find that Chinese reverse merger firms are more negatively affected by the U.S. regulatory actions than US reverse merger firms. The effects on US reverse mergers are modest and short-lived. Second, if, as the SEC announcement cautioned, it is reverse mergers that are prone to fraud, we expect no negative reactions for Chinese IPO firms. Again, as in Ang et al. (2012), we find significant negative market reactions for Chinese IPO firms that subject themselves to the scrutiny of the US IPO process.

The U.S. regulatory actions against Chinese reverse mergers listed in the U.S. should have been irrelevant to the Chinese firms listed in China. Note that there are no reverse merges in China. US-listed Chinese reverse mergers do not meet the stringent listing requirements to get listed in China. The Chinese firms listed in China have stronger financial performance, stronger corporate governance and better financial reporting quality than Chinese reverse mergers listed in the U.S. markets. But if the U.S. regulatory actions cause concerns about the financial reporting quality of all Chinese firms, we expect to observe spillover effects on Chinese firms listed in China as well. We document spillover effects on both A-shares (2,292 firms) held by primarily domestic investors and B shares held by both foreign and domestic investors (102 firms) although the market reactions are more negative for B-shares. Investors seem to perceive that the accounting irregularities uncovered at accused CRMs may be widespread among all Chinese firms.

Next we evaluate the earnings quality of the Chinese firms listed in China using U.S. firms as the benchmark. Using 1,334 Chinese firms listed in China and 3,287 U.S. firms over 2001-2011, we find that the earnings quality of the Chinese firms is no worse than that of the U.S. firms. Chinese firms do not carry any unique or elevated risk of accounting fraud. We repeat our analysis using nine alternative models of earnings quality plus a factor score and using samples matched on year, industry, and size and matched using the propensity score.

Results are robust. Overall results indicate that Chinese firms may even have better earnings quality than similar U.S. firms. This is consistent with Holmes (2010) who reported that accounting fraud is less common in China-based companies than in similar-sized US-based companies. This is also consistent with the anecdotal evidence that firms listed in China or Hong Kong actually show superior financial reporting quality because legal penalties for financial fraud are more severe in Hong Kong and China than in North America (Borzykowski, 2011; DeFotis, 2011).

This is the first comparative study on the earnings quality of the Chinese firms listed in China vs. the U.S. firms. This study puts the earnings quality of the Chinese firms into perspective and helps global investors assess accounting information risk for optimal asset allocation decisions. This study is timely as the Shanghai stock market has recently become open to global investors. Our study is related to concurrent CRM studies (Chen et al., 2012; Darrough et al., 2012; Givoly et al., 2012; Lee et al., 2013).

The empirical evidence on the Chinese firms listed in China is particularly important as the presence of the US-listed Chinese firms is minimal by any measure. The 2,491 firms listed in China as of June 2013 dwarf the 56 Chinese IPOs and the 159 CRMs listed in the U.S. (PCAOB, 2011). The CRMs had a market capitalization of $12.8 billion and the Chinese IPO firms had a market capitalization of $27.2 billion (PCAOB, 2011), accounting for a tiny fraction of the U.S. capital markets valued at more than $20 trillion.

This study is timely for investors who are torn between the fear of accounting fraud and the unique investment opportunities furnished by the Chinese stocks. China became the second largest economy in 2011 and its GDP doubles that of Japan in 2014. China has the fastest economic growth of 7.4% in 2014. Chinese companies are gaining an increasingly stronger presence on the global capital markets. [3] The Chinese stock market is largely immune to foreign shocks, thereby providing effective diversification for global investors (Rösch & Schmidbauer, 2008). The Chinese stock market has been a hedge as well as a safe

[3] Chinese companies made up 37% of global IPO issuance, 64% of Asia's IPO and 40% of regional (Asia ex-Japan) bond issuance in 2010 according to Dealogic (Flatt, 2011).

haven for the G7 stock markets in both sub-sample periods 1993–1999 and 2000–2008 (Lai & Tseng, 2010).

This study provides empirical evidence relevant to the U.S. congress that has been concerned about the financial reporting of Chinese firms. For instance, the US congress held hearings on "Chinese Fundraising Activities in the US Capital Markets" in 2001 and on "China's Presence in the Global Capital Markets" in 2004. The US-China Economic and Security Review Commission warned U.S. investors in 2002 about the information risks associated with investing in Chinese stocks (Baker et al., 2012). This study is also relevant to the Wall Street in its competition with emerging financial centres in Asia as more emerging market companies might choose to raise funds in Asia. China has more companies traded on the NASDAQ than any other country outside of the US (Lazaroff, 2012).

This paper continues as follows. Section 2 reviews prior literature and develops hypotheses. Section 3 discusses research design. Section 4 presents descriptive statistics and empirical results. Section 5 concludes with a summary and discussion.

2. Prior literature and hypothesis development

2.1. Spillover effects against the Chinese firms listed in China

There has been a significant increase in reverse mergers (RM) on the U.S. capital markets in the last decade. The increase is partly driven by the increasing number of Chinese private firms that went public via reverse mergers on the U. S. markets. Those Chinese firms were guided by US professional firms to choose the RM route which bypasses the scrutiny, expense and time of registering an IPO.

The appeal of the China growth story attracted investors to US-listed Chinese stocks which generated remarkable returns until early 2010. For instance, the Bloomberg China Reverse Mergers (CRM) index generated a return of 156% versus 2% return for S&P 500 from December 2008 to January 2010 (Darrough et al., 2012). The strong performance of Chinese stocks even defied negative coverage of accounting issues in the media until the

Public Company Accounting Oversight Board (PCAOB) issued Alert No. 6 on July 12, 2010 highlighting the auditing problems related to Chinese reverse mergers. CRMs have since faced negative publicity, an extraordinary flurry of regulatory actions, fraud allegations, stock price crashes, auditor resignations, suspensions, lawsuits, and FBI actions (Bikard, 2011; Darrough et al., 2012; PCAOB, 2010, 2011; SEC, 2011).[4]

There were concerns about potential spillover effects on the US-based reverse mergers (RM) which are typically small-cap firms responsible for the creation of most jobs. These concerns are legitimate as reverse merger (RM) firms have a bad reputation for accounting fraud (Flatt, 2011; Floros & Shastri, 2009; Templin, 2012). Recent studies demonstrate that RM firms exhibit lower earnings quality than firms who go public through an IPO (Chen et al., 2012; Chu et al., 2012; Givoly et al., 2012).

Recent studies (Ang et al. 2012; Darrough et al., 2012; Lee et al., 2013), however, have documented little spillover effects against RMs based in the US or other countries but significant spillover effects against CRMs not accused of accounting fraud. This result is puzzling as US-based RMs are also prone to earnings management (Chen et al., 2012; Chu et al., 2012; Givoly et al., 2012; Siegel & Wang, 2013). CRMs even exhibit better earnings quality and stronger financial performance than their US counterparts and even-matched IPO firms (Darrough et al., 2012; Humphery-Jenner, 2012; Lee et al., 2013).[5]

The spillover effects also extend to bigger and stronger Chinese IPO firms listed on the U.S. markets (Ang et al. 2012; Darrough et al., 2012). It is important to note that Chinese firms have to obtain regulatory approval in China before going public through an IPO overseas; similar screening is not applicable either to CRMs or to US-based firms. Chinese IPO firms are bigger, financially stronger, face lower risk of lawsuit for fraud, have more analyst following and lower leverage and better financial reporting quality than CRMs (Ang et al., 2012; Jindra et al., 2012). The pattern of spillover effects suggests that that the *reverse*

[4] See Appendix A for a list of regulatory actions related to Chinese reverse mergers.

[5] An alternative explanation for the bewildering pattern of spillover effects might be related to the wording or interpretation of the PCAOB alert (PCAOB, 2010, 2011) and the SEC warning (SEC, 2011) targeting Chinese firms.

merger identity of CRMs seems to be fine but its *Chinese* identity seems to be in trouble. That raises a question about the potential spillover effects on the Chinese firms listed in China that also share the *Chinese* identity. But it is not clear whether such spillover effects will extend to the Chinese firms listed in China as there are no reverse mergers in China and US-listed CRMs are not listed in China. Hence we state our first hypothesis in the null form as follows:[6]

$H1_0$: *The US regulatory actions against Chinese reverse mergers have no spillover effects on the Chinese firms listed in China.*

2.2 Financial reporting quality in China vs. the US

The economic boom since 1978 in China has generated a demand for a strong capital market.[7] The rapid development of stock markets, the influx of foreign investment and the rise of the private sector have generated a demand for a solid financial reporting system. Prior literature has documented primary determinants of financial reporting quality as follows (see Bushman & Piotroski, 2006; Thornton, 2002):

Accounting standard: China has revolutionized its accounting standard by issuing four increasingly-refined sets of accounting standard, successfully converging with IFRS (IASB, 2006; Liu et al., 2011). Street and Gray (2002) suggest that the successful convergence with IFRS in China might be driven by the incentives to overcome negative perceptions and gain investor acceptance. Prior literature (Barth et al., 2008; Daske et al., 2008) demonstrates that adopting IFRS improves financial reporting quality and facilitates efficient capital markets. Liu et al. (2011) document a significant decrease in earnings management and increase in value relevance after the mandatory adoption of IFRS in 2007 in China, suggesting that the Chinese regulatory oversight is effective. Compared with IFRS or

---

[6] Darrough et al. (2012) report that the spillover effects are observed only after the PCAOB published Alert No. 6 on July 12, 2010. So it is the regulatory move rather than scandals or negative publicity that highlighted the accounting problems among the CRMs. The pronounced effects might be because the PCAOB alert is the first major regulatory move against the US-listed Chinese firms (Darrough et al., 2012) and negative publicity was previously more than offset by the appeal of the China growth story.

[7] The Shanghai and Shenzhen stock exchanges were established in December 1990 and July 1991, respectively. China had the largest IPO market in 2007 (Jia et al., 2009). By the end of 2007, the market capitalization in China reached US$4.5 trillion, second only to the United States (Liu et al., 2011).

US GAAP, Chinese standards are rigid, more specific and prescriptive, leaving much less room for earnings management (Chen, Lee & Li, 2008; Kimbro, 2005). [8]

Audit quality: China has revolutionized its auditing standards and auditing profession in an attempt to improve audit quality (Firth et al., 2011; Gul et al., 2003). Two new sets of auditing standards modelled after the International Auditing Standards became effective in 1996 and 1997, respectively (Sami & Zhou, 2008). Auditors are subject to administrative penalties, monitoring and sanctions by regulators and the Chinese Institute of Certified Public Accountants (Chen et al., 2011; Defond et al., 2000). In an unprecedented move, the Chinese Supreme Court issued a legal document in 1996 highlighting legal liabilities for auditors (Gul et al., 2003). In 2002, the Chinese Supreme Court defined auditors' liabilities for damages to investors for undetected material misstatements; negligent auditors became subject to Joint and Several liability clauses. In addition, the 2005 Security Act mandates that auditors be held liable for damages to investors (Chen et al., 2011). It is the radical change from the absence of legal risk to the presence of legal risk rather than the absolute level of legal risk that exerts a significant impact on the incentives of auditors. In contrast, the combined impact of the Private Securities Litigation Reform Act of 1995 and the 1994 Supreme Court decision caused litigation against auditors to drop off sharply despite allegations of accounting fraud in the majority of securities lawsuits in the U.S. (Coffee, 2006; Liu & Elayan, 2013).

Empirical evidence shows that the Chinese auditors are playing an increasingly effective policing role in the financial reporting process. For instance, Chen et al. (2001) report significant increases in the modified audit opinions (MAOs) following the first set of auditing standards issued in 1995. About 11% of listed companies received MAOs each year, much higher than the 0.98% in the US in 1992 (Rittenberg & Schwieger, 1993). Other studies (e.g., DeFond et al., 2000; Sami & Zhou, 2008) confirm the effectiveness of the new auditing

---

[8] In China, straight line is the only depreciation method allowed with residual values fixed at 3-5%;; bad debt provision is set at 0.3–0.5% of receivables; assets cannot be re-valued without official approval from government (Kimbro, 2005).

standards in improving audit quality, earnings quality, and value relevance, and reducing information asymmetry. In 2005, the total adjusted profits (assets) after audits were 21.66% (4.03%) of total unadjusted profits (assets) before audits.

Increasing effectiveness of regulators: The China Securities Regulatory Commission (CSRC) has been the de facto regulator since the 1999 Securities Law (Firth et al., 2011; Jia et al., 2009; Layton, 2008). Partly modeled after the SEC, the CSRC is more powerful and plays a more active role than its U.S. counterpart (Liu et al., 2010). For example, all the IPO or SEO applications in China must be approved by the CSRC which has the power to approve or decline applications without giving any justification and plays a screening role to protect investors. This screening process is not applicable in the U.S. Humphery-Jenner (2012) has documented the effectiveness of the CSRC in screening Chinese firms for public listings in China or overseas. While the CSRC has stringent listing requirements, the SEC has no formal listing requirements. [9] As such, many Chinese companies find it easier to get a listing in the U.S. than in China (Aubin, 2011).

Like the SEC, the CSRC has limited resources. Layton (2008) argues that enhancing the CSRC's resources will render it an effective agency to detect, punish, and deter fraud. Towards that end, the CSRC aggressively recruits staff from regulatory agencies in Hong Kong as well as from auditing and law firms (Jia et al., 2009). In contrast, the SEC has downsized its workforce by more than 50% over the last five decades due to a steady increase in civil cases which are dealt with outside the SEC (Peng, 2007).

Empirical studies have documented increasing effectiveness of the CSRC and the stock exchanges in enforcing standards and listing rules and sanctioning fraudulent behaviour over the past two decades (Baker et al., 2012; Liebman & Milhaupt, 2008). About 20% of the listed firms were convicted by the CSRC for fraud (Sun & Zhang, 2006). The CSRC and the exchanges took 581 enforcement actions between 1994 and 2007 (Jia et al., 2009). In contrast, Karpoff et al. (2008) identify 788 enforcement actions by the SEC and the

---

[9] See http://www.sec.gov/answers/listing.htm. NYSE or NASDAQ listing standards are much less onerous than the CSRC listing requirements; the post-listing obligations are more stringent in the US than in China (Humphery-Jenner, 2012).

Department of Justice between 1978 and 2006. Note that the US has far more firm-year observations during the sample period. Firth et al. (2011) identify 813 restatements in 2000-2005 in China. On average, about 3.7% of listed firms restate their financial numbers each year in China. Additionally, Liebman and Milhaupt (2008) find that public stock exchange criticisms, a novel mechanism of securities regulation, led to significant negative effects on stock prices.

Legal enforcement: China has amended its corporate law four times to strength legal enforcement (Jia et al., 2009; Zou et al., 2008). The Supreme Court issued detailed provisions on private securities litigation related to false disclosures in 2003, representing a breakthrough exposing directors and managers to civil liabilities (Zou et al., 2008). The 2005 amendments to corporate and security law unprecedentedly provide legal provisions for statutory derivative lawsuits and empowered shareholders to take legal actions against directors and managers for fraud.

Recent evidence indicates some effectiveness of enforcement. For instance, the first successful civil lawsuit was concluded against a listed company in November 2002 (Chen et al., 2006). On May 25, 2005, the court ordered Guangxia Industry Inc. to compensate its minority shareholders. The chairman of Guangxia Industry Inc. was sentenced to a three-year jail time for faking revenue. Zou et al. (2008) document a non-trivial level of perceived securities litigation risk in China. Specifically, firms with more agency problems and earnings management are more likely to seek Directors' and Officers' (D&O) insurance coverage against potential securities lawsuits. The decision to purchase D&O insurance is positively related to the presence of independent directors and litigation risk proxies. The results are consistent with prior D&O insurance studies conducted in jurisdictions with common-law traditions.

It is also reported that firms listed in China or Hong Kong actually show superior financial reporting quality because legal penalties for financial fraud are more severe in Hong Kong and China than in North America (Borzykowski, 2011; DeFotis, 2011). Criminal prosecution could face up to death penalty in China but not in the US (Chen et al., 2006). Managers face minimal penalties for overstating earnings in the US as corporate insiders rarely contribute to lawsuit settlements (Coffee, 2006; Romano, 1991). Without a system of greater managerial liability, deterrence through private enforcement is a mirage in the U.S. (Coffee, 2006).

Earnings management incentives: Healy and Wahlen (1999) classify earnings management incentives into three categories for U.S. firms: (1) capital market incentives, (2) contracting incentives, and (3) regulatory incentives. U.S. firms manage earnings in order to increase offering prices before SEOs and IPOs or stock-based acquisitions (Teoh, Welch, & Wong, 1998a, 1998b), circumvent dividend constraints (Healy & Palepu, 1990) or debt covenants (Watts & Zimmerman, 1986) or lower market assessment of earnings volatility (Trueman & Titman, 1988). U.S. firms may understate accounting earnings to gain advantages during labour union wage negotiations or management buyout takeovers (Chung et al., 2002; Perry & Williams, 1994). Executive bonuses or equity-based compensation may also induce earnings management (Bergstresser & Philippon, 2006; Watts & Zimmerman, 1986). Stock price consideration and analysts create strong incentives for earnings management in the U.S. (Graham et al., 2005).

The incentive structure of the Chinese firms is quite different. In China, controlling state shareholders pay little attention to stock prices. Analysts play a primitive role in the Chinese market and their forecasts have little impact on stock prices (Wang et al., 2008). Chinese managers have negligible shareholdings in their firms (Chen, Choi & Jiang, 2008). Option-based compensation did not exist until 2005; the use of options was minimal even after 2005 (Conyon & He, 2012; Wang & Yung, 2011). Compensation contracts of CEOs in state-controlled listed firms put less weight on accounting performance and more emphasis on social and political goals (Chen et al., 2011). Yang et al. (2012) conclude that personal incentives play a much smaller role in earnings management in China than in the U.S.

Prior literature documents three regulatory incentives for earnings management in China: 1) to meet the stringent profitability requirement for going public, 2) to meet the stringent profitability requirement for post-IPO equity offering, and 3) to meet profitability requirement to avoid trading suspensions or delisting (e.g., Aharony et al., 2010; Chen, Lee & Li, 2008; Chen et al., 2011; Firth et al., 2011; Jian & Wong, 2010). But the stringent listing requirements in China restrict the issuance of shares to the largest and most profitable firms obviating the need for earnings management. Effective 2001, the CSRC makes adjustments to accounting earnings and uses core earnings when evaluating firm profitability for the IPO and SEO approval (Chen, Lee & Li, 2008). The regulatory incentives for earnings management are also counterbalanced by potential regulatory penalties (Chen & Yuan, 2004). Managers may be barred from serving as managers or directors of a listed company and face up to death sentence for fraud; firms could lose access to capital market. The incentives to boost earnings and meet the stringent profitability requirements for IPOs eased as the Small and Medium Enterprises (SME) Board was launched to deal exclusively with securities of small and medium enterprises in June 2004.

While some studies argue that, like the U.S. firms, the Chinese firms have incentives to inflate earnings in order to issue shares at higher IPO prices (e.g., Aharony et al., 2010; Chen et al., 2011), Wang (2005) found no evidence of earnings management prior to the IPO. In fact, Kimbro (2005) finds that Chinese firms use discretionary accruals to decrease earnings prior to IPOs as China exhibits the greatest degree of IPO underpricing. Chinese firms might be interested in banking income to meet the stringent profitability requirements for post-IPO equity financing or to avoid delisting. Reputation concerns might motivate managers to manage earnings to avoid delisting (Chen, Lee & Li, 2008). The Chinese "shame" culture also means that managers have incentives to avoid losing face in the event of getting caught in fraud (Wang &Yung, 2011). Firms might manage earnings for tax purpose or tunneling incentives but they tend to offset each other such that there is no discernable earnings management (Lo et al., 2010).

In summary, while there is a perception that accounting fraud is widespread among the Chinese companies, there are reports that the Chinese firms even have higher financial reporting quality than U.S. firms. While it is true that the U.S. has a well-developed infrastructure for financial reporting, it also has to deal with major accounting scandals and restatements. While China has taken dramatic measures to improve its financial reporting system, there is plenty of empirical evidence of earnings management. A comparative review of the major determinants of financial reporting quality does not seem to yield a clear-cut conclusion. It is generally believed that the legal liability and the rigorous SEC enforcement improve earnings quality when foreign firms cross list in the U. S. Yet Eng and Lin (2012) report that Chinese firms cross-listed in the U.S. and Hong Kong do not show better earnings quality compared with those Chinese firms listed in China alone. There seems to be a consensus that more compliance and transparency is required in the U.S. than in China (Donville & Schatzker, 2012). But there is no empirical evidence on the earnings quality of the Chinese firms listed in China vs. the U.S. firms. Hence our second hypothesis is stated in the null form as follows:

H2$_0$: *There is no difference in the earnings quality between the Chinese firms listed in China and the U.S. firms.*

3. Research design

3.1 Data and samples

Data for the Chinese companies listed in China are downloaded from the China Stock Market & Accounting Research (CSMAR) database. Data for the U.S. companies are downloaded from COMPUSTAT and CRSP. Data on reverse mergers are downloaded from Dealflow; we did a Google search as a supplement.

We choose to use the 2001-2010 firm-year observations for two reasons. First of all, the Chinese stock exchanges were established in 1990 and 1991, respectively. The financial reporting infrastructure was in the preliminary stages prior to 2001 representing an outdated picture. In fact China has been experiencing significant improvements even over the sample period. Second, the number of stocks was quite small in the early years. For instance, there were 6, 13, and 70 stocks in 1990, 1991, and 1992, respectively. Third, annual report data were available until 2011 at the time the study was conducted. We truncate top and bottom 1% of the dependent and independent variables as well as control variables to improve normality and ease the impact of outliers.

We estimate the abnormal stock returns using the Fama-French (1993) three-factor model as the return-generating process. We estimate average abnormal return (AAR), cumulative abnormal return (CAAR), and test statistics as in Cowan (1992).

3.2 Measurements of earnings quality and perceived earnings quality

There is no universally accepted definition or measure of earnings quality and no single proxy is likely to cover all the dimensions of financial reporting quality. We use two alternative versions of the modified Jones model and the modified Dechow-Dichev model. The two models have been widely used in the accounting literature (e.g., Chen et al., 2012; Givoly et al., 2009; Hope et al., 2013; Wang, 2006). We also use a discretionary revenue model (McNichols & Stubben, 2008; Stubben, 2010) and the ratio of accruals to cash flows (Burgstahler et al., 2006) as well as a principal component factor as a comprehensive proxy for earnings quality. See Appendix B for details on the proxies.

In addition, we use two alternative models of conditional conservatism as the proxies for earnings quality. Greater conditional conservatism suggests that firms are more likely to recognize economic losses in accounting earnings. Thus greater conditional conservatism indicates better earnings quality given the dominant incentives of managers to inflate earnings. We also run Mishkin (1983) test for additional analysis. The first model of Mishkin test regresses accounting earnings on the operating cash flows and accruals in the previous year to gauge the information content contained in accounting accruals about the earnings in the following year. The greater information content indicates higher accrual quality. The Mishkin test also allows us to gauge the degree of overpricing of accruals and evaluate the perceived earnings quality for the Chinese firms and the U.S. firms. We also obtain abnormal returns for the deciles sorted on accruals to quantify the consequences of misperceived earnings quality for the Chinese firms and the U.S. firms, respectively.

3.3 Empirical models

We run the following regression using the 2001-2011 firm-year observations to compare the earnings quality of the U.S. firms and the Chinese firms listed in China.

$$EQ_t = \beta_0 + \beta_1 CHI_t + \gamma Controls_t + \varepsilon_t \tag{1}$$

Where *EQ* is earnings quality, the natural logarithm of one of the six proxies as well as the principal component factor; *CHI* is a dummy variable equal to one for the Chinese firms listed in China and zero otherwise; control variables are firm size, ROE, leverage, sales growth, asset growth, capital need in the following year, inventory, net loss, loss in a previous year, firm age, book to market ratio, and ROA. If the earnings quality of the Chinese firms is lower than that of the US firms, we expected to see a positive β_1. Higher *EQ* values represent lower earnings quality.

We compare the conditional conservatism of U.S. firms and Chinese firms using the two alternative models below developed by Ball and Shivakumar (2005).

$$\Delta NI_t = \beta_0 + \beta_1 D\Delta NI_{t-1} + \beta_2 \Delta NI_{t-1} + \beta_3 D\Delta NI_{t-1} \times \Delta NI_{t-1} + \beta_4 CHI + \beta_5 CHI \times D\Delta NI_{t-1} + \beta_6 CHI \times \Delta NI_{t-1} + \beta_7 CHI \times D\Delta NI_{t-1} \times \Delta NI_{t-1} + \gamma Controls + \varepsilon_t \tag{2}$$

Where ΔNI is the change in net income scaled by lagged total assets; $D\Delta NI$ is a dummy variable equal to one for negative ΔNI in the prior year. β_2 measures the persistence of positive ΔNI; β_3 measures the differential persistence of negative ΔNI. Conditional conservatism, characterized by more timely recognition of losses, means that negative ΔNI will be less persistent than positive ΔNI and predicts negative β_3. β_7 measures the differential persistence of Chinese versus US firms. If Chinese firms have less conditional conservatism, β_7 is expected to be positive.

$$ACC_t = \beta_0 + \beta_1 DCFO_t + \beta_2 CFO_t + \beta_3 DCFO_t \times CFO_t + \beta_4 CHI + \beta_5 CHI \times DCFO_t$$
$$+\beta_6 CHI \times CFO_t + \beta_7 CHI \times DCFO_t \times CFO_t + \gamma Controls + \varepsilon_t \quad (3)$$

Where *ACC* is total accruals; *CFO* is operating cash flows; *DCFO* is a dummy variable equal to one for negative *CFO*. Both *ACC* and *CFO* are deflated by lagged total assets. The role of accruals in mitigating noises in operating cash flows predicts that β_2 will be negative (Dechow et al., 1998). Conditional conservatism, characterized by more timely recognition of losses, reduces the negative correlation between *ACC* and *CFO* and predicts a positive incremental coefficient on β_3. β_3 is thus a measure of conditional conservatism. If Chinese firms have less conditional conservatism, β_7 is expected to be negative.

We estimate the forecasting equation (#4) and the valuation equation (#5) below to perform the Mishkin (1983) test.

$$\text{EARN}_{t+1} = \gamma_0 + \gamma_1 \text{ x CFO}_t + \gamma_2 \text{ x ACCR}_t + \nu_{t+1} \quad (4)$$
$$\text{Ab\_Ret}_{t+1} = \alpha + \beta \text{ x } (\text{EARN}_{t+1} - \gamma_0 - \gamma^*_1 \text{ x CFO}_t - \gamma^*_2 \text{ x ACCR}_t) + \varepsilon_{t+1} \quad (5)$$

where EARN_{t+1} is net income at Year *t+1*; CFO_t is operating cash flows deflated by lagged assets at Year *t*; ACCR_t is total accruals, the difference between EARN and CFO at Year *t*; Adj_Ret_{t+1} is abnormal returns at Year *t+1* calculated as the difference between a firm's buy-and-hold annual return ending three months after the fiscal year end, inclusive of dividends and any liquidating distributions, and the buy-and-hold return on a size matched value-weighted portfolio of firms. The forecasting coefficients gauge the persistence of *CFO* and *ACCR*. Higher coefficients on *ACCR* indicate greater information content contained in the accruals about future earnings. If the market valuation coefficient is greater than its forecasting counterpart, the market overprices that earnings component and vice versa.

4. Results

4.1 Descriptive statistics

Table 1 presents descriptive statistics. The Chinese firms have higher (lower) earnings quality for five (one) out of the six proxies than the U.S. firms. Recall that higher values of earnings quality measures indicate lower earnings quality. The Chinese firms are much smaller than the U.S. firm. Chinese firms have stronger financial performance (i.e., higher ROE and ROA and lower percentage of net losses) than the U.S. firms. This might be related to the more rigorous listing requirements in China allowing only healthy firms to go public and consistent with the faster economic growth in China. This might partially explain the better earnings quality of the Chinese firms as stronger financial performance obviates the need for earnings management. Chinese firms show much higher growth rate than the U.S. firms (sales growth, asset growth, and book to market ratio), consistent with the rapid economic growth in China. Capital need is similar between the two samples.

Untabulated results show moderate correlations among the four measures based on the modified Jones and modified DD models but weaker correlations between these four and the discretionary revenue measure. There is rather weak correlation between the ratio of accruals to cash flow and the other five measures. Financial performance based on ROE, ROA, and net losses is positively correlated with earnings quality, indicating that strong financial performance reduces the incentives for earnings inflation.

4.2 H1 results on the spillover effects

Panel A of Table 2 reports the market reactions to the U.S. regulatory actions against CRMs for three groups of firms listed on the U.S. exchanges: Chinese reverse mergers (CRM), Chinese IPO firms, and US-based RMs. Panel A shows significant negative market reactions for CRMs for most regulatory actions as well as on the aggregate. The spill-over effects also extend to the Chinese IPOs but the effects are less pronounced compared with CRMs; negative market reactions are moderate and short-lived for U.S. reverse mergers. This is consistent with the findings of recent studies on the Chinese reverse mergers (Ang et al., 2012; Darrough et al., 2012).

Panel B of Table 2 reports negative market reactions for the 2,292 A-shares (held primarily by domestic investors) and 102 B-shares (held by both domestic and foreign investors) listed in China. The spill-over effects on B-shares are more severe. The spill-over effects also extend to the Chinese firms listed in China.

4.3 H2 results on accrual quality

Table 3 presents the results on the earnings quality of the Chinese firms listed in China vs. the firms listed in the U.S. The coefficients on *CHI* are negative for all the models except when *ACC/CFO* is used as the proxy. [10] The negative coefficient indicates that the Chinese firms listed in China have higher earnings quality than the U.S. firms. Recall that higher values indicate lower earnings quality. The coefficient on *CHI* is also negative when we use the factor score as the broader proxy for earnings quality. Results are robust to control variables and robust to industry and year fixed effects. Results remain unchanged when we match Chinese firms with U.S. firms on year, industry and size as reported in Table 4. Results remain intact when we use the propensity score matching method. Results are also robust to the exclusion or inclusion of cross-listed firms in the U.S. sample. We repeat this robustness test because cross-listed firms are also subject to the U.S. financial reporting infrastructure such as standards, regulation and private litigation and cross-listed firms are relevant for investors and regulators.

The coefficients on control variables are generally consistent with previous studies. For example, the coefficients on *SIZE* are negative across the models and samples except for a few instances where *ACC/CFO* is used as the proxy. This is consistent with prior literature (Ashbaugh-Skaife et al., 2008; Chen et al., 2012; Hope et al., 2013; Wang, 2006) indicating that larger firms show better earnings quality. Consistent with Wang (2006), the coefficients on *LEV* are negative across the models and samples except when *ACC/CFO* is used as the proxy, indicating that debt contracting constrains earnings management. This is also consistent with the conservatism literature that *LEV* is positively related to conditional conservatism (Liu et al., 2013). The coefficients on both sales growth and asset growth are

[10] Hope et al. (2013) show that the ratio of accruals to cash flows and the discretionary revenue measure are likely to measure different aspects of financial reporting quality than the modified Jones and modified DD models.

positive across the models and samples although they are negative when *ACC/CFO* is used as the proxy. This is consistent with prior literature (Ashbaugh-Skaife et al., 2008; Chen et al., 2012; Hope et al., 2013; Wang, 2006). Consistent with Hope et al. (2013), the coefficients on capital need are positive across the models and samples although they are negative when *ACC/CFO* is used as the proxy, indicating that firms with upcoming debt or equity financing plans are more likely to manage accruals in an attempt to boost earnings. The coefficients on *LOSS* are positive across the models and samples, consistent with Ashbaugh-Skaife et al. (2008) and Wang (2006), indicating that firms inflate accruals to avoid reporting net losses. The coefficients on book-to-market ratio are negative across the models and samples although they are positive when *ACC/CFO* is used as the proxy, consistent with Chen et al. (2012) and Ashbaugh-Skaife et al. (2008). In short, overall results indicate that Chinese firms listed in China do not carry any unique or elevated risk of accounting fraud when we use U.S. firms as the benchmark.

4.4 Empirical results on conditional conservatism

Panel A of Table 5 shows negative coefficients for β_3, consistent with the more timely recognition of losses implied by conditional conservatism. The result indicates that U.S. firms display conditional conservatism. The result also shows negative and statistically significant β_7, indicating that Chinese firms are even more conservative than U.S. firms. The results are robust to controls for firm size and leverage (Ball & Shivakumar, 2005). Untabulated results show that the result is also robust to additional control for book-to-market ratio (*BM*), which is positively related to conditional conservatism (Liu et al., 2013). The results remain the same whether or not year and industry- fixed effects are included in the models. The results are similar when we repeat our analysis using the samples matched on year, firm size, and industry. In short, the results from the earnings changes model show that the Chinese firms are more conservative than U.S. firms.

Panel B of Table 5 shows that β_3 is positive and statistically significant, consistent with the more timely recognition of losses implied by conditional conservatism. The results suggest that U.S. firms display conditional conservatism. The coefficients β_7 are negative and statistically significant. This indicates that the Chinese firms are less conservative than U.S. firms. The results are similar when we run the regression without any controls or with controls for firm size, leverage, book to market, or year and industry fixed effects. In summary, while the results from the earnings changes model show that Chinese firms are more conservative, the results from the accruals-based model show that U.S. firms are more conservative.

4.5 Mishkin test results

Table 6 presents the results of Mishkin tests. First we evaluate the information content contained in accruals about earnings in the following year. The more information content, the higher the accrual quality. For U.S. firms, the forecasting coefficients on accruals and cash flows are 0.50 and 0.81, respectively; for Chinese firms, they are 0.52 and 0.62, respectively. In other words, the coefficient on accrual is 38% of the total coefficients on accruals and cash flows for U.S. firms; it is 46% for Chinese firms. To put it another way, the coefficient on accrual is 62% of the coefficient on cash flows for U.S. firms, compared with 84% for Chinese firms. Therefore, accounting accruals of Chinese firms provide more information about earnings in the following year than accounting accruals of U.S. firms. This result suggests that Chinese firms exhibit greater accrual quality than U.S. firms.

Second, we compare the forecasting coefficients with the valuation coefficients for Chinese and U.S. firms. Marginal significance is zero for cash flows and accruals of both U.S. and Chinese firms. Therefore, cash flows and accounting accruals are overpriced by the investors in both U.S. and China. This is consistent with the accrual anomaly documented in prior literature (Sloan, 1996; Pincus et al., 2007). But the overpricing of accruals is much more severe for U.S. firms than for Chinese firms. The valuation coefficient on accruals is 1.50, three times the forecasting coefficient of 0.50 on accruals for U.S. firms. In contrast, the valuation coefficient on accruals is 0.96, 1.85 times the forecasting coefficient of 0.52 on accruals for Chinese firms. The difference in the valuation and forecasting coefficients on accruals is 1.00 for U.S. firms, more than twice the difference of 0.44 for Chinese firms. This is consistent with the perception that U.S. firms have greater earnings quality than Chinese firms. It also indicates more severe overestimation of the accrual quality of U.S. firms. This is consistent with Alam et al. (2015) who document that investor perception of accrual quality affects market pricing of accruals leading to investment losses for investors.

5. Conclusions and discussions

Starting in 2010, U.S. regulators have taken a series of actions to address the accounting fraud at some Chinese reverse merger firms listed on the U.S. exchanges. Recent studies have documented significant spillover effects against Chinese firms not accused of fraud but not against U.S. reverse mergers. We confirm significant spillover effects against Chinese reverse mergers as well as Chinese IPOs not accused of fraud. U.S.-based reverse mergers are mostly immune. We also document significant spillover effects against the Chinese firms listed in China. This suggests that investors have switched their attention from the China growth story to accounting irregularities among Chinese firms.

There seems to be a perception that accounting fraud is widespread among Chinese firms. Yet there is no empirical research putting into perspective the financial reporting quality of Chinese firms. Misconceptions about Chinese companies are costly not only to innocent Chinese companies but also to global investors as Chinese companies are gaining an increasingly stronger presence in global capital markets. Using the 2001-2011 firm-year observations, we evaluate the earnings quality of Chinese firms listed in China by using U.S. firms as the benchmark. Overall results demonstrate that Chinese firms do not carry any unique or elevated risk of accounting fraud. In fact, we provide some evidence that Chinese firms may even have better earnings quality than U.S. firms.

Appendix A: U.S. Regulatory Actions with regard to Chinese Reverse Mergers

July 12th, 2010: The Public Company Accounting Oversight Board (PCAOB) issued Staff Audit Practice Alert No. 6 alerting investors to the auditing problems related to Chinese reverse mergers.

September 9th, 2010: In a letter to the SEC and the PCAOB, the House Financial Services Committee questioned the accuracy of audits done for publicly traded Chinese companies and urged agencies to address the issue. Rep. Lee said, "China is the second-largest economy, and it's growing at such a rapid pace [that] there is an opportunity for exploitation and fraud.

March 14th, 2011: the PCAOB office of Research and Analysis (ORA) issued a research note entitled "Activity Summary and Audit Implications for Reverse Mergers Involving Companies from the China Region. It provides some statistics about Chinese reverse mergers which represent 26 percent of all reverse merger transactions. It reiterates its concern about the auditing problems related to the Chinese reverse mergers.

April 4th, 2011: In a speech before the Council of Institutional Investors Annual Conference, SEC Commissioner Luis Aguilar expressed deep concern over foreign reverse mergers including Chinese reverse mergers.

April 27th, 2011: in response to a congressional inquiry by the Chairman of the Committee on Oversight and Government Reform, SEC Chairman Mary L. Schapiro issued a letter seeking to assure Congress and the public that the SEC "has moved aggressively to protect investors from the risks that may be posed by certain foreign-based companies listed on U.S. exchanges" -- particularly those companies based in China. An SEC task force has been set up to probe accounting problems at foreign reverse mergers including Chinese reverse mergers.

May 26th, 2011: the NASDAQ Stock Market submitted to the SEC its revised and enhanced rulemaking proposal containing proposed additional listing requirements for reverse merger companies.

June 9th, 2011: the U.S. Securities and Exchange Commission SEC took an extraordinary step and issued a bulletin warning investors to be "proceed with caution" when considering to invest in foreign reverse merger companies that are financially weak, prone to "fraud and other abuses", and carry unique risks.

July 22nd, 2011: The NYSE and Amex submitted proposals to enhance the listing requirements for reverse mergers.

November 9th, 2011: The SEC issued orders approving more rigorous listing requirements for reverse mergers on the NYSE, Amex and Nasdaq exchanges.

Appendix B: Earnings quality models [11]

The first measure is based on the modified Jones model (Kothari et al., 2005; Hope et al. 2013). We estimate the following model for each industry-year for 2001-2010, where industry is defined as the first two digits of the SIC code with at least ten observations.

$$ACCR_{it} = \beta_0 + \beta_1\left(\frac{1}{Assets_{i,t-1}}\right) + \beta_2 \Delta REV_{it} + \beta_3 PPE_{it} + \beta_4 ROA_{it} + \varepsilon_{it} \qquad \text{(A1)}$$

Where ACCR is total accruals, measured as the change in non-cash current assets minus the change in current liabilities excluding short term debt, minus depreciation and amortization expense; *ΔRev is* the annual change in revenues; *PPE* is the net property, plant, and equipment. All of the above variables are deflated by lagged total assets. *ROA is* net income divided by average total assets.

The second measure is based on the performance-adjusted cross-sectional variation of the Jones Model (Kothari et al., 2005). We estimate the model below by industry-year (2-digit SIC code and Chinese equivalent) for 2001-2010.

$$TA_{it} = \beta_0 + \beta_1\left(\frac{1}{A_{i,t-1}}\right) + \beta_2(\Delta REV_{it} - \Delta AR_{it}) + \beta_3(PPE_{it}) + \beta_4(NI_{it}) + \varepsilon_{it} \quad \text{(A2)}$$

Where *TA* is total accruals, defined as net income minus operating cash flows;[12] $A_{i,t-1}$ *is* lagged total assets; ΔREV is the change in net revenues for firm i from year *t-1 to t;* ΔAR is the change in accounts receivable for firm i from year *t-1 to t; PPE* is the net property, plant and equipment; *NI* is the net income. All of the variables are deflated by lagged total assets. We use the absolute value of the error term as our proxy for earnings quality.

The third measure is based on the modified Dechow and Dechev (2002) model (Ball & Shivakumar, 2006; Wang, 2006).

$$ACC_t = \alpha_0 + \alpha_1 CF_t + \alpha_2 CF_{t-1} + \alpha_3 CF_{t+1} + \alpha_4 DCF_t + \alpha_5 DCF_t * CF_t + \varepsilon \qquad \text{(A3)}$$

[11] As is the convention in the literature, we drop financial services firms (SIC 6000 to 6900) as they have special accounting practices making estimating abnormal accruals difficult.

[12] We use net income rather than income before extraordinary items because the latter is not available for the Chinese firms. The extraordinary item is not applicable to the Chinese sample. In the accounting conservatism literature, Pope and Walker (1999) find country differences in income before extraordinary items between the U.K. and U.S. firms and recommend using net income rather than the latter for international samples. We find that the accrual quality measures are highly correlated using either income measure for the U.S. sample.

Where *ACC* is total accruals, measured as net income minus operating cash flows, deflated by average total assets; *CF* is operating cash flows deflated by average total assets; *DCF* is a dummy variable equal to one if the change in cash flows at *t* is less than zero.

The fourth measure is based on another version of the modified cross-sectional Dechow and Dechev (2002) model (Ball & Shivakumar, 2006; Chen et al., 2012; Givoly et al., 2009; Hope et al., 2013).

$$WCA_{i,t} = \beta_0 + \beta_1 OCF_{i,t-1} + \beta_2 OCF_{i,t} + \beta_3 OCF_{i,t+1} + \beta_4 \Delta REV_{i,t} + \beta_5 PPE_{i,t} + \beta_6 DOCF_{i,t} + \beta_7 OCF_{i,t} \times DOCF_{i,t} + \varepsilon_{i,t} \quad \text{(A4)}$$

Where *WCA* is working capital accrual, measured as the change in non-cash current assets minus the change in current liabilities other than short-term debt and taxes payable; *CFO* is cash flow from operations; *ΔRev* is annual change in revenues; *PPE* is the net property, plant, and equipment. All variables are scaled by lagged total assets; *DCFO* is a dummy variable equal to one if operating cash flows are negative. The modified DD models are estimated for each industry (i.e., two-digit SIC code or Chinese equivalent) and requires at least 20 firm-year observations per industry. The absolute value of residuals is used as a proxy for earnings quality.

The fifth measure is based on McNichols and Stubben (2008) and Stubben (2010). Specifically, we use the following regression for each industry-year (i.e., two-digit SIC code or Chinese equivalent) that has at least 20 observations:

$$\Delta AR_{i,t} = \beta_0 + \beta_1 \Delta REV_{i,t} + \varepsilon_{i,t} \quad \text{(A5)}$$

Where *ΔAR* is the annual change in accounts receivable scaled by lagged total assets; *ΔRev* is the annual change in revenues scaled by lagged total assets. The absolute value of residuals from the models is used as a proxy for earnings quality.

The sixth measure is based on the ratio of the absolute value of accruals to cash flows (Burgstahler et al. 2006; Chen et al., 2012; Hope et al. 2012). The literature review suggests that firms have incentives to overstate earnings by using reserves or engaging in aggressive accounting practices. Accruals can be temporarily inflated to boost earnings but if cash flows remain unaffected, higher ratio of accruals to cash flows indicates lower earnings quality. On the other hand, however, cookie-jar reserve earnings management could be mistakenly interpreted as higher earnings quality. Cash flows could also be managed. Nevertheless, we conduct our analysis using this measure as a robustness test. The greater the values, the lower the earnings quality.

Appendix C: Mishkin (1983) test

The Mishkin (1983) test is based on a set of jointly estimated equations, namely a forecasting equation and a valuation equation, using an iterative nonlinear least squares procedure proceeding in two stages. In the first stage, the forecasting equation and the valuation equation are estimated without any constraints imposed on the coefficients. In the second stage, the rational pricing constraint is imposed such that the valuation and forecasting coefficients are equal. The two equations are then jointly estimated to test whether the valuation coefficients are different from their forecasting counterparts.

The likelihood ratio statistic is used to test the null hypothesis that the information contained in the earnings components is fully reflected in stock prices, i.e., $\gamma_j = \gamma^*_j$, (j=1, 2, 3). The likelihood ratio is asymptotically distributed as $\chi^2(q)$ and computed as follows:

$$2n*Ln(SSR^c / SSR^u)$$

where q is the number of rational pricing constraints imposed; n is the number of sample observations; Ln is the natural logarithm operator; SSR^c is the sum of squared residuals from the constrained regressions; SSR^u is the sum of squared residuals from the unconstrained regressions. The null hypothesis of rational pricing is rejected if the likelihood ratio statistic is sufficiently large.

Table 1: Descriptive Statistics

Jones1 (Jones2) is the absolute value of earnings quality from modified Jones Model 1 (2). DD1 (DD2) is the absolute value of earnings quality from modified Dechow-Dichev Model 1 (2). DR is the absolute value of discretionary revenues. ACC/CFO is the ratio of magnitude of accruals to operating cash flows. The higher the earnings quality measures, the lower the earnings quality. Market value is the number of shares times the closing price. ROE is return on equity. LEV is the total debt divided by the lagged assets. Sales_growth (Assets_growth) is the annual growth in sales (assets) from prior year. Capital_need is the one-year-ahead percentage change in common stock, preferred stock, and long-term debt. Inventory is the inventory deflated by average assets. Loss is a dummy variable equal to one for net losses. BM is the book-to-market ratio. ROA is return on assets. The samples exclude the top and bottom 1% of all the variables and the financial services firms.

Table 2: Spill-over Effects of the US Regulatory Actions against CRMs

Panel A: spill-over effects on the Chinese firms listed in the U.S.

The table presents the three-day (t-1 through t+1) cumulative average abnormal returns (CAR) for the release of each regulatory announcement as well as the aggregate CAR using the Fama-French (1997) three-factor model. Announcements dates represent the press release dates of the regulatory statements with regard to reverse mergers. JKZ is the Jackknife Z-statistics of the cumulative average abnormal return. ***, **, * denotes a level of significance at 1%, 5%, and 10%, respectively.

Table 3: Earnings quality: Chinese firms listed in China vs. U.S. firms

This table reports the results from regressing earnings quality on the country dummy variable and control variables. *Jones1 (Jones 2)* is the log transformed absolute value of earnings quality from modified Jones Model 1 (2). *DD1 (DD2)* is the log transformed absolute value of earnings quality from modified Dechow-Dichev Model 1 (2). *DR* is the log transformed absolute value of discretionary revenues. *ACC/CFO* is the log transformed earnings quality from the ratio of magnitude of accruals to operating cash flows. *FRQ* is the factor score obtained from the six proxies for earnings quality using the principal component analysis. The higher the values, the lower the earnings quality. *CHI* is a dummy variable equal to one for Chinese firms listed in China and zero otherwise. *Size* is the natural logarithm of market value (number of shares times closing price). *ROE* is return on equity. *LEV* is the total debt divided by the lagged assets. *Sales_growth (Assets_growth)* is the annual growth in sales (assets) from prior year. Capital_need is the one-year-ahead percentage change in common stock, preferred stock, and long-term debt. *Inventory* is the inventory deflated by average assets. *Loss (Loss_lag)* is a dummy variable equal to one if net income is less than zero for the current (previous) year. Firm_age is the number of years listed in the capital market for Chinese firms and the number of years in the CRSP database as of the end of fiscal year for US firms. *BM* is the book-to-market ratio. *ROA* is return on assets. The table reports the coefficient estimates, the two-sided *t*-values, the number of observations, and R^2. The top and bottom 1% of all the variables are dropped. ***, **, and * indicate statistical significance at the 1%, 5%, and 10% levels, respectively (two-tailed *t*-test).

Table 4: Earnings quality: Chinese vs. U.S. firms matched on year, industry, and size

This table reports the results from regressing earnings quality on the country dummy variable and control variables. *Jones1 (Jones 2)* is the log transformed absolute value of earnings quality from modified Jones Model 1 (2). *DD1 (DD2)* is the log transformed absolute value of earnings quality from modified Dechow-Dichev Model 1 (2). *DR* is the log transformed absolute value of discretionary revenues. *ACC/CFO* is the log transformed earnings quality from the ratio of magnitude of accruals to operating cash flows. *FRQ* is the factor score obtained from the six proxies for accrual quality using the principal component analysis. The higher the earnings quality measures, the lower the earnings quality. *CHI* is a dummy variable equal to one for Chinese firms listed in China and zero otherwise. *Size* is the natural logarithm of market value (number of shares times closing price). *LEV* is the total debt divided by the lagged assets. *Sales_growth (Assets_growth)* is the annual growth in sales (assets) from prior year. Capital_need is the one-year-ahead percentage change in common stock, preferred stock, and long-term debt. *Inventory* is the inventory deflated by average assets. *Loss (Loss_lag)* is a dummy variable equal to one if net income is less than zero for the current (previous) year. Firm_age is the number of years listed in the capital market for Chinese firms and the number of years in the CRSP database as of the end of fiscal year for US firms. *BM* is the book-to-market ratio. *ROA* is return on assets. The table reports the coefficient estimates, the two-sided *t*-values, the number of observations, and R^2. The top and bottom 1% of all the variables are dropped. ***, **, and * indicate statistical significance at the 1%, 5%, and 10% levels, respectively (two-tailed *t*-test).

Table 5: Conditional conservatism for the Chinese firms listed in China vs. U.S. firms

This table compares the conditional conservatism of the Chinese firms listed in China vs. the US firms using two alternative models developed by Ball and Shivakumar (2005). ΔNI is the change in net income scaled by lagged total assets. $D\Delta NI$ is a dummy variable equal to one for negative ΔNI in the prior year. *ACC* is the accruals measured as the difference between net income and operating cash flows, standardized by lagged total assets. *CFO* is the operating cash flows standardized by lagged total assets. *DCFO* is a dummy variable equal to one if *CFO* is negative. *CHI* is a dummy variable equal to one for Chinese firms listed in China. *Size* is the natural logarithm of total assets. *LEV* is the total debt divided by lagged total assets. The regressions exclude the top and bottom 1% of ΔNI, ACC, and CFO. ***, **, and * indicate statistical significance at the 1%, 5%, and 10% levels, respectively (2-sided *t*-stat). The *t*-statistics are based on robust standard errors with cluster analysis at the firm level to control for cross-sectional correlation as one firm contributes more than one observations to the samples.

Test of market efficiency	$\gamma_1=\gamma^*_1$	$\gamma_2=\gamma^*_2$		Joint test
Likelihood ratio statistic	61.58	92.92		93.58
Marginal significance	0.00	0.00		0.00

ARN_{t+1} is net income at Year t+1; CFO_t is operating cash flows deflated by lagged assets at Year t; $ACCR_t$ is total accruals, the difference between EARN and CFO at Year t; Adj_Ret_{t+1} is abnormal returns at Year t+1 calculated as the difference between a firm's buy-and-hold annual return ending three months after the fiscal year end, inclusive of dividends and any liquidating distributions, and the buy-and-hold return on a size matched value-weighted portfolio of firms. The forecasting coefficients gauge the persistence of CFO and ACCR. Higher coefficients on ACCR indicate greater information content contained in the accruals about future earnings. If the market valuation coefficient is greater than its forecasting counterpart, the market overprices that earnings component and vice versa.

Abstract

The current ERP systems research focuses on understanding the relationship between the investment in ERP systems and the related performance impact. Due to the research designs used and the nature of the variables included in prior research models, the evidence on the contribution of ERP systems to firm performance is not entirely consistent. This study synthesizes the process-oriented and resource-based theoretical perspectives and proposes a research model that investigates the process through which organizations generate business value from their ERP systems investments. In doing so, the study examines the role of ERP systems competences and business process performance in enhancing organizational performance. The results show that the ERP technical and human competences and the complementarity between them have positive effect on business process performance. The results also show that business process performance is an important factor that mediates the relationship between ERP systems competences and organizational performance. The research findings offer valuable contributions to the theory and practice on how ERP systems enhance organizations performance.

Keywords: *ERP systems, organizational performance, business process performance, ERP systems competences.*

Introduction

The contribution of enterprise resources planning (ERP) systems to organizational performance has received great attention in prior accounting information systems (AIS) research. This attention matches the large investments that organizations have made in ERP systems over the last two decades. The evidence from early AIS studies regarding the incremental contribution of ERP systems to organizational performance is not entirely consistent (HassabElnaby et al. 2012; Wieder et al. 2006). However, few studies show some evidence of ERP systems payoff that is measurable across limited financial ratios (Poston and Grabski 2001; Hunton et al. 2003). The lack of consistent evidence of the performance impact of ERP systems is attributed to the research models and methodologies used in prior ERP systems payoff studies (Wieder et al. 2006). For instance, prior studies focus less on the impact of ERP systems at the business process level where ERP systems are supposedly used and pay more attention to the organizational-level performance impact (Matolcsy et al. 2005; Wier et al. 2007). Therefore, ignoring the business process performance impact of ERP systems will reduce the chance of finding evidence of the impact of the systems on the organizational performance (Elbashir et al. 2008; Davern and Kauffman 2000). This is because unrelated factors may confound the effect of ERP systems on the organizational performance (Melville et al. 2004; Davern and Kauffman 2000).

ERP systems are expected to enhance organizations' performance mainly because of their role in supporting business processes (re)design thereby enabling timely access to consistent information across diverse functional areas of the organization (Grabski et al. 2011; Weir et al. 2007). As such, achieving the desired performance outcome from ERP investments will require a significant amount of business process re-engineering (BPR) (Cheng and Wang 2006; Dorien and Wolf 2000). BPR will help organizations to align their business processes with the ERP systems concept, whereby business process benefits are achieved (O'Leary 2000; Weir et al. 2007). However, prior ERP systems studies take BPR for granted and assume that it is a natural outcome of any ERP systems implementation. Prior research also indicates that achieving organizational performance of ERP systems requires a great deal of organizational commitments towards investing in complementary ERP-related resources (Cheng and Wang 2006; Dorien and Wolf 2000). These resources include human and technical, which are considered the key factors for the success of ERP systems (Stratman and Roth 2002; Mata et al. 1995).

The purpose of this study is to revisit the ERP systems payoff theme and propose a research model that explains the process through which ERP systems contribute to organizational performance. In doing so, we draw on the process-oriented and the resource-based views of the firm and propose a research model that explicitly considers the role of business process performance related to BPR as mediating the relationship between ERP systems resources and organizational performance (Mooney et al. 1995; Barua et al. 2000; Tallon et al. 2000; Soh and Markus 1995; Subramani 2004). Two ERP systems resources, human and technical competences, are depicted in the research model as the antecedents of organizational performance impact of ERP systems, whereby both their individual and complementary effects on ERP performance impact were tested. Drawing on recent AIS studies, the research model examined in this study depicts the performance impact of ERP systems at the business process and organizational levels (Elbashir et al. 2008; Irani 2002; Hunton et al. 2003; Nicolaou et al. 2003).

To test the research model, we used survey to collect data from Chinese companies that are listed in the Shanghai and Shenzhen stock exchange which adopted ERP since 1999. We targeted multiple respondents, including CFOs and CIOs and functional managers from 421 organizations. We received usable responses from 65 organizations which represent a response rate of 15%. Our results show that both ERP technical and human competences are positively related to business process performance and indirectly, positively affect organizational performance through business process performance. Our results also indicate that the complementarity between ERP technical and human competences has positive contribution to the business process performance.

This study makes several contributions to the ERP literature. First, we apply the concept of IT competences to the ERP setting and break down ERP competences into technical and human aspects while examining their roles, separately and jointly, in ERP business value creation. Second, we propose theoretically and examine empirically the framework of the impact of ERP systems technical and human competences on firm performance via business process. Our proposition and examination enriches ERP theory and presents some evidence in relation to the process of ERP systems business value creation. Finally, our empirical results justify the breakdown of ERP resources into technical and human parts by showing different effects (i.e. directly and indirectly) of the technical and human competences of ERP systems on organizational performance.

The remainder of the paper is organized as follows: the next section describes the theoretical foundation and research hypotheses. Then, the methodology and results are described. Finally, the findings, limitations, and recommendations for future research are discussed.

Theory and Hypotheses Development

Demonstrating the bottom-line contribution of ERP systems has been a major challenge for AIS researchers over the last two decades (Stratman 2007; Wier et al. 2007). Early studies show that ERP systems investments have limited effect on organizational performance (McAfee 2002; Poston and Grabski, 2001). However, there is now a consensus among researchers that ERP systems can help organizations to improve their operational efficiency and effectiveness (Wier et al. 2007). The challenging research question now is not whether ERP systems create business value, but a richer understanding of the processes through which ERP systems create value to the organization (Melville et al. 2004). Answering these questions requires opening the "black box" of the basic research model of ERP systems that was tested in prior ERP payoff studies, which proposes a direct relation between ERP systems investments and organizational performance. Decoding the "black box" will require examining both the organizational resources that complement ERP systems investments and the processes through which organizations convert ERP systems investments into organizational performance.

The resource-based view suggests that acquiring ERP systems guarantees neither positive return on investment nor improvement in other indicators of competitive advantages (Stratman, 2007; Beard and Sumner, 2004; Mata et al. 1995). This is because ERP systems are a public commodity that can easily be procured in the market by all organizations. To achieve competitive advantages from their ERP systems investments, organizations will need to invest in other complementary resources including technical and managerial resources (Melville et al. 2004; Barua et al. 2000). These resources are necessary for exploiting ERP systems investments and creating capabilities and competences that are necessary for enhancing competitive advantage

(Barney et al. 2001; Teece et al 1997; Mata et al. 1995). Drawing on the Melville et al. (2004) framework of IT business value, we propose technical and human competences, and the synergy between them as the drivers of business process performance.

Most prior ERP systems payoff studies used organizational performance as the dependent variable of the research models. Recent studies argue that the organizational performance impact of ERP systems can be best measured at its immediate (business process) where the systems are used (Mooney et al. 1995; Tallon et al. 2000; Subramani 2004; Melville et al. 2004; Ray et al. 2005; Grabski et al. 2011; Weir et al. 2007). Failing to examine the ERP systems payoff at the business process level may reduce the ability to explain effectively how, why, or why not the business value is created from ERP systems (Elbashir et al. 2008). We examine the business value of ERP systems in this study at both the business process and organizational levels.

Figure 1 depicts the conceptual model tested in this study. We draw on the process-oriented approach and the resource-based view perspective to motivate and test a set of factors as the enablers of the performance impact of ERP system. The performance impact of ERP systems is examined at both the business process and organizational levels. Two ERP systems competences constructs, *human* and *technical*, are modeled to have association individually and jointly with the business process performance of ERP systems. The research model also suggests that the business process performance mediates the relation between the ERP competence constructs and organizational performance.

[Insert Figure 1: the conceptual model here]

ERP systems competence and business process performance

The value of ERP systems stems from thier ability to integrate diverse business processes and functional areas as well as enabling management's need for timely access to consistent information that are required for managerial decisions (Grabski et al. 2011). Important performance outcomes of ERP systems are informational, automational, and transformational benefits (Ramirez et al. 2010). The *informational* benefits are enabled by the ERP systems as a result of managing all transactional data that are generated by business processes and functional areas to create a database across the whole organization. The *automational* benefits include operational efficiency of the business processes, such as saving in time and labor costs that arise as the result of using the ERP systems to automate business processes. The *transformational* benefits arise as the result of using the ERP systems to (re)design business processes and innovative activities that contribute to the enhancement of the operational effectiveness (Subramani 2004).

Achieving business process benefits from ERP systems investments is not a straightforward process and will require the firm to build specialized ERP resources including technical and human competences that will enable the organization to leverage the installed ERP systems (Stratman and Ruth 2002).

We include these two competences, ERP technical and human, in our research model as the antecedents of the ERP performance (Melville et al. 2004).

ERP Technical competences is a multifaceted construct that captures the technical knowledge and expertise that organizations need prior to and post ERP systems implementation. These include competencies that enable strategic planning for the system, provision of the necessary physical and human resources, and resolving ERP technical challenges (Meliville et al. 2004, Stratmen and Roth 2002). Technical competencies enable organizations to implement BPR techniques and align the newly (re)designed business processes with an effective implementation of the ERP system. ERP technical competencies also allow organizations to engage in continuous improvement of their ERP systems implementation to continuously improve the alignment of systems and business processes. Such an alignment will help the organization to achieve operational efficiency and effectiveness of their business processes. This leads to the following hypothesis:

H_1: *ERP technical competences are positively related to the business process performance.*

ERP human competences is a multifaceted construct that refers to the managerial knowledge, expertise, and skills that organizations possess that are used to manage the ERP systems projects (Stratmen and Roth 2002). These competences involve understanding the business processes requirements and the consequences of BPR, understanding the role of ERP systems in supporting business strategies, managing ERP systems, and fulfilling the needs of the users of ERP systems. Therefore, ERP human competences will enhance all the stages of ERP systems implementation and creating better alignment of the systems and the business process that results in enhanced business process performance. This leads to the following hypothesis:

H_2: *ERP human competences are positively related to the business process performance.*

The complementarity between human and technical competences:

Complementarity describes the enhancement of a resource and its ability to produce greater return to the organization in the presence of another complementary resource (Zhu 2004; Migrom and Roberts, Barua et al. 2000). Technical and human competences complement each other and create synergies that lead to enhanced ERP systems performance. For instance enhancing strategic ERP planning, which is a technical competency will entail the organization to collect and use information to create new knowledge on ERP strategy. However, this process will also enhance managerial competences related to how to fill in the knowledge gap of the organization which is necessary for better ERP systems implementation. While the two competences contribute individually to the performance of business process, the synergy between the two resources will have an incremental contribution.

If duplicating the ERP human and technical competences by firms is not an easy process, duplicating the synergy between these two competences is even more difficult due to the path-dependent process that will involve time, complex resources and capabilities to build (Zhu 2004). Drawing on H_1 and H_2, this lead to the following hypothesis:

H_3: *The Complementarity between ERP human and technical competences are positively related to the business process performance.*

Business process performance and organizational performance:

First-order business processes benefits are the leading indicators of organizational competitive benefits (Elbashir et al. 2008). An organization's performance impact of ERP systems depends on the effectiveness of the ERP system in facilitating the business processes redesign and generating both the operational efficiency and effectiveness benefits (Subramani 2004; Ray et al. 2005). Organizations that generate greater benefits from their ERP system investments across their business processes will be able to generate organizational performance. Consistent with the two-stage model of benefits suggested in prior literature (Elbashir et al. 2008; Melville et al. 2004; Subramani 2004), business processes benefits from ERP systems are expected to enhance the organizational-level performance (sales growth, profit margin, ROI). This leads to the following hypothesis:

H_4: *Business process performance impact of ERP systems are positively related to the organizational-level performance.*

Control Variables:

We include the firm size and ERP systems sophistication constructs as control variables in the research model to discount rival hypotheses that relate to firm-specific factors driving the performance impact of ERP systems at business processes and organizational levels.

Firm size is used in prior IS literature to proxy for the size of the organization resource base that can enhance ERP performance (Zhu 2004; Subramani 2004). Large firms are more able to invest speculatively in different ERP systems supporting activities and resources such as employee training (Chatterjee et al. 2002; Subramani 2004). We use the logarithm of the total assets as the proxy for firm size (Melville et al. 2004).

ERP systems sophistication is included in the research model to capture the level of organization's deployment of ERP systems modules. Organizations that implement more ERP systems module may have a better chance to achieve business value. This is because increased ERP systems models will support a larger proportion of the business processes (Armstrong and Sambamurthy 1999). We use the number of ERP systems modules implemented by the organization (e.g. financial, HR, and inventory management.) to capture the level of ERP systems sophistication.

Research design

Data was gathered through a large survey that targeted 421 Chinese companies that are listed in Shanghai and Shenzhen Stock Exchanges, which have adopted ERP systems between 1999 and 2007. Multiple responses were solicited from each organization at different managerial levels including CFO, CIO and ERP systems users. This strategy enabled the collection of rich data while eliminating biased responses (Huber and Power 1985; Sethi and King 1994). 215 responses were received from 65 organizations to realize a response rate of 15%. The average response of the multiple responses is used to represent the organization.[1] An ANOVA test was conducted to test for non-response bias. Early and late responses were compared in paired samples of 10 and 20 responses. The results show that there were no significant differences ($p < .05$) on any of the variables of the study. We also conducted Harman's one-factor common method test (Podsakoff & Organ, 1986). The results show neither a single factor emerged from the exploratory factor analysis nor did one general factor account for the majority of the variance in the measurement items used in the model.

Table 1 displays the descriptive statistics of 65 companies that responded to the survey. The surveyed companies are medium to large enterprises with a

[1] Following Armstrong and Sambumurthy 1999, we used correlations among the responses of multiple respondents on the main constructs of the study to test for consistency among respondents of the same organization. The results show that all the correlations are positive and significant at the 1% level of significance.

mean of 988 million Yuan in total assets. More than 50% of respondents' age fall between 36-45 and about 50% of the respondents have 11-15 years of work experience.

Operationalization of the Constructs:

Organizational Performance is a high-order construct which refers to overall firm performance which is captured at the financial and non-financial dimensions. 18 items were adapted from prior studies to measure these two dimensions whereby ten items relate to financial and eight items to non-financial dimensions (Shang and Seddon 2000; Kaplan and Norton 1992; Melville et al. 2004; and Mukhopadhyay and Kekre 2002). The confirmatory factor analysis (CFA) test supports the use of 12 items, six of them loads on non-financial dimension and the remaining six items loads on the financial dimensions of firm performance. The measurement items for the organizational performance measure are reported in Appendix A.

Business processes performance of ERP systems refers to the performance outcome of ERP systems at the business process level that is attributable to the contribution of the systems to enable the BPR. Business process performance is operationalized as a second-order construct using eight items that capture two dimensions of BPR benefits, *cost rationalization* and *work restructure* (Lawler et al. 2001; Ramirez et al. 2010). The CFA supports the use of seven items, three for cost rationalization and four for work restructuring. (See Appendix A).

ERP systems competences refer to a portfolio of managerial and technical skills and expertise that are necessary for enabling the deployment of ERP systems to enhance the business process of the organization (Stratman and Ruth 2002). ERP systems competences are conceptualized as a high-order construct with two second-order dimensions that are proposed by Stratman and Roth (2002) : (1) ERP systems technical competences, which are measured with 40 items that capture the following four first-order dimensions of technical competences: ERP training, IT skills, strategic ERP planning, and executives commitment; (2) ERP systems human competences, which are measured with 39 items that capture four first-first order dimensions human competences: business process skills, learning, change readiness, and project management. Consistent with prior studies (e.g. Elbashir et al. 2011) we created four composite variables for each of the two ERP systems competences by averaging the respondents' score for each of the four dimensions of the two ERP competences. The measurement items of the ERP systems technical and human competences are reported in Appendix A.

The initial draft of the measurement items included in the instrument was validated using feedback and comments received from a group of ERP experts who work at a leading ERP software company in Asia-Pacific region. This was followed by a pilot test that was conducted with ten senior executives including financial managers and CIOs who were asked to answer the survey and comment on its content and structure. The feedback at the pilot test stage was incorporated in the final draft of the survey. The final list of the measurement items are shown in Appendix A. The final survey version was translated into Chinese (Mandarin) language using expert translator. To ensure the accuracy of the translation, the Chinese-translated version of the survey was retranslated by another expert to English. Then, the translated version was compared with the original English version. The results of the comparison show no difference between the meanings of the same questions in the two versions of the survey.

Data Analysis and Results

Partial Least Square (PLS) was used to test the properties of the scales used to measure the constructs (measurement model) and examine the strength of the relations between the constructs (structural model). PLS is the most suitable structural equation modeling (SEM) technique compared to other SEM techniques such as LISREL. This is due to the small sample size used in this study and the formative constructs tested in the research model (Gefen et al. 2000; Chin et al. 2003).[2] The bootstrap resampling method (1000 samples) in PLS was used to estimate the t-value, which determines the significance of the path coefficients.

---

[2] We have tested for possible multicollinearity in relation to the measurement items of the formative constructs (technical and human). The variance inflation factor (VIF) scores for the items of the formative measures are between 2 and 4 which are within the acceptable range (Petter et al. 2007). These results indicate that multicollenarity does not represent any major threat to the validity of results reported in this study.

Properties of the Measurement Model

Multiple tests, suggested in prior studies, were performed to assess the construct validity and reliability (Churchill 1979; Straub 1989). The output from PLS in relation to the measurement model was used to examine the properties of the measures including internal consistency and the convergent and discriminant validity of the measurement items. Items that loaded 60% or above were retained in the measurement model (Hulland 1999). We use the indicator weight rather than loading to test the formative construct validity.

Reliability refers to the extent to which the measurement items used are consistent in what they intend to measure (Straub 1989; Hulland 1999; Zhu and Kraemer 2002). Table 2 shows the composite reliability for all constructs are above the cut-off of 0.70 (Nunnally 1978). This indicates that all the constructs measures have very good reliability (DeVellis 1991).

Content validity: The construct measures used in the study are supported by the prior literature and represent the domains that they were intended to measure (Carmines and Zeller 1979). Subsequent tests including a pilot test that used peers and experts' opinion were conducted to add to the confidence the researchers placed on the content validity of the measures.

Convergent validity examines whether measures that should be related are related (Hair et al. 1998). Item loading together with the average variance extracted (AVE) were used in the study to examine the convergent validity of the constructs that are measured with reflective items (Straub 1989). Table 1 shows that all the items have significant loadings, which indicate their significant contribution to the measured construct. Moreover, AVE for all the constructs are above 0.50 which demonstrates the convergent validity of the measurement items (Fornell and Larcker 1981). This also indicates that each of the measured constructs explain more than 0.50 of the variation in the observed variables.

[Insert Table 2: Individual item loadings, composite reliability, average variance extracted (AVE) statistics.]

Discriminant validity examines the relationship between measures of similar and different constructs to provide more evidence that the scales used are measuring distinct constructs. Table 3 shows that the values of the square root of the AVE (on the diagonal) are all greater than the inter-construct correlations (off the diagonal). This demonstrates that the measures exhibit satisfactory discriminant validity.

[Insert Table 3: Inter-Construct Correlations and Square Root of EVA Statistics]

An additional test of discriminant validity was also conducted in this study. All measurement items were assessed to ensure that each measurement item has a higher loading on its assigned factor than on the other factors (Chin 1998; Gefen et al. 2000). The results are presented in Table 4. Each of the measurement items loaded higher on the appropriate construct than on the other constructs (Chin 1998; Gefen et al. 2000). These results provide further support for the adequacy of discriminant validity of the measures used in this study.

[Insert Table 4: Measurement Items Loading and Cross-loading]

Results:

The test of the structural model involves estimating the path coefficients that link between the latent variables under investigation and R^2, which represents the amount of the variation in the dependent variables that is explained by the independent variables (Wixom and Watson 2001). Overall, the result suggests the model has good predictability. The coefficients for all paths between the constructs tested in the model are significant and above 0.21. The results also indicate that 67% of the variance in organizational performance and, 50% of the variance in business process performance are explained by the model.

[Insert Figure 3: Path Coefficients and R^2 Values of the Structural Model of ERP systems Payoff]

Significance of the Control Variables:

The results regarding the control variables are summarized in Panel B of Table 5. Surprisingly none of the control variables are significantly related to business process or organizational performance. In particular, the result fails to support the theoretical argument of prior IT payoff studies that firm size and the level of IT sophistication enhance organizational performance. One plausible explanation is that the effect of firm size and the level of IT sophistication are better captured by ERP systems competences that are included in the model.

[Insert Table 5: Panel B: Control Variables]

Hypothesis testing:

Hypotheses were tested within the structural equation model shown in Figure 1 based on the magnitude and significance of path coefficients estimated using PLS. The hypothesis that posit the complementarity between technical and IT resources was tested by using the incremental change in R^2 due to the introduction of the interaction term in addition to the magnitude of the interaction term's path (Zhu 2004).

In H_1 and H_2, we predict that the ERP systems technical and human competences will be positively associated with the business process performance. The results shown in Figure 2 and Table 5 support the two hypotheses with strong and significant direct relationships. The coefficients of the structural path were 0.21 ($p < .0.05$) and 0.34 ($p < .0.01$), respectively. This result supports the theorization that improvement in ERP systems technical and human competences, have a positive influence on the business processes performance.

In H_3, we predict that the complementarity between ERP systems technical and human competences is positively associated with the business process performance. The basic premise underlying the research model is that the research model with the complementarity between technical and human competencies is superior to the alternative research model without the complementarity. We tested the two models and compared the results (Table 6). As shown by the increase in R^2, our research model using the Complementarity has superior predictive value of business process performance when compared to the models that only capture the main effects of the two ERP systems competences separately. The magnitude of the relationship between the complementarity and business process performance provides further evidence of the importance of dually developing technical and human competences in order to leverage the value of ERP systems at the business process level. The variance explained in the business process performance construct as the result of the introduction of the interaction term has increased by 13% (from 37% to 50%), while the coefficient of the structural paths leading from the Complementarity to business process performance was 0.38. This result supports the theorization that the strength of the Complementarity has a positive influence on the business processes performance.

H_4, examines whether business process performance impacts organizational performance. The results shown in Figure 2 and Table 5 support H_4 (0.81, $p <$

0.001). These findings support the theorization that improvements in business process performance translate into improved organizational performance.

[Insert Table 5: Panel A: Summary of Hypotheses Test Results]

Following the test for the direct effects in our model, we examined the indirect effect of the ERP systems competences on organizational performance via business process performance. As noted in the theory section, the business process performance is viewed as being driven by the level of the ERP systems competences that the organizations build over time. We estimate the path coefficients of the indirect effects using the product term of the coefficients of the associated direct paths. We used bootstrap procedures to construct 95 percent ($p < 0.05$) confidence intervals for testing the significance of the indirect effects (Hayes 2009). The indirect effects and total effects are reported in Table 7.

The results show that the technical competences indirectly affect organizational performance through business process performance (0.17, $p < 0.05$). The human competences are also significantly indirectly related to organizational performance through business process performance (0.28, $p < 0.05$). These results indicate that ERP systems competences contribute directly to the business process performance and indirectly to organizational performance.

We also conducted the mediation test suggested by Baron and Kenny (1986) to examine whether business process mediates the relation between the two ERP competences and organizational performance.[3] The results of the tests indicate that the business process performance fully mediates the relations between ERP systems technical and human competences and organizational performance.

Discussion, Conclusion and Implications

This study aims to improve our understanding on how ERP systems resources promote firm performance. The study synthesizes perspectives from the process-oriented and resource-based view literature in order to propose and test an integrated research model of the business value of ERP systems. Drawing on the process-oriented view, the study posits that business process performance is an important stage towards achieving enhanced organizational performance. The empirical data provided a strong support for the hypotheses suggested in the research model.

We hypothesized that ERP systems competences represented by technical and human competences are important antecedents of ERP business value. Our

---

[3] We followed the four steps suggested by Baron and Kenny (1986) to test the extent to which business process performance mediates the relation between the two ERP systems competences and organizational performance: (1) Test that ERP systems competences predicts organizational performance. (2) Test that ERP systems competences predicts business process performance. (3) Test that ERP systems competences and business process performance are simultaneously predict organizational performance. (4) Test that business process performance mediates (completely or partially) the relation between ERP competences and organizational performance.

path analysis results show that both ERP technical and human resources directly relate to business process performance and indirectly affect organizational performance through business process performance. The findings imply that developing ERP competences is a resource-intense, path-dependent process that requires skilled personnel as well as a wide range of relevant IT components. The result of this study suggests that organizations that have developed ERP competences will have the necessary ERP resource foundations that will enable them to exploit the implemented ERP systems in their business strategies and activities. ERP technical and human competences are found to have a significant impact on business process and organizational performance.

This study makes several contributions. First, the study represents an important attempt to open the "black box" of ERP systems investments and understand the mechanisms through which ERP systems create business value. A large number of studies have investigated the relation between ERP systems investments and ERP systems payoff. However, when it comes to the question of how organizations create such value from ERP systems, the literature falls short. Therefore, a theory explaining how investments in ERP systems can be turned into organizational performance is an outstanding challenge to the AIS community. The resulting analysis presented in this study serves to explain why some organizations are able to leverage their ERP systems investments and generate a higher competitive advantage than others.

Business process performance related to BPR, which has not been examined adequately in prior literature, is found to be a major driver of organizational performance. This finding suggests future ERP systems payoff studies should capture the BPR and business process performance in the research model. Second, the study provides evidence that ERP technical and human competences are important antecedents for the successful deployment of ERP systems. In order to further enhance ERP systems performance, organizations need to develop these competencies and create a synergy between these resources. Third, despite the growing literature of the business value of ERP systems, there is a dearth of research that tests the link between the business process and organizational performance of ERP systems. This study links the two performance outcomes by examining a research model that predicts a relation between the business process performance impact of ERP systems and organizational performance. In doing so, the study argues that acquiring and developing high quality ERP systems software applications is not necessarily sufficient for organizations to create business value (Mata et al. 1995; Carr 2003). Business value from ERP systems is determined by the business process performance impact that organization accrue from using these systems (Parsons 1983; Porter and Millar 1985; Armstrong and Sambamurthy 1999; Piccoli and Ives 2005).

Finally, the study provides some insights regarding the claim that "IT Doesn't Matter" (Carr 2003) that was made in prior IT payoff studies. Failing to differentiate between ERP systems and ERP competences, which represent the organization's ability to exploit ERP systems, is a fundamental flaw that may lead businesses to make the erroneous conclusion that "IT doesn't matter". Developing high quality ERP competences is path dependent and takes a longer time. Therefore, organizations should continue investing in ERP competences, including technical and managerial knowledge and skills that convert ERP systems investments into capabilities that are fundamental for successful business strategies.

Limitations

The findings of this study should be considered in the light of its inherent limitations. First, the findings are based on self-reported data, which may be subject to common method variance or potential respondent "self-selection" bias. However, the multiple tests (reliability and CFA) and the good psychometric properties reported in the study support the validity of the results. Moreover, capturing data from multiple respondents of the same organization may be viewed as offsetting any respondents' bias. Prior studies also found that senior and middle managers' perception to be a good proxy for organizational performance (Dess and Robinson 1984; Mahmood and Soon 1991; Sethi and King 1994; Tallon et al. 2000; Zhuang and Lederer 2003). Future research can extend this study by using archival data instead of survey data, time series data, objective performance measures, quantifying the organizational structure and culture changed as the result of the ERP implementation, and adopting a field or case study methodology.

Second, the model suggests causal relations and multistage (i.e. process performance, and then organizational performance) while using cross sectional data which only allows testing the association between the variables of the research model. As the study attempts to understand a complex phenomenon in a natural setting and generalize the findings, the experimental method may not be the best option. Future research should consider using longitudinal data.

Third, the study did not capture the size of organizations' investments in ERP systems which could have some influence on the level of organizational performance impact of ERP systems. However, the study includes a control variable to capture the number of ERP modules used by the firm, which can represent the level of the organizations' maturity with ERP systems and the level of investment.

Fourth, the study did not control for factors that may moderate the relation between business processes benefits and organizational performance such as competitive response and environmental change. This is an area for future research.

In summary, the empirical results reported in this study provide explanations for some of the inconsistencies in the findings reported in prior ERP payoff studies. The study clearly differentiates between ERP infrastructure as the

ERP foundation and ERP competences that enable the deployment of the ERP infrastructure to support business process and functions. The result shows that business process performance is an important variable, and when included the explanatory power of the model increase significantly. The findings also demonstrate a positive indirect relation between ERP competences and organizational performance via business process performance.

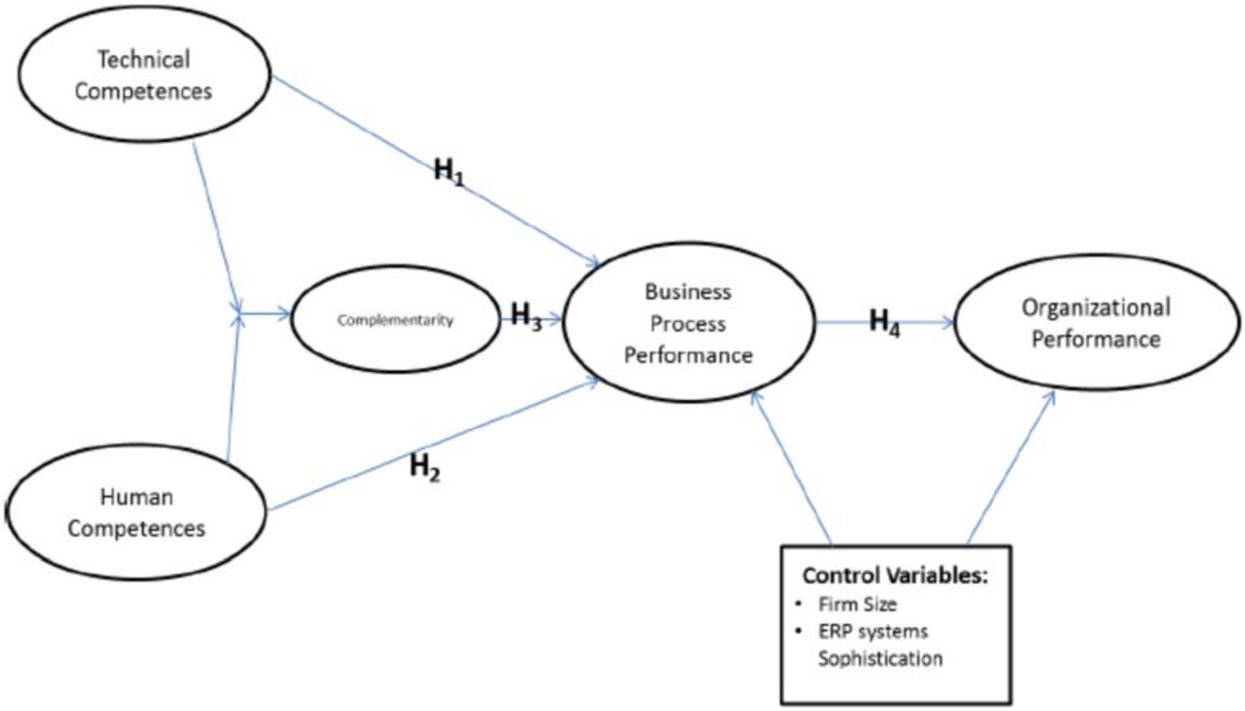

Figure 1: The conceptual Model

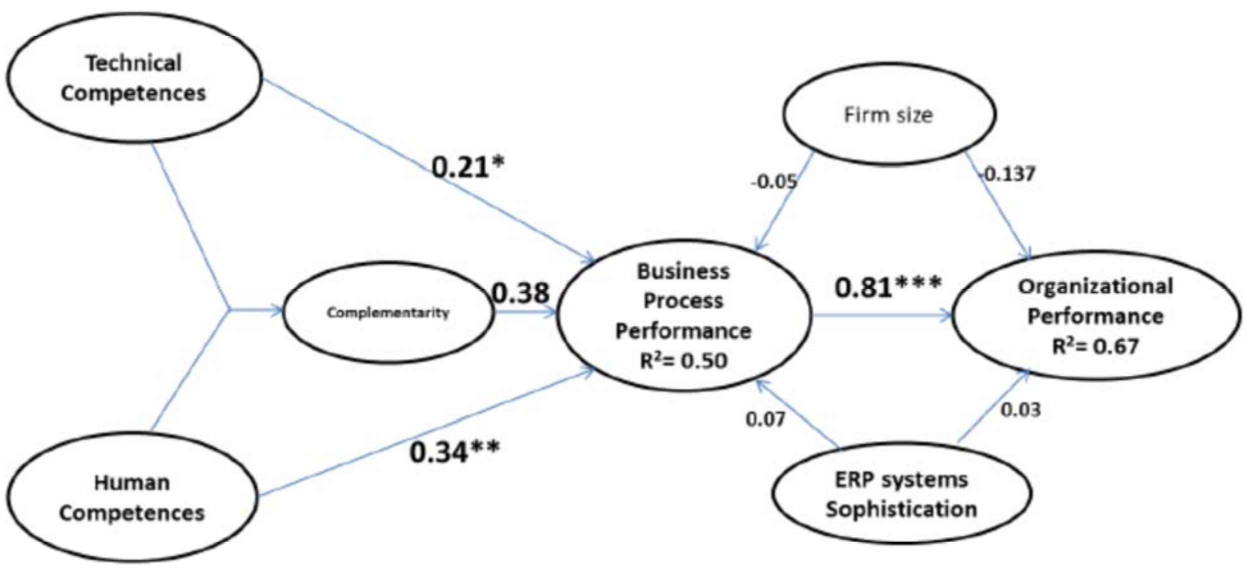

Figure 2: Path Coefficients and R^2 Values of the Structural Model of ERP systems Pay-off

Table 1: The questionnaire and descriptive statistics (65 listed companies)

Initial issue				Measurement	
ERP Software Category (based on UFIDA classification)					
Financial Accounting				65 (100%)	
Management Accounting				13 (20%)	
Supply Chain Management (SCM)				21 (32.31%)	
Customer Relationship Management (CRM)				12 (18.46%)	
Manufacturing and product management				16 (24.62%)	
Human Resource Management (HRM)				13 (20%)	
Office automation (OA)				26 (40%)	
Decision Support System				4 (6.16%)	
Group Management				7 (10.76%)	
Internet sales				4 (6.15%)	
Enterprise Application Integration				5 (7.70%)	
	N	Mean	Std.	Min	Max
Total assets (Yuan in Million)	65	988.10	849.33	106.33	2354.34
Age*	215	2.49	0.59	1	3
Less than 25 years old	10(4.7%)				
26-35 years old	87(41.3%)				
36-45 years old	116(54%)				
Work Experience **	215	2.56	0.91	1	4
Less than 5 years	36(16.7%)				
6-10 years	49(22.8%)				
11-15 years	105(48.4%)				
More than 15 years	28(12.1%)				

* On the questionnaire, Age = 1, if younger than 25 years old, = 2 if aged 26 to 35 years old, = 3 if aged 36 to 45 years old.

** On the questionnaire, Work experience = 1, if less than 5 years, = 2, if 6 to 10 years = 3, if 11 to 15 years, = 4 if more than 15 years.

Table 2: Individual item loadings, composite reliability, average variance extracted (AVE) statistics.

Measurement Items	Loading	Standard Error	*T*-Statistics
Dimensions of Firm performance			
1. The Financial Dimension of Firm Performance: (Composite Reliability = 0.91, AV E = 0.62)			
PEFI1: Operating income	0.819	0.044	18.602
PEFI2: Sales growth rate	0.790	0.049	16.047
PEFI3: Return on investment (ROI)	0.854	0.029	29.533
PEFI4: Return on assets (ROA)	0.811	0.056	14.397
PEFI5: Operating return on assets (OIA)	0.761	0.062	12.236
PEFI8: Selling, general and administrative expenses over sales (SGAS)	0.662	0.080	8.279

2. The Non-Financial Dimension of Firm Performance: (Composite Reliability = 0.86, AV E = 0.52)			
PENF2: Ratio of good output to total output at each production process	0.658	0.082	8.066
PENF3: Manufacturing lead time	0.750	0.061	12.197
PENF4: Rate of material scrap loss	0.835	0.041	20.370
PENF5: Labor efficiency variance	0.762	0.051	15.065
PENF6: Number of new patents	0.633	0.124	5.099
PENF10: Personnel development	0.648	0.080	8.114
Dimensions of Business Process Performance			
1. Work restructure Benefits: (Composite Reliability = 0.89, AV E = 0.66)			
PEBP1: Process simplification	0.770	0.063	12.182
PEBP2: improve the coordination among different units of the firm	0.856	0.032	26.867

PEBP3: Major information system redesign	0.831	0.040	21.042
PEBP4: Enriched multi-skilled individual jobs	0.798	0.044	18.295
2. Cost rationalization Benefits: (Composite Reliability = 0.81, AV E = 0.59)			
PEBP5: The efficiency and productivity of business processes	0.793	0.058	13.713
PEBP6: Doing the same work with fewer	0.761	0.053	14.490
PEBP7: Doing the same work with less supervision	0.754	0.067	11.192

Dimensions of ERP Systems Competences

A. Human Competences: (Formative measures)			
	Weight	Standard error	T-statistics
1. ProMgt: Project management	0.226	0.230	0.982
2. BPSkills: Business process skills	0.403	0.263	1.533
3. **Learn:** learning	0.116	0.179	0.645
4. ChangeRead: change readiness	0.863	0.100	8.662
B. Technical Competences: (Formative measure)			
	Weight	Standard	T-
1. Train: Training	0.308	0.214	1.440
2. ITSkills: IT skills	0.948	0.084	11.282
3. StratItPlan: Strategic IT planning	0.484	0.201	2.412
4. ExecutCom: Executive commitment	0.465	0.187	2.490

Table 3: Inter-Construct Correlations and Square Root of Average Variance Extracted statistics (n=65)

	1	2	3	4
1. Financial	**0.79**			
2. Non-financial	0.69	**0.72**		
3. Cost rationalization	0.70	0.71	**0.77**	
4. Work restructure	0.70	0.69	0.73	**0.81**

a Diagonal elements are the square roots of the average variance extracted statistics. Off-diagonal elements are the correlations between the latent variables calculated in PLS.

Table 4: Measurement Items loading and cross-loading

	Financial	Non-financial	Work restructure	Cost rationalizati
PEFI1	**0.819**	0.564	0.537	0.655
PEFI2	**0.790**	0.488	0.477	0.445
PEFI3	**0.854**	0.557	0.540	0.575
PEFI4	**0.811**	0.638	0.553	0.504
PEFI5	**0.761**	0.494	0.570	0.566
PEFI8	**0.662**	0.522	0.662	0.580
PENF2	0.493	**0.658**	0.536	0.623
PENF3	0.413	**0.750**	0.544	0.562
PENF4	0.547	**0.835**	0.540	0.607
PENF5	0.557	**0.762**	0.536	0.466
PENF6	0.460	**0.633**	0.389	0.354
PEBP1	0.545	0.512	**0.770**	0.601
PEBP2	0.629	0.598	**0.856**	0.614
PEBP3	0.622	0.554	**0.831**	0.576
PEBP4	0.486	0.585	**0.798**	0.589
PEBP5	0.544	0.540	0.509	**0.793**
PEBP6	0.614	0.628	0.614	**0.761**
PEBP7	0.460	0.453	0.557	**0.754**

Table 5: Path Coefficients – Test Variables

Panel A: Path/Hypothesis	**Path Coefficient**	**T- value**
ERP Technical Competences ---> Process Performance	0.209	1.892*
ERP Human Competences --- -> Process Performance	0.343	3.189**
Business Process Performance ----> Organizational Performance	0.810	16.393***
Panel B: Control Variables		
Firm size ---> Business Process Performance	-0.051	0.542
Firm size ---> Organizational Performance	-0.137	1.740
ERP Sophistication ---> Business Process Performance	0.069	0.745
ERP Sophistication ---> Organizational Performance	0.026	0.324

* Indicates that the coefficient is significant at the $p < .05$
** Indicates that the coefficient is significant at the $p <. 01$
*** Indicates that the coefficient is significant at the $p <. 001$

Table 6: test of the complementarity

		Business Process Performance	
Model	**Independent Variable**	**Coefficient**	R^2
Model 1:			37%
	Human competences	0.43	
	Technical competences	0.27	
Model 2: (Figure 2)			50%
	Human competences	0.34	
	Technical competences	0.21	
	Complementarity	0.38	
Increase in R^2 Model 1 vs. Model 2			13%

Table 7: Indirect Effects and 95% Bootstrap Confidence Interval

ERP human competences -----> Business process performance -----> organizational performance	0.28 (-0.085 - 0.455)
ERP technical -----> Business process performance -----> organizational performance	0.17 (-0.103 – 0.433)

Appendix A

Please indicate the extent to which you agree or disagree with each of the following statements by circling the relevant number (1= strongly disagree and 7 = strongly agree):

Technical ERP Resources:

Strategic IT Planning

1. We constantly review our IT capabilities against strategic goals.	1	2	3	4	5	6	7
2. IT plans are redesigned as required to meet evolving conditions.	1	2	3	4	5	6	7
3. Strategic IT planning is a continuous process.	1	2	3	4	5	6	7
4. Written guidelines exist to structure strategic IT planning in our organization.	1	2	3	4	5	6	7
5. Top management is not involved in strategic IT planning. (reversed coded)	1	2	3	4	5	6	7
6. Strategic IT planning includes inputs from all functional areas.	1	2	3	4	5	6	7
7. The business impact of proposed ERP system changes is not evaluated against strategic goals.	1	2	3	4	5	6	7
8. IT plans for functional areas are driven by the overall ERP Entity IT plan	1	2	3	4	5	6	7
9. IT planning is driven by the ERP Entity`s strategic business plan.	1	2	3	4	5	6	7

Executive Commitment

1. Functional managers willingly assign resources to the ERP project as they are needed.	1	2	3	4	5	6	7
2. The need for long-term ERP support resources is recognized by management.	1	2	3	4	5	6	7
3. Executive management is enthusiastic about the possibilities of ERP.	1	2	3	4	5	6	7
4. Executives have invested the time needed to understand how ERP will benefit the enterprise.	1	2	3	4	5	6	7
5. Executives mandate that ERP requirements have priority over unique functional concerns.	1	2	3	4	5	6	7
6. Top management has clearly defined commitments. the ERP Entity's business goals.	1	2	3	4	5	6	7

7. All levels of management support the overall goals of the ERP Entity.	1	2	3	4	5	6	7
8. Employees who support the ERP project are distracted by other commitments.	1	2	3	4	5	6	7

IT Skills

1. The internal IT staff have the ability to conduct routine ERP system maintenance.	1	2	3	4	5	6	7
2. There is a high degree of technical expertise in the IT organization.	1	2	3	4	5	6	7
3. The database administrator is an expert in the ERP database management system.	1	2	3	4	5	6	7
4. Internal IT team members understand custom ERP software programs.	1	2	3	4	5	6	7
5. The IT staff are able to efficiently implement ERP system upgrades.	1	2	3	4	5	6	7
6. The IT staff have the technical ability to conducta formal validation of all system changes.	1	2	3	4	5	6	7
7. IT staff are able to analyze the technical impact of proposed system changes.	1	2	3	4	5	6	7
8. The IT staff actively builds relationships with business managers.	1	2	3	4	5	6	7
9. IT staff offer ideas on how IT can be used to achieve business goals.	1	2	3	4	5	6	7
10. IT staff communicate with functional use groups in the ERP Entity.	1	2	3	4	5	6	7
11. The IT organization provides a service to the business.	1	2	3	4	5	6	7
12. IT project members have limited ERP software expertise.	1	2	3	4	5	6	7
13. IT staff are not responsive to the needs of business managers.	1	2	3	4	5	6	7

ERP Training

1. Specific user training needs were identified early in the implementation.	1	2	3	4	5	6	7
2. A formal training program has been developed to meet the requirements of ERP system users.	1	2	3	4	5	6	7

3. Training materials have been customized for each specific job.	1	2	3	4	5	6	7
4. We seldom update training materials to reflect system changes.	1	2	3	4	5	6	7
5. Training materials target the entire business task, not just the ERP screens and reports.	1	2	3	4	5	6	7
6. Employees are tracked to ensure that they have received the appropriate ERP system training.	1	2	3	4	5	6	7
7. All users have been trained in basic ERP system skills.	1	2	3	4	5	6	7
8. ERP system training review sessions are scheduled.	1	2	3	4	5	6	7
9. The training needs of each user group have not been identified.	1	2	3	4	5	6	7
10. Training is conducted by consultants.	1	2	3	4	5	6	7

Human ERP Resources:

Business Process Skills

1. There is a high level of business process knowledge within the ERP Entity.	1	2	3	4	5	6	7
2. Employees understand how their actions impact the operations of other functional areas.	1	2	3	4	5	6	7
3. Employees understand how their daily business activities support the goals of the ERP Entity.	1	2	3	4	5	6	7
4. Managers are not clear on how ERP-focused business processes support the goals of the ERP Entity.	1	2	3	4	5	6	7
5. The operational processes of the ERP Entity are formally documented.	1	2	3	4	5	6	7
6. Our ERP Entity's business process documentation reflects actual operational activities.	1	2	3	4	5	6	7
7. Functional managers are able to document cross-functional business process flows.	1	2	3	4	5	6	7
8. Business process design is driven by customer requirements.	1	2	3	4	5	6	7
9. Managers are skilled at analyzing business processes for customer benefits.	1	2	3	4	5	6	7

Learning

1.	Benchmarking is used to identify cutting-edge ERP techniques.	1	2	3	4	5	6	7
2.	We keep track of ERP developments related to our industry.	1	2	3	4	5	6	7
3.	Cross-functional groups meet regularly to discuss new uses for the ERP system.	1	2	3	4	5	6	7
4.	Internal groups meet regularly to share new methods of using the ERP system.	1	2	3	4	5	6	7
5.	ERP improvement suggestions are regularly collected from multiple employee levels.	1	2	3	4	5	6	7
6.	Business experiments are conducted to evaluate potential improvements in the way we use ERP.	1	2	3	4	5	6	7
7.	ERP experimentation is encouraged even if the proposed improvement is unsuccessful.	1	2	3	4	5	6	7
8.	External ERP experts are invited to suggest better ways to use the ERP system.	1	2	3	4	5	6	7
9.	Users are discouraged from exploring alternative methods of using ERP to generate business value.	1	2	3	4	5	6	7
10.	The potential customer benefit of new ERP techniques is not formally evaluated.	1	2	3	4	5	6	7

Change Readiness

1.	Employees understand how they fit into the new ERP Entity.	1	2	3	4	5	6	7
2.	Employees have input into how their jobs will change with new ERP business processes.	1	2	3	4	5	6	7
3.	Management actively works to alleviate employee concerns about ERP.	1	2	3	4	5	6	7
4.	An ERP support group is available to answer concerns about ERP job changes.	1	2	3	4	5	6	7
5.	The roles of all employees under the ERP system have been clearly communicated.	1	2	3	4	5	6	7
6.	The change readiness of employees impacted by the ERP system is regularly assessed.	1	2	3	4	5	6	7
7.	Employees are not prepared for a series of ERP-related changes as the system evolves.	1	2	3	4	5	6	7
8.	ERP-focused changes to the employee reward system have been communicated.	1	2	3	4	5	6	7
9.	Employees recognize the need for organizational change.	1	2	3	4	5	6	7

Project Management

1. The tasks to be performed during the ERP project are clearly de	1	2	3	4	5	6	7
2. The responsibilities of project team members are clearly definec	1	2	3	4	5	6	7
3. There is a formal management process to track external cc activities.	1	2	3	4	5	6	7
4. Problems found during reviews of external project members tracked to closure.	1	2	3	4	5	6	7
5. Measurements are used to determine the status of project tasks.	1	2	3	4	5	6	7
6. Project tasks are reviewed on a periodic basis.	1	2	3	4	5	6	7
7. The ERP project leader is able to track project tasks to completi	1	2	3	4	5	6	7
8. The ERP project leader is experienced in project management.	1	2	3	4	5	6	7
9. Project tasks are reviewed on an event-driven basis.	1	2	3	4	5	6	7
10. The relative priority of different categories of change requests documented.	1	2	3	4	5	6	7
11. Resources are assigned to ERP system change requests acco prioritization rules.	1	2	3	4	5	6	7
12. ERP project tasks are tracked against proposed business benefit	1	2	3	4	5	6	7

Business Process Performance

1. Process simplification	1	2	3	4	5	6	7
2. improve the coordination among different units of the firm	1	2	3	4	5	6	7
3. Major information system redesign	1	2	3	4	5	6	7
4. Enriched multi-skilled individual jobs	1	2	3	4	5	6	7
5. The efficiency and productivity of business processes	1	2	3	4	5	6	7
6. Doing the same work with fewer people	1	2	3	4	5	6	7
7. Doing the same work with less supervision	1	2	3	4	5	6	7
8. A lower overall cost structure.	1	2	3	4	5	6	7

Non-financial performance							
1. Materials efficiency variance	1	2	3	4	5	6	7
2. Ratio of good output to total output at each production process	1	2	3	4	5	6	7
3. Manufacturing lead time	1	2	3	4	5	6	7
4. Rate of material scrap loss	1	2	3	4	5	6	7
5. Labor efficiency variance	1	2	3	4	5	6	7
6. Number of new patents	1	2	3	4	5	6	7
7. Number of new products launches	1	2	3	4	5	6	7
8. Time-to-market new products	1	2	3	4	5	6	7
9. Employee satisfaction	1	2	3	4	5	6	7

FAMILY FIRM AND BOARD COMPOSITION – EVIDENCE FROM TAIWAN

Ken Hung

Texas A&M International University

Ken.hung@tamiu.edu

Boards of directors play an important role in the corporate governance mechanisms of publicly listed companies. Existing empirical studies on corporate boards of directors have focused primarily on large U.S. and U.K. firms with dispersed ownership and have closely examined the relationship between managerial ownership and board composition (Lasfer, 2006). In contrast to widely held firms, family firms tend to hold a concentrated ownership structure, which can lead to a particular type of agency problem. The different agency environment in family firms suggest that it is important to study whether and how family-controlled ownership influences board composition.

One characteristic of widely held firms is the separation of ownership and control, which gives rise to agency conflicts, namely principal-agent conflicts between the interests of owners (principals) and managers (agents) (Jensen & Meckling, 1976). Because professional managers do not bear a significant share of the financial effects of their decisions, managers have incentives to take actions contrary to stockholders' interests (Fama & Jensen, 1983). In listed family-controlled firms, concentrated family ownership reduces traditional owner-manager conflicts because "the family's wealth is so closely linked to firm welfare, families may have strong incentives to monitor managers and minimize the free-riding problem inherent with small, diffused shareholders" (Anderson & Reeb, 2003: 1305). However, concentrated ownership has led to the development of a new agency conflict between minority shareholders and the controlling owners, generally referred to as principal-principal conflicts. Because the interests of controlling and minority shareholders are not closely aligned, controlling shareholders are perceived to have strong opportunistic incentives to expropriate wealth from minority shareholders by making decisions that maximize their personal interests (Anderson & Reeb, 2003). Thus, in family firms, corporate boards could play an important role in limiting the power of controlling shareholders to expropriate the interests of minority shareholders by scrutinizing important decisions (Yeh & Woidtke, 2005).

Although family-controlled firms exist in developed countries, they are not as common as in East Asian countries, including Taiwan. As Young et al. (2008) point out, principal-principal conflicts are characterized by extensive family ownership and control, poor institutional protection of minority shareholders, and weak governance' environment. Hence, controlling owners have greater incentives to influence firms' decision making in Taiwan due to its relatively high concentration of ownership, weak legal systems, and abundance of family firms. In such instances, board composition may also be influenced by controlling shareholders (Yeh & Woidkte, 2005). Shyu and Lee (2009) find that in Taiwanese listed firms, an average of 71% of board members are controlled by a family group. Therefore, Taiwan provides an ideal setting for examining the effect of family ownership on board composition in an institutional environment that differs noticeably from its counterpart in developed countries.

Further, It will be investigated the extent to which an external monitoring mechanism—namely, institutional shareholders—impacts board composition. When institutional shareholders are block-holders with relatively large equity stakes, they have the capacity to influence managerial decisions and actions (Yoshikawa & Rasheed, 2010). Mak and Li (2001) argue that institutional shareholding can reduce the likelihood of expropriation by family owners through improvements in board composition. Additionally, since the dependent variable "outsider proportion" is disproportionally clustered around selected values, this study differs from most previous studies in that an ordered-probit regression model will be used to examine the relationship between corporate ownership and board composition. As a result, the results can provide insight into the differential impact of the external and internal structure of corporate ownership in Taiwan on board composition.

Hypothesis 1: Family ownership is negatively associated with the proportion of outside directors on the board.

Hypothesis2: Institutional ownership is positively associated with the proportion of outside directors on the board.

Data and Sample:

The empirical analysis is conducted using corporate data on all companies listed on the Taiwan Stock Exchange from 2005 to 2012. Financial companies are excluded from this study, as the nature of corporate governance in financial companies differs from that in non-financial companies (Filatotchev et al., 2005). After removing observations with missing data, the final sample size is 1,271 firms and 7,919 firm-year observations. All the data are obtained from a database maintained by the Taiwan Economic Journal (TEJ), a leading credit analysis research agent. TEJ provides detailed and complete financial information on companies in Taiwan.

Dependent variables: The proportion of outsider directors and outside director ratings

As mentioned previously, this study adopts three models to examine the influence of corporate ownership structure on outside directors: the ordered-probit, fixed-effects, and random-effects regression models. Therefore, the dependent variable is defined in two ways. First, a continuous variable (%OUTDIR) is used to measure outside directors based on the percentage of outside directors to the total number of directors on the board.

Using a secondary variable (R_OUTDIR), firms will be further grouped into nine categories in terms of the proportion of outsider directors, and numerical values will be assigned to the nine categories in order to conduct an ordered-probit analysis.

Categories of outside directors are presented as:

The proportion of outside	Assigned rank
0.000- 0.100	1
0.101- 0.200	2
0.201- 0.300	3
0.301- 0.400	4
0.401- 0.500	5

0.501- 0.600	6
0.601- 0.700	7
0.701- 0.800	8
0.801- 1.000	9

The firms that have a proportion of outsider directors ranging from 0.801-1.000 are assigned a value of 9, 0.701- 0.800 of 8, 0.601- 0.700 of 7, 0.501- 0.600 of 6, 0.401- 0.500 of 5, 0.301- 0.400 of 4, 0.201- 0.300 of 3, 0.101- 0.200 of 2 and 0.000- 0.100 of 1.

Independent variables: Corporate ownership structure

Traditionally, corporate ownership has been operationalised along two dimensions: internal ownership (managerial ownership) and external ownership (institutional/block-holder ownership) (Mark & Li, 2001). Rather than taking the perspective of managers, this study focuses on family ownership as an internal ownership characteristic. Therefore, the corporate ownership structure investigated in this study includes family and institutional shareholding. Family ownership (FAMOWN) is measured by a numerical measure that indicates the percentage of common stock owned by family members, with a larger value indicating greater family interests in the firm. Institution ownership (INSOWN) is the percentage of shares that institutions own in the firm divided by the total number of outstanding shares.

Control variables:

To isolate the effects of test variables on the proportion of outside directors, several control variables based on the literature will be used. These control variables include firm size, return on assets, financial leverage, the operating cash flow, and sales growth. Firm size (SIZE) is the natural logarithm of total assets. Return on assets (ROA) is calculated as operating income divided by total assets. Financial leverage (LEV) is the ratio of financial liabilities to total assets. The operating cash flow (CFO) is defined as the cash flow from operations scaled by lagged total assets. Sales growth (SALEGR), measured as the year to year percentage change in total sales.

Research Method:

Iwasaki (2008) groups firms into nine categories based on the proportion of outside directors and define R_{it} to be the category of company i in year t. R_{it} is continuous, and its range is the set of real numbers. It presents the rank of %OUTDIR of a company. The ordered-probit model consists of two parts. The first part maps the outside director categories R_{it} into a partition of the unobserved linking variable R_{it}^* as follows:

$$R_{it} = \begin{cases} 1 & \text{if } R_{it}^* \le \mu_1 \\ j & \text{if } \mu_{j-1} < R_{it}^* \le \mu_j \quad \forall j \in J \\ 9 & \text{if } R_{it}^* \ge \mu_8 \end{cases}$$

Where $J = 1,2,3,4,5,6,7,8$. μ_r $r = 1,2,3,4,5,6,7,8$ are threshold variables that define the partitions of the range of R^*_{it} associated with each value of a rank and are independent of t.

The second part of the ordered-probit model relates R^*_{it}'s to the observed variables that measure the ownership structure variables of company i by means of a linear model.

$$R^*_{it} = \beta' X_{it-1} + \varepsilon_{it}$$

where β is the vector of slope coefficients of explanatory variables. X_{it} is vectors of observed explanatory variables measured at year t. The random variable ε_i is an unobserved error term with standard normal distribution and constant variance. Since the percentage of outsiders on the board and ownership structure determinations are simultaneous, modeling the relationship between the two can incur endogeneity problems if contemporaneous ownership structure and outside directors ratio are used. To control for endogeneity problems, the methodology of Harford et al. (2008) will be followed to examine whether the lagged value of the firm's %OUTDIR and governance variables are related to a firm's future %OUTDIR.

From the slope parameter and threshold estimates, it is relatively straightforward to calculate the probability of a company falling into in rank r. Given the cumulative normal function $\Phi(\beta' X)$, the probability of categorization for a company can be shown as below:

$$\Pr(R = r) = \begin{cases} \Phi(\mu_r - \beta' X) & \text{if } r = 1 \\ \Phi(\mu_r - \beta' X) - \Phi(\mu_{r-1} - \beta' X) & \text{if } r = 2,3,4,5,6,7,8 \\ 1 - \Phi(\mu_{r-1} - \beta' X) & \text{if } r = 9 \end{cases}$$

where $\beta' X$ is a set of specific values of X for the estimated coefficients β and the threshold values μ's. It could be detected the influence of governance variables on %OUTDIR by calculating the marginal effects of the explanatory variables on the probability of %OUTDIR. For example, the marginal effect of family ownership (FAMOWN) on the probability of rank 4 %OUTDIR is:

$$\frac{\partial \Pr(R = 4)}{\partial FAMOWN} = [\Phi(\mu_3 - \beta' X) - \Phi(\mu_4 - \beta' X)] \times \beta_2$$

Notice that the sum of the marginal effect equals zero.

Additionally, this study employs the fixed-effects and random-effects regression models to compare the results of the ordered-probit model. Consequently, An analysis reports fixed-effects, random-effects estimation to control for the endogenous problem and provides a comparison of the results of the ordered-probit regression model.

Work to be Done:

After the completion of a panel data analysis, the effects of ownership structure on the proportion of outside directors will be examined. Questions and answers will be elaborated and worked out on the following three tasks.

1. **Estimated results of fixed-effect, random-effect and ordered-probit models**
2. **Marginal effects of ordered-probit model**
3. **Impacts of family ownership on board composition of different models**

Consumer social resources and value co-creation: an empirical study in education services

Nguyen Manh Tuan

Dang Kim Oanh

Consumer role in value co-creation is recently an emerging theme in service research. In the contemporary networked economy, consumer social resources, specifically social capital and social identity, are opportunely suggested as the determinants of value co-creation. A survey study with SEM analysis of 334 consumers in 9 educational institutions shows 10 out of 11 hypotheses empirically supported. The findings reinforce that social capital and social identity, as operant resources, direclty influence consumer satisfaction and loyalty, and in an indirect way through value co-creation.
Keywords: *value co-creation, social capital, social identity, operant resources.*

1. Introduction

Service dominant logic (S-D logic), a mainstream in service literature, provides that consumer value co-creation is a fundamental way to create organizational competitive advantages (Prahalad & Ramaswamy, 2004), or to realise value propositions (Vargo & Lusch, 2008). Co-creation is essentially both networked and social (Vargo & Lusch, 2008), and often seen as the outcomes of the process of resource integration (Hilton et al, 2012) in which, customer operant resources is apparent (Vargo & Lusch, 2008).

In the modern business environment, service value is positioned in value networks that comprise various actors including service providers, customers, potential customers and other stakeholders. The value networks in turn, on one hand, are often based on the vast social networks supported by modern information and communication infrastructures (Lusch et al, 2010), and, on the other hand, strongly depend on the roles of social actors (Vargo & Lusch, 2008).

Taking the view of value proposition forming by social networks and social actors, our objective is to examine which consumer socially operant resources affect and how their impact on customer co-creation is. To be specific, this study investigates customer social capital and social identity as the antecedents of their co-creation behaviors in an education services context, and clarifies consumer satisfaction and loyalty as the consequences of the value co-creation.

The paper is structured as the following. Next is the theoretical background along with hypothesized model where, the concepts of value co-creation, consumer social resources and satisfaction and loyalty are brought together and the research hypotheses are stated. The methods and findings of our model testing are presented then. Finally, some managerial implications, contribution to the literature, and conclusions are drawn.

2. Theoretical framework and hypothesized model

Defintions of consumer loyalty, satisfaction, co-creation, social capital and social identity

Consumer loyalty in this study is defined as a consistent commitment to rebuy or repatronize preferred product or service (Oliver, 1999). Against Oliver's (1999) popular pattern of cognitive-affective-cognative, this definition better suits the phase of cognative or behavior intention, which is also often assumed by most consumer behavior researchers such as Zeithaml et al (1996).

This paper adopts the view of overall satisfaction that is a consumer's cumulative evaluation of service outcome against a standard of pleasure versur displeasure (Oliver, 1999). In comparison to the transaction specific satisfaction, the cumulative one may be a better antecedent of loyalty (Oliver, 1996) and it is just the reason for our choice herein. Assuming that satisfaction occurs when consumption fulfillment is pleasurable (Oliver, 1997), our examining consumer different needs as determinants to achieve the needs fulfillment is invoked (Au et al, 2008) as presented below.

Value co-creation or value co-production is used interchangeably or differently in the same management literature (Hilton et al, 2012). The differences can be that, while the former takes place in the usage stage, the latter may show itself within the production preparation process (Etgar, 2008). This paper needs not distinguish the two concepts, and defines co-creation as joint activities by customers and service providers (and perhaps, others) involved in direct interactions for the benefits of one or more parties (Gronroos, 2012).

Gronroos (2012) recently synthesized a conceptual model of value co-creation relying on both well known Eiglier and Langeard's (1975) servuction model and Gronroos's (1978) interactive marketing model. The core of the comprehensive conceptualization is the combination between the resource categories and co-creation activities, in which resources are inputs and activities are relevant outcomes. In the same vein, co-creation is considered resource integration (Hilton et al, 2012). Hilton et al also noted that supplier resources has historically received great interest in the literature, but now customers as resource integrators are getting increased attention. Out of three sorts of customer resources as physical, cultural and social ones, the study only examine the customer social resources that are the vast social support ranging from professional networks and relationships of friends and families to various communities of practice (Arnould et al, 2006).

To be specific, this paper focuses on the customer social capital and social identity. Whereas the former is generally the intangible resources based on the relationships among the members of social communites and networks (Nahapiet & Ghoshal, 1998), the latter refers to one's knowledge on whether or not (s)he belongs to some social group or category (Hogg & Abrams, 1988). The two focal social resources are to some extent representatives of social networks and social actors that are the intrinsic nature of value co-creation as introduced previously. It should be noted that the two sorts of resources adopted are also the typical forms of operant ones (i.e knowledge, skills, relationships, etc) that according to S-D logic are playing the increasingly important roles as key source of competitive advantage (Vargo & Lusch, 2008).

Social capital as determinants of co-creation and satisfaction

Although social capital can occur at many different levels ranging from individuals, organizations, inter-organizations to societies (Tsai & Ghoshal, 1998), it in this study is defined as the combination of the real and potential resources involved in the relational networks possessed by an individual (Nahapiet & Ghoshal, 1998). Alternativey, it is viewed as the personal perceptions of one's ability to extract benefits from the relevant social structures and relations (Portes, 1998). To this end, social capital should be characterized as the three dimensions: structural, cognitive and relational (Nahapiet & Ghoshal, 1998).

Structural capital is the overall pattern of social interactions or links between individuals in a network, which refers to where one's location is in the structure, or who one reach (Burt, 1992), how strong the tie strength is (e.g. intensity and frequency of communications) (Granovetter, 1973). In this study, the structural dimension is understood as the meaningful links between consumers or students and education service provider, on and by which the former gets itself involved in the whole process of posing service requirements, fine tunes service specification, tests out service scheme, consumes service packages, etc. Such channels explicitly foster the integration and exchange of knowledge of partners to anticipate value (Nahapiet & Ghoshal, 1998) and facilitate cooperative behavior (Putnam et al, 1993).

Relational capital is the trusted reciprocity of any relations in a network, which refers to any exchange is mutual and fair to any parties (Blau, 1964). In this study, the relational dimension is identified as student's specific interactions with education service provider such as trustworthiness, friendliness and commitment to the process of service production and delivery. When such social trusts are established in a network, business partners spend much more their time and efforts into joint activities (Nahapiet & Ghoshal, 1998).

Cognitive capital is the public good aspect of social relationships (Coleman, 1990), which refers to the common norms and shared understanding toward the benefits of the network (Nahapiet & Ghoshal, 1998). Focusing on its own interest, this paper considers the cognitive dimension as student's sharing ideas and their joint enhancement of conditions and capabilities to work together with education service provider and others for the whole service value. This sharing apparently binds different members of the collective and makes collaborative actions possible (Cohen & Prusak, 2001).

In brief, social capital is a sort of productive resources that have analytically two key properites: (i) facilitate collaboration and participation, and (ii) serve mutual benefits of individual and the whole network (Putnam, 1995). For the first feature, recent studies also provide support for the influence of social capital, for example, on knowledge sharing in virtual communities (Chiu et al, 2006), on knowledge acquisition in technology-based firms (Yli-Renko et al, 2001), on firm resource exchange and combination (Tsai & Ghoshal, 1998), or on firm innovation (Martínez-Cañas et al, 2012). Therefore, we propose the following hypotheses:

H1a: Structural capital is positively related to value co-creation

H1b: Relational capital is positively related to value co-creation

H1c: Cognitive capital is positively related to value co-creation

Concerning the second feature, consumer cooperative interactions with service provider reflect the whole service process that is changing from single transaction type to relationship type over time (Gronroos, 1994). With respect of consumers, the service value centers around their needs to be satisfied (Etgar, 2008). According to Etgar (2008), the needs to be fulfilled may be in the form of: (i) consumer preferences as well as differentiation toward customized performance, (ii) consumer seeking of socially status and esteem as well as consumer desire for control; and (iii) consumer self-expression and uniqueness as well as self-oriented appreciation of value as freedom, enjoyment, confidence etc. Such needs are completely inline with Au et al (2008)'s equitable needs fulfillment model that shows the three respective kinds of fulfillments: performance, relatedness and self-development ones. It is also noted that the three needs fulfillment are just the predictors for consumer satisfaction in Au et al (2008)'s work. In the same argument, Sun et al (2012) empirically reported the positive influence of social capital on customer satisfaction with IT services. This possibly leads to the following hypotheses:

H2a: Structural capital is positively related to consumer satisfaction

H2b: Relational capital is positively related to consumer satisfaction

H2c: Cognitive capital is positively related to consumer satisfaction

Social identity as determinants of value co-creation and satisfaction

Social identity is conceptualized as individual's perception of what constitutes to the "us" (Tajfel & Turner, 1986). For each individual, social identity shows itself as the process of self-categorization (which positions the person into social groups or communities such as engineers, students, etc) as well as the process of comparison (by which the person identifies some similarities with other members and some dissimilarities with non-members). As a result, in view of social identity, the community objectives, concerns and even bias strongly shape individual member's attitudes and behaviors (Turner et al, 1987). Recently empirical evidence reported that social identity positively influences on knowledge sharing of participants in an e-learning environment (Hwang, 2010).

In education, considering himself/herself as an active member of an educational institution, he/she could adapt his/her intentional and actual behaviros to those that are inherently determined by the institution. In other words, student social identity on their learning environment is also a sort of their motivation to collaborate with others to make progress for each and every of them. Thus, we propose:

H3: Social identity positively influences value co-creation.

In the same vein, when consumers spend more their efforts on social identity along with the interactive process of service development and delivery, their learning needs are fulfilled and, hence, their satisfaction is also formulated (Au et al, 2008). We, therefore, hypothesize the following:

H4: Social identity positively influences consumer satisfaction.

Satisfaction as outcome of value co-creation

The current education contexts commonly follow the learner-centric paradigm, and hence, student engagement and esatisfaction is also more imprortant. Theoretically, consumer satisfaction with services is the direct result of their experience on the service delivered (Westbrook, 1987). More, their experience is also reinforced when consumer put themselves into value co-creation activities that are increasingly popular in the age of consumer connectedness and empowerment of service providers (Prahalad & Ramaswamy, 2004). For this, the following hypothesis is suggested:

H5: Value co-creation positively influences consumer satisfaction.

Loyalty as joint outcome of co-creation and satisfaction

Consumer loyalty is defined here as their commitment to a particular service offered by some provider, and often embodied in their intention to stay with consuming the service (Zeithaml et al, 1996). Similar to satisfaction, consumer loyalty is subject to their service experience, and as a more specific manner, their activities and enjoyment in service interaction leads them to recommend the provider to others (Lam et al, 2004). On this link, we advance the following hypothesis:

H6: Value co-creation positively influences loyalty.

Finally, service marketing literature tradionally suggests that satisfaction is also a key determinant of consumer attitudinal and behavioral loyalty (Geyskens et al, 1999). We, thus, come to the following hypothesis:

H7: Satisfaction positively influences loyalty.

3. Methods

Sample design

Co-creation activities commonly appear in high interaction services (Auh et al, 2007), under many forms such as interaction intensity in service encounter, level of interdependence between providers and consumers, or information richness in service development and delivery (Kellogg & Chase 1995). For educational settings, as contacts among learners, and especially, contacts between learners and teachers are key interactions of service experience, the survey respondents selected are students those who have participated and are participating the schools in HCM City, VietNam.

Data is gathered through the convenience sampling with questionnaires distributed directly to students of 9 institutions including college and vocational schools as well as English training centers. A total responses of 376 was received over 2 months of questionnaire delivery. Finally, after removing the responses of excessive missing information, 334 valid responses were ready for further analysis. Of the entire valid sample, 53,9% were female; 50% were between 18 and 26 years old, 30.2% between 27 and 30 years old, 16.5% between 31 and 45 years old, and 3.3% over 45 years old; 55% studied for a university degree or a higher education level, 24.9% participated in foreign language training, 10.8% in soft skills training, and 9.3% in other vocational training.

Measurement

All measurement items of theoretical constructs are adapted and revised from previous studies with the support of a focus group of two lecturers of service marketing field and three students of business administration field. The measurement scale adopted is a fivepoint Likert-type one ranging from 1 as completely disagreed to 5 as completely agreed.

The scale of social capital is adapted from Sun et al (2012), of social identiy from Hwang (2010), of co-creation from Auh et al (2007), and of satisfaction and of loyalty from Yang & Peterson (2004).

Data analysis

Anderson & Gerbing (1988)'s two-step SEM approach is implemented using SPSS/AMOS 21.0 to firstly evaluate measurement model and then structural model. For measurement model, Cronbach's alpha and exploratory factor analysis (EFA) were used for pretest of research instrument. Then confirmatory factor analysis (CFA) was applied for testing its convergent and discriminant validity, composite reliability and overall fit (Hair et al, 2006). For structural model, SEM technique with Maximum Likehood estimation and Bootstrap approach to evaluate the overall fit of research model and hypotheses (Hair et al, 2006).

Findings

Measurement model

In instrument pretest, Cronbach's alpha results show that after elimating three items of total item correlation coefficient of less than 0.3, all measurement scales exceed the mimimum reliability (0.6) (Chau, 1997), and EFA check indicates that the factor structure of theoretical constructs is acceptable when all facor loadings are greater than the threshold of 0.5 (Nunnally & Bernstein, 1994).

Next, CFA results reveal that the model fit indices, against cut-off values suggested by Chau (1997), are satisfactory, with CMIN/df=2.011 (<3), RMSEA=0.055 (<0.08), GFI=0.901 (>0.9), TLI=0.928 (>0.9) và CFI=0.941 (>0.9).

The convergent validity of the instrument is acceptable with that both the composite reliability (CR) values are all greater than 0.7 and average variance extracted (AVE) values range from 0.49 to 0.69 (recommended cut-off is usually 0.5 (Bagozzi & Yi, 1988)). The discriminant validity of the constructs is adequate when the square roots of average variance extracted are greater than the correlation between two latent variables (Bagozzi & Yi, 1988). In summary, Table 1 and Table 2 show that the measurement model exhibits an adequate fit with the gathered data.

Table 1. Loadings, average variance extracted (AVE) and composite reliability (CR

Constructs	Indicators	Standardized factor loadings	AVE	CR
Co-creation	DS23	0.76	0.68	0.86

Structural model

The first step is to test the assumed casual relationship among the constructs. The model fit indices are adequate (Table 3): chi-square statistic=1.984 (<3); GFI=0.900, TLI=0.930, CFI=0.941 (all is greater than 0.9), RMSEA=0.054 (<0.08). Next is to test the model hypotheses. The results (Figure 1) shows that 10 out of 11 hypothezied paths are empirically supported at the 0.001 and 0.05 levels of significance.

Table 3. Tests of structural model

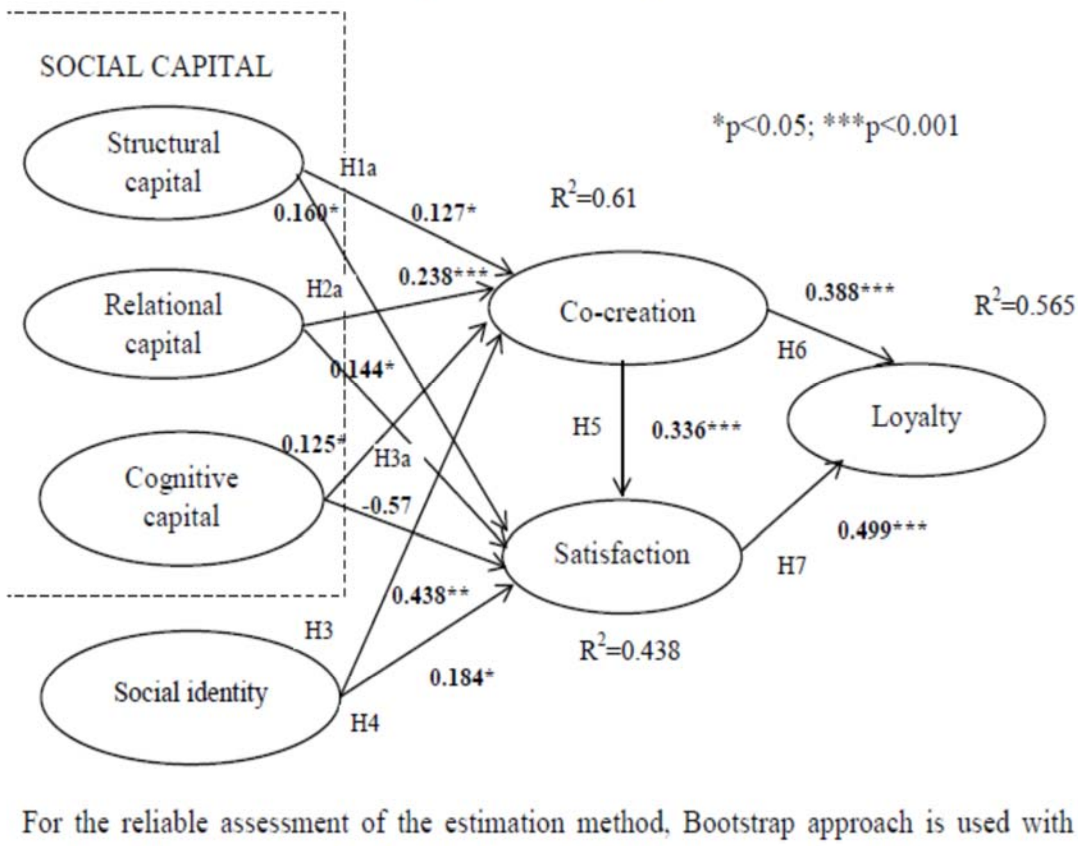
Hypotheses	*Regression relationships*	*Regression coefficients*	*Directions*	*Results*
H1a	Structural capital → Co-creation	0.217	+	Supported
H1b	Relational capital → Co-creation	0.238	+	Supported
H1c	Cognitive capital → Co-creation	0.125	+	Supported
H2a	Structural capital → Satisfaction	0.160	+	Supported
H2b	Relational capital → Satisfaction	0.144	+	Supported
H2c	Cognitive capital → Satisfaction	-0.57	-	Unsupported
H3	Social identity → Co-creation	0.438	+	Supported
H4	Social identity → Satisfaction	0.184	+	Supported
H5	Co-creation → Satisfaction	0.336	+	Supported
H6	Co-creation → Loyalty	0.388	+	Supported
H7	Satisfaction →Loyalty	0.449	+	Supported
Model fit indices				
	Chi-square statistic (CMIN/df)	1.984		
	GFI	0.900		
	TLI	0.930		
	CFI	0.941		
	RMSEA	0.054		

Hypotheses H1a, H1b, H1c and H3 that are supported show the positive influence of both student social capital and social identity on their co-creation behaviors. In specific, social identiy is the stronger determinant with the highest regression coefficient of 0.438. Next, the positive influence of student social capital on their satisfaction is also confirmed with the two dimensions of structural capital and relational capital while the dimension of cognitive capital has not the significant relation. As a result, hypotheses H2a and H2b are supported but H2C is not.

Co-creation shows the positive and significant influence on both student satisfaction and loyalty, which is that both hypothesis H5 and H6 are supported respectively. In comparison to co-creation, social identity also exhibits an active effect on student satisfaction but with a lower strength. In addition, that hypothesis H7 is supported, which is quite consistent with previous studies, also show the strong and significant link (regression coefficient of 0.449) between student satisfaction and loyalty.

Concerning the explanatory power via the determined coefficient R^2, social identity and social capital account for 61% variance of co-creation. While social identity, social capital and co-creation account for 43.8% variance of satisfaction that in turn, along with co-creation account for 56.5% variance of loyalty.

Figure 1. Model testing results



For the reliable assessment of the estimation method, Bootstrap approach is used with the number of bootstrap samples N=500. The result (Table 4) shows that the boostrap estimates have sufficiently small variations, and they are statistically insignificant. Consequently, the model estimation is adequate.

Table 4. Bootstrap estimates with N=500

4. Conclusion

Discussion

The present study empirically validates the power of co-creation in the explanation of consumer satisfaction and loyalty in education services. The actively participatory roles of students could lead to their satisfaction and long time collaboration with their schools.

Our findings show that, in a consistency with previous studies, co-creation has a positive influence on satisfaction (as in Dong et al, 2008) and on loyalty (as in Auh et al, 2007). A small difference is that, while in Dong et al (2008), the effect of co-creation on satisfaction is stronger than that is on loyatlty, in this paper, the effect of co-creation on loyatlty is stronger than that is on satisfaction. Our result, based on Ajzen (1991)'s theory of planned behavior (TPB) where it is claimed that the formation of attitude (e.g. satisfaction) is established in prior to that of behavioral intention and actual behavior (e.g loyalty), is more theoretically fit than that of Dong et al (2008). Consequently, the meaningful challenge of customer value via co-creation (Hilton et al, 2012) is empirical validated in our model.

Our study also adequately confirms that social capital and social identity are the predictors of co-creation in educational services. The determinants are posivitely and significantly related to co-creation as expectedly. The interesting note is that the influencing strength of social identiy is higher than that of social capital. This is a primary distinction between our study and Yoon's (2004) where social identiy acted only a moderator for the relationship between social capital and usage of social network services, a sort of co-creation (Prahalad & Ramaswamy, 2004).

Theoretical implications

The paper offers a new understanding of service marketing, which is the role of predictors of social capital and social identity toward consumer co-creation activities. This may be a newly theoretical insight in comparison to Auh et al's (2007) where co-creation is explained by consumer competencies, consumer motivation and the clear communication between consumer and provider.

Next our results also demonstrate a simultaneously positive effect of social capital, social identity and co-creation on consumer satisfaction. This outcome could provide an insightful complement to (i) Dong et al's (2008) work where satisfaction is predicted only by co-creation, and (ii) Sun et al's (2012) study where social capital is a direct determinant for satisfaction. Consequently, with the strongest influence of social capital (against social identity and co-creation) on satisfaction, the role of partial mediator of co-creation between social capital as well as social identiy and satisfaction could be revealed.

Managerial implications

The study's findings suggest some practical implications for service providers. Firstly, at their's looking forward to consumer co-creation, they may get benefits because it direcly leads to consumer satisfaction and loyalty. Secondly, for their enhancing consumer co-creation, they may exploit consumer perceived social identity and social capital. This is to focus both identification of consumer communities throughout service development and delivery (i.e. social identity) and interaction within community and across community (i.e. social capital). Service providers necessarily consider the focus as their long term investment, starting with changing in their perceptions of service climate, and then empowering frontline employees (Heskett et al, 1994) to draw and support their consumers during service process as relevant and powerful service co-creators.

Thirdly, from view of customer, students by themselves need to reinforce their active collaboration in school activities for their own benefits in both the learning process and outcomes. Next, consumers in general are required to improve their social capital as both the requirements of globalization contexts with ubiquitously networked connections and the motivation leads them to fully experience services as Cova (1997) commented on the valuable link between communities and contemporary consumption. Finally, on this link, the role of social identity cannot be missed in shaping consumer behaviors. Specially, in education services, social identity helps students to position and consider themselves as responsible members of educational institutions to seek and contribute to both organizational and individual benefits.

Limitations and further research

The convenience sampling of the study may not help us to have good representative of the general population of education service consumers in HCM City, VietNam. Therefore, the generalization of its findings should be validated more, for example in other service settings such as health care, finance, consultancy of business development, etc.

Furthermore, in addition to social capital and social identity as typical social resources, other consumer resources which belong to cultural and physical ones (Arnould et al, 2006) could be prospective determinants of co-creation in next research avenue.

Conclusion

The study confirms that consumer co-creation is an important predictor for their satisfaction and loyalty. Consequently, service providers may focus on the meaningful determinants of co-creation such as social capital and social identity of their consumers. It can be an interesting point of the paper findings, which highlights that some sort of consumer socially operant resources rather than consumer motivation could act as significant antecedents of co-creation, a typical behavior of service world, and hence, to maintain key source of competitive advantage of service providers as indicated within S-D logic.

Abstract: Due to the problem of data sparseness, financial statements based approach to bank risk measurement and aggregation is receiving increasing attention from researchers. However, most of the studies curtly ignore off-balance sheet items when measuring risk based on financial statements. The more detailed disclosure of off-balance sheet items in financial reports makes it possible to incorporate off-balance sheet items into risk measurement. Specifically, other than balance sheet assets, off-balance sheet items are corresponded with risk exposures, which making risk exposures more accurate and rational.

In the experiment, we construct two hypothetical banks of different sizes based on Chinese banks and calculate their economic capital respectively. The results show that : (1) Ignoring off-balance sheet items in risk integration will lead to deviations. The total risk of large bank is overestimated while small bank's total risk is underestimated; (2) By comparing economic capital with regulatory capital, we find that large bank operates more robustly, which is corresponded with lower profitability of large bank.

Keyword: Risk aggregation, Financial statement, Off-balance sheet, Risk measurement

1. Introduction

Recent days, in order to circumvent the limitations of the credit scale, commercial banks accelerate the expansion of off-balance activities. A popular explanation for the explosive growth in banks' off-balance sheet activities is to reduce regulatory taxes, such as capital adequacy requirements. And as part of the financial innovation process, engaging in off-balance sheet activities has become a tendency for banks. At the end of 2011, off-balance sheet financial derivatives and credit items of the four largest state-owned banks are 5682 and 7958 billion, which account for 11.1% and 15.5% of balance sheet total assets respectively. Moreover, their off-balance sheet items grow at an average rate of 3.8% in the first half of 2012. In addition, from the perspective of regulatory standards, the business scope under supervision extends from balance sheet items to off-balance sheet items. A risk-based capital requirement for some off-balance sheet activities has enacted. Some characteristics of off-balance sheet activities, such as blind expansion and high-risk, making the existence of off-balance sheet items is a key cause for financial crisis which started in 2007. The role of banks' off-balance sheet activities are highlighted in the public commentary on sub-prime crisis (Barrell and Davis, 2008). Therefore, we should not ignore off-sheet items in risk measurement.

For the purpose of incorporating off-balance sheet items into risk measurement, financial statements based on approach is a feasible method. The core of this method is utilizing actual data from a set of commercial banks' financial statements to develop empirical proxies for different risk types. While many previous studies used simulated risk data, which can hardly measure risk in an authentic way. After getting distributions of different risk types, aggregating different risk types to acquire total risk and calculate economic capital. The reason why total risk is necessary for banking supervision is that different types of risk may interact with each other and they are inseparable (Jarrow and Turnbull, 2000). The correlation among risks may lead to further losses in some extreme situations (Li & Feng et al. 2012) Economic capital is increasingly receiving attention because with the outbreak of subprime crisis, many large-scale UK and US banks collapsed or were forced to raise capital during 2007–2009. This phenomenon reflects that previous regulatory capital can't guarantee the soundness of banks. Furthermore, capital management and allocation are key issues for top management decisions (Li et al. 2015). As a result, the way to get accurate economic capital through risk aggregation becomes a research hotspot. A significant example is that economic capital modeling has become fundamental planks of Pillar 2 compliance (Alexander and Sheedy, 2008).

Many papers focusing on risk measurement and aggregation is based on financial statements. Kretzschmar et al. (2010) split aggregate asset positions by exposure type and credit class to study whether the current dominant practice leads to undercapitalization of banks before subprime crisis. In their research, a simplifying assumption is taken that derivatives are excluded in the assets portfolio and off-balance sheet exposures for credit lines are not specifically modeled. However, in reality, the proportion of undrawn credit lines varies widely across asset portfolios. Therefore, such a simple assumption for off-balance sheet exposures makes the effectiveness of qualitative conclusions can't be guaranteed. Given the importance of off-balance sheet items, Drehmann et al. (2010) not only take account of the repricing characteristics of assets and liabilities, which have been considered by Alessandri & Drehmann (2010) when integrating credit and interest rate risk, but also square up the repricing characteristics of off-balance sheet items. Such a modification makes the hypothetical bank's interest rate sensitivity gap more accurately to reflect that of a realistic commercial bank. Researches has realized that one drawback of making balance sheet as a data source is that we cannot obtain first-hand risk profit & loss data. Fortunately, Kuritzkes and Schuermann (2007) found that mapping income statement of US banks into risk types is a way to get risk profit & loss directly. However, the income statements are of significant difference in US and China. For this reason, Li & Yi et al. (2012) utilize quarterly panel data of Chinese income statement to model risk contributions and then employ copula method to measure Chinese bank's total risk.

It is worth noting that above researches only focus on one financial statement, either income statement or financial statement. While Inanoglu and Jacobs (2009) match risk types with items from both income statement and balance sheet. In particular, balance sheet items are regarded as proxy of liquidity risk whereas profit & loss items are proxies of other risk types, which creating the problem of data inconsistency. Rosenberg and Schuermann (2006) establish corresponding relationship between risk types and balance sheet to acquire risk exposures and map risk types into income statement to obtain risk profit & loss, which making full use of information in financial statements. Although Rosenberg and Schuermann (2006) realize that off-balance sheet items can be larger, they still follow the usual treatment of ignoring off-balance sheet items, which may lead to inaccurate results because both balance sheet assets and off-balance sheet assets can generate profit or loss. In general, the income generated by off-balance sheet items accounted for over 50% of total income in American banks and in China, this proportion is 8% on average. Therefore, previous studies did not make full use of off-balance sheet data, which may lead to deviation in conclusions. What's more, the more detailed disclosure of off-balance sheet activities makes it possible to incorporate off-balance sheet items to measure risk.

The objective of this paper is to model risk distributions more accurately and rationally by bringing off-balance sheet items into risk measurement. Specifically, by mapping risk types into income statement and balance sheet & off-balance sheet assets we obtain risk profit & loss and risk exposures, respectively. For the purpose of modeling risk distributions, risk returns are calculated by dividing risk profit & loss to risk exposures. Then weighted average method is employed to measure total risk. In the empirical study, the data source is quarterly financial statements data of all Chinese listed commercial banks from 2007 to 2013. And a large and a small hypothetical bank are constructed from Chinese listed commercial banks to examine our approach.

2. Approach

2.1 Risks in This Research

It is generally accepted that any large, international active financial institutions, regardless of the business they are engaged (e.g. banking, brokerage, insurance or wealth management), are faced with at least three risk types: credit risk, market risk and operational risk (Inanoglu and Jacobs, 2009). As subprime crisis broken out, liquidity risk has attracted widely attention because it played an important role in the entire financial system. Lin (2000) also found that banks are faced with different types of risks, such as credit risk, market risk, operational risk and liquidity risk. Therefore, we will aggregate these four risk types.

Credit risk refers to the potential loss caused by counterpart or debtor defaults in the process of trading credit products (BCBS, 2004). Market risk is the impact on earnings brought about by adverse price movements in the bank's principal trading positions (BCBS, 2005). Liquidity risk is the risk that a given security or asset cannot be traded quickly enough at reasonable price in the market to prevent a loss or make a required profit (IOSCO, 1998). A widely used definition of operational risk is the one contained in the Basel II regulations. This definition states that operational risk is the loss resulting from inadequate or failed internal processes, people and systems, or from external events.

2.2 The Correspondence between Risks Types and Financial Statements

The risk exposures and risk profit & loss can be acquired by mapping risk types into balance sheet & off-balance sheet assets and income statement respectively. The specific corresponding relationship is shown in figure 1.

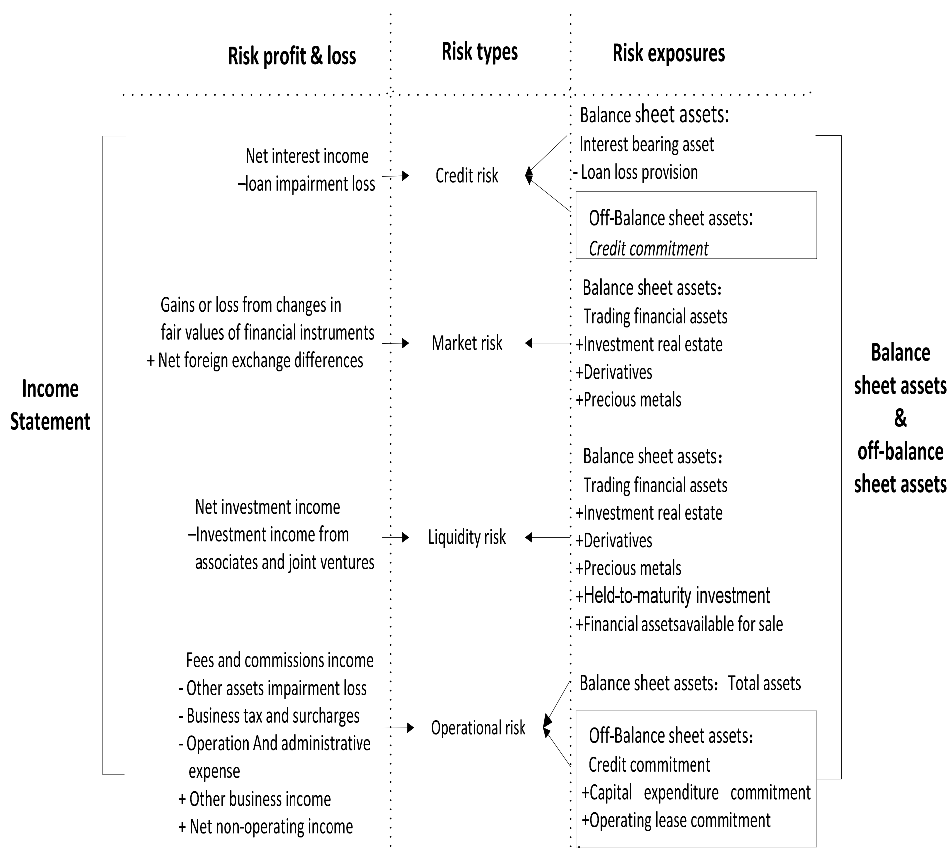

Figure 1 The correspondence between risk types and financial statements

The major source of credit risk is interest-bearing assets, which include loan, due from central bank, due from banks and other financial institutions, accounts receivable investment, buying back the sale of financial assets, lending to banks and other financial institutions and bond-investment. The changes in scale of interest-bearing assets will cause fluctuations in net interest income. In addition, if there is obvious evidence to show that the loan impairs, we should record loan impairment loss. So credit risk profit & loss equals to net interest income less loan impairment loss. For credit risk exposure, it consists of interest-bearing assets, loan loss provisions and off-balance sheet credit commitment. To be specific, credit commitment is classified into guarantee business and credit business. Guarantee business is made up of bank's acceptance bill, letter of credit and letter of guarantee. The reasons why credit commitment is part of credit risk exposure are as follows. Banks acting as guarantors in guarantee business will assume credit risk because if applicants renege banks have to perform the contract. And credit business consists of loan commitment and line of credit card, which are loans in nature. With respect to market risk, gains or losses from fair values of financial instruments are affected by price fluctuations of financial instruments while net foreign exchange differences are determined by changes of foreign exchange. Sum of these two items are equal to market risk profit & loss. For market risk exposure, the value of trading financial assets, investment real estate, derivatives and precious metal are influenced by market factors (i.e. price, interest rate, foreign exchange)so they are elements of market risk exposure. At the request of new accounting standards which issued at 2006, off-balance sheet derivatives are accounted at fair value in the balance sheet derivatives account.

As for liquidity risk, net investment income reflects the gains or losses from the process of trading ready to liquidate financial assets. However, investment income from associates and joint ventures is generated by long-term equity investment, which is made to control or influence other companies other than get short-term investment income. Therefore, liquidity risk profit & loss is equal to net investment income less investment income from associates and joint ventures. The financial assets held to liquidate immediately at required belong to liquidity risk exposure. Specifically, they are trading financial assets, investment real estate, derivatives, precious metals, held-to-maturity investment and financial assets available for sale. Similar to market risk, off-balance sheet derivatives which undertake liquidity risk have been disclosed in the balance sheet.

Finally, the remaining items in the income statement are matched up with operational risk. Rosenberg and Schuermann (2006) deem that all assets and activities of the bank are in some way subject to operational risk. We follow this standpoint to get operational risk exposure, which equals to balance sheet total assets plus off-balance sheet total assets. In particular, off-balance sheet business consists of credit commitment, derivatives and investment banking. Unfortunately, the disclosure of off-sheet items is limited and different among banks. Hence, we just consider credit commitment, capital expenditure commitment and operating lease commitment.

2.3 Procedure of Risk Measurement and Aggregation

The risk profit & loss is not comparable among different banks because banks are different in terms of scale, capital allocation, investment strategy and management level. So after collecting original risk data, we need to preprocess the data to get risk return which is comparable among banks. Value-at-Risk (VaR), pioneered by J.P. Morgan, has become a standard measure for financial risk. Therefore, it is still being employed here for risk measurement. Finally, weighted-average method is applied for risk aggregation and calculation of economic capital. The procedure of data preprocess can be divided into four steps:

Firstly, risk return which is defined as risk profit & loss to risk exposure is the target. So the risk return is simply

$$r_{i,j,t} = \left(\frac{R_{i,j,t}}{RE_{i,j,t}} \right) \quad (1)$$

where $R_{i,j,t}$, $r_{i,j,t}$ and $RE_{i,j,t}$ stand for risk profit & loss , risk return and risk exposure of bank i, risk j at time t ,respectively.

In the second step, we perform mean adjustment for risk return so as to get expected risk return, which can be written as

$$r'_{i,j} = \left(\frac{1}{T_i} \sum_{t=1}^{T_i} r_{i,t} \right) \quad (2)$$

where T_i is the number of quarters of bank i and $r'_{i,j}$ is the expected risk return of risk j, bank i.

The next step aims to get random fluctuations of risk returns, which reflect the macroeconomic background and operating conditions of banking. The random fluctuations of risk returns is defined as

$$\Delta_{i,j,t} = r_{i,j,t} - r'_{i,j} \quad (3)$$

Finally, in order to meet the requirements of analyzing a specific bank (i.e. i=k), we assume that the risk distributions of all banks are independent identically distributed. After combing random fluctuations of risk returns and a specific bank's expected risk returns, the specific bank's risk returns which is used to model risk distributions are already obtained.

$$r_{k,j,t} = r'_{i,j} + \Delta_{k,j,t} \quad (4)$$

The following is choosing a tool to measure risk. VaR has nevertheless become a standard for measuring and assessing risk (Inanoglu and Jacobs, 2009). The definition of VaR at a specific level $\alpha \in (0, 1)$ is written as

$$VaR = \inf\{l : P(L \le l) \le (1-\alpha)\} \quad (5)$$

which means that VaR is the smallest number l which makes the probability of loss L exceeding l is not larger than(1-α).

After getting VaR of four risk types, weighted average method is employed to aggregate risk. The principal of weighted average method is assuming that the linear correlation coefficient among different risk types is 1 and the risk contribution to total risk is reflect by risk weight, which is the relative size of risk exposure. The specific formulas are shown as

$$\text{Add-}VaR_i(\alpha) = \sum w_{i,j,t} VaR_j(\alpha) \qquad (6)$$

$$w_{i,j,t} = \frac{RE_{i,j,t}}{\sum RE_{i,j,t}} \qquad (7)$$

where $\text{Add-}VaR_i(\alpha)$ refers to the total risk of bank i; $w_{i,j,t}$ is the weight of risk j and bank i at time t; $VaR_j(\alpha)$ is the VaR of risk j when confidence level is (1-α); $RE_{i,j,t}$ is the exposure of risk j and bank i at time t.

The weighted average method is similar to simple summation approach in principle, which assumes all inter-risk correlation coefficients are equal to one and ignores potential diversification benefits. This assumption imposes an upper bound on the true capital figure so it is perceived as a conservative approach (Embrechts et al. 1999).

3. Empirical Analysis

3.1 Data Description

The risk data is collected from financial statements of all 16 A-share listed Chinese commercial banks which are displayed in figure 2. In order to get data as much as possible, we collect a panel of quarterly data from 2007Q1 to 2013Q3. However, the quarterly data of ABC and CEB between 2008 and 2009 are unavailable because they were listed at 2010. Besides, 2007Q2 data of BOB, 2007Q1 data of NJCB, NBCB and CCB is not available. In total, we obtain 407 pieces of valid data to model risk distributions.

It is noteworthy that the value of off-balance sheet assets, loan impairment loss and loan loss provision is only disclosed in annual and semi-annual report. For the purpose of getting quarterly risk returns, we assume that the Q1value of off-sheet assets is equal to that of semi-annual, the Q3value of off-sheet assets is equal to that of annual. As for loan impairment loss and loan loss provision, we use semi-annual and annual data to calculate the mean of two ratios. One is the ratio of loan impairment loss and assets impairment loss. Another is the ratio of loan loss provision and loan. Then these two averages are applied to quarterly financial statements to obtain quarterly loan impairment loss and loan loss provision.

The objective of this paper is to calculate economic capital of Chinese commercial banks while our results are not specific to a realistic commercial bank. To resolve this problem, we construct hypothetical banks, in accordance with Rosenberg and Schuermann

(2006), Kretzschmar et al. (2010), Alessandri and Drehmann (2010). In particular, a large hypothetical bank and a small hypothetical bank are established for comparison. The large hypothetical bank is the average of the three largest banks (ICBC, BOC and COB) while the small hypothetical bank is the average of the three smallest banks (BOB, NJCB and NBCB).

ICBC	Industrial and Commercial Bank of China	CITIC	China CITIC bank
BOC	Bank of China	HXB	Bank of China
CCB	China Construction Bank	CIB	Industrial Bank Co., Ltd.
ABC	Agricultural Bank of China	PAB	Ping An Bank
BCM	Bank of Communications	BONJ	Bank of NanJing
CMB	China Merchants Bank	BOB	Bank of BeiJing
SPDB	Shanghai Pudong Development Bank	BONB	Bank of NingBo
CMBC	China Minsheng BankingCorp.,Ltd.	CEB	China Everbright Bank

Figure 2 The Chinese listed commercial banks and their abbreviations

3.2 Empirical Results

The results in table 1 are Add-VaR of two hypothetical banks which reflects the total loss per asset when all risk types take place simultaneously. We know that small bank's absolute value of Add-VaR is larger than that of large bank at any confidence level. This implies that either in extreme environment or relative modest condition, the total loss per asset of small bank is larger. To be specific, at 99.9% confidence level, Add-VaR is -0.63%for large bank while -0.81% for small bank. At 90% confidence level, Add-VaR change to -0.12% and -0.20 for large bank and small bank, respectively.

Table 1 VaR of large and small hypothetical banks in 2013Q3 by weighted average method

Confidence level	99.9%	99%	98%	95%	90%
Large hypothetical bank	-0.0063	-0.0044	-0.0035	-0.0028	-0.0012
Small hypothetical bank	-0.0081	-0.0057	-0.0047	-0.0038	-0.0020

Table 2 illustrates the amount of economic capital for 2013Q3 with the unit of one billion CNY. At extreme condition, expressed by99.9% confidence level, the economic capital equals 243 billion CNY for large bank and 15billion CNY for small bank. At 90% confidence level, which means a relative modest market environment, the amount of economic capital is 48 and 4 billion for large bank and small bank, respectively.

Table 2 2013Q3 economic capital of hypothetical banks (Unit: billion CNY)

Confidence level	99.9%	99%	98%	95%	90%
Large hypothetical bank	-242.8271	-170.5955	-135.8897	-107.8299	-47.8591
Small hypothetical bank	-14.6939	-10.3180	-8.4297	-6.9588	-3.6414

3.3 Results Analysis

The empirical results are analyzed in two dimensions: regulatory capital and economic capital without off-balance sheet items. Comparing economic capital with regulatory capital, we conclude that whether regulatory capital is enough to cover bank risks, which of great importance for robust operation. And the difference created by off-balance sheet items tells us the role of off-sheet items played in risk aggregation. What's more, we also want to have an overlook about the trends of Add-VaR and economic capital from 2007 to 2013, which can reveal some difference between large banks and small banks.

At the request of China Banking Regulatory Commission (CBRC), the minimum ratio of regulatory capital to risk-weighted assets is 8% for a bank. Therefore, 8% is applied to calculate annual regulatory capital the bank should maintain. At the result of lacking of risk-weighted assets of 2013, we conduct time series analysis for 2007 - 2012 annual risk-weighted assets to obtain the predictive value of 2013 annual risk-weighted assets. As we all know, both regulatory capital and economic capital are the concepts of capital stock for a given time extension. Due to the probationary period for regulatory capital is one year time, so the economic capital we obtain cannot be compared with annual regulatory capital directly because panel quarterly data is used in empirical experiment. According to the square root of time rule, T periods of VaR can be obtained by multiplying $\sqrt{T}$ and VaR for a single period. Thus, the quarterly economic capital multiplied by $\sqrt{4}$(i.e. 2) can be transformed into annual economic capital.

The main contribution of this paper is paying attention to off-balance sheet items in risk aggregation. So comparing economic capital obtained under conditions of considering off-balance sheet items or ignoring off-balance sheet items can help us to understand the role of off-balance sheet items played in measuring total risk. Figure 3 shows the results of 2013 annual regulatory capital and economic capital at 99.9% confidence level with the unit of one billion CNY.

	Large hypothetical bank	Small hypothetical bank
Economic capital (without off-balance sheet items)	496.4526	29.0822
Economic capital (with off-balance sheet items)	**485.6542**	**29.3878**
Regulatory capital	718.8705	30.1408

Figure 3 2013 annual economic capital and regulatory capital (Unit: billion CNY)

The results shown in figure 3 tell us that the regulatory capital is enough to cope with risks faced by commercial banks because it is larger than economic capital. This is in line with the current robust operation of Chinese commercial banks. Li et al. (2013) found that Chinese banking system is in a stable state, which is backed up with the evidence that chance of large scale contagion in Chinese banking system is quite low.

Furthermore, regulatory capital is significantly greater than the economic capital for large bank while slightly larger than economic capital for small bank. This shows that large banks operates more robustly compared with small banks. And CBRC has realized that large banks have stronger ability of risk control and better capital adequacy than small banks. In a word, the stability of Chinese commercial banks is optimistic and this is good news because cumulative output loss caused by banking crisis reached as much as 15%–20% of annual GDP (Hoggarth et al. 2002).

Figure 3 also tells us that ignoring off-balance sheet items in risk measurement will lead to deviation. And some previous studies have paid attention to the riskiness of off-balance sheet activities. Traditionally, off balance sheet activity was seen as a risk reducing tool. With the deepening of studies, researchers found that the effect generated by off – balance sheet is not consistent. Upper (2011) established that the possibility of contagion for banks with large derivatives will be underestimated when off –balance sheet exposures are ignored. The findings established by Karim et al. (2013) appear to be the case that off balance sheet activity is not risk-increasing risk, and may have had a reverse effect on risk. Papanikolaou & Wolff (2014) got the conclusion that off-balance sheet leverage exposures increases the individual risk of banking firms making them vulnerable to financial shocks. In other words, off-balance sheet items are negatively linked to the soundness of the whole banking system. So there is not a consistent view. The conclusion we got is that the deviation in risk measurement generated by off-balance sheet items is different between large banks and small banks. Particularly, small bank's risk is underestimated if off-balance sheet items are ignored because the economic capital is larger when taking account of off-sheet items in risk aggregation. Unlike small banks, large bank's risk is overestimated if ignoring off-sheet items because the economic capital is smaller when considering off-sheet items. This conclusion is also consistent with our knowledge that small bank is more inclined to engage in high-risk off-balance sheet activities because high risk means high returns. The explosive growth of off-balance sheet activities is aimed to avoiding supervision and pursuing higher yield among intense competition. Papanikolaou & Wolff (2014) demonstrate that the banks which focus on traditional business typically face less risk compared to those engaged in modern financial innovation and new financial services. And stated-owned banks play a leading role in traditional deposit & loan market, so small banks only engaged in high-risk off-balance sheet activities for making profit. The explosion of off balance sheet activities allowed banks to generate an increase in non-interest income and additional fee while placing the assets off the balance sheet. This improved profitability further by not carrying costly regulatory capital for these assets (Karim et al. 2013).

To illustrate more intuitively, figure 4 tells us that the difference of relative scale of off-balance sheet items between large banks and small banks is the reason for different directions of deviation. The vertical axis reflects the magnitude of change in total risk, Add-VaR and economic capital after incorporating off-balance sheet items in risk aggregation.

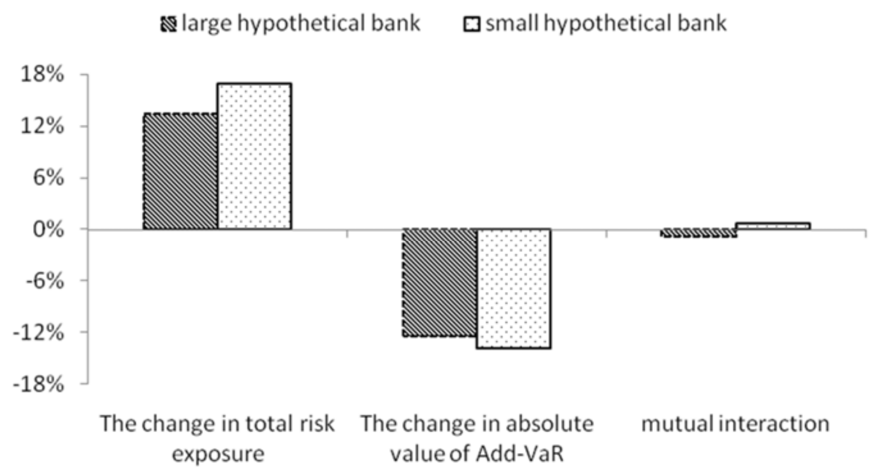

Figure 4 Changes brought about by off-balance sheet items

From figure 4, it is clearly that the mutual interaction, which reflects changes in economic capital, is different between banks of different sizes. Specifically, the increase in total risk exposure is the ratio of off-balance sheet assets to balance sheet total assets. And this increase means that the denominator of risk return increases. Therefore, Add-VaR decreases after considering off-balance sheet items. As for mutual interaction, changes in economic capital I mean, is the combination of both risk exposure and Add-VaR so it determined by relative scale of off-balance sheet items. Therefore, the relative scale of off-balance sheet items is the essential reason for the difference in mutual interaction. However, the mutual interaction changes a little after considering off-sheet items. There are two causes for this result. First, from the perspective of mathematical formula, economic capital is the product of absolute value of VaR and risk exposure. The risk exposure increases while absolute value of VaR decreases when off-sheet items are considered. Under the mutual interaction, the economic capital takes place a small change. Another reason is that the scale of off-balance sheet items is significantly smaller compared with the balance sheet total assets. At the end of 2011, the four largest stated-owned banks' average ratio of off-balance sheet assets to balance sheet assets is 26.6% while the corresponding ratio exceeds 100% in US or European banks. However, with the rapid expansion of off-balance sheet items, the deviation in risk aggregation without off-balance sheet items will be increasingly larger.

The commercial banks' profitability also catches our attention because too much economic capital will hinder commercial banks' earnings. The profitability can be reflected by computing overall risk return based on financial statements method. Uniquely, overall risk exposure is the sum of credit risk exposure, market risk exposure, liquidity risk exposure and operational risk exposure. And overall risk profit & loss equals to net income. By preprocessing risk data, we can get overall risk return, which is illustrated in table 3 as the measurement of profitability.

Table 3The profitability of hypothetical banks

Confidence level	99.9%	99%	98%	95%	90%
Large hypothetical bank	0.0007	0.0008	0.0010	0.0015	0.0018
Small hypothetical bank	0.0008	0.0009	0.0011	0.0016	0.0016

Table 3 tells us that the commercial banks' profitability varies with different scales. Large commercial bank's overall risk return is 0.01% lower than that of small commercial bank at any confidence level. This means that the large commercial bank is less profitable. And this is corresponded with the result we just find by comparing economic capital and regulatory capital that large commercial bank are most robust in operation. The regulatory capital far exceeds economical for large bank while small bank's regulatory capital has small amounts over the economic capital. And regulatory capital is the funds banks put aside for coping with risks so it can't participate in lending or investment. Therefore, excessive regulatory capital reduces the profitability of large commercial banks.

In addition, the trends of Add-VaR and economic capital at 99.9% confidence level from 2007Q1 to 2013Q3 help us to grasp the changes of total risk faced by commercial banks.

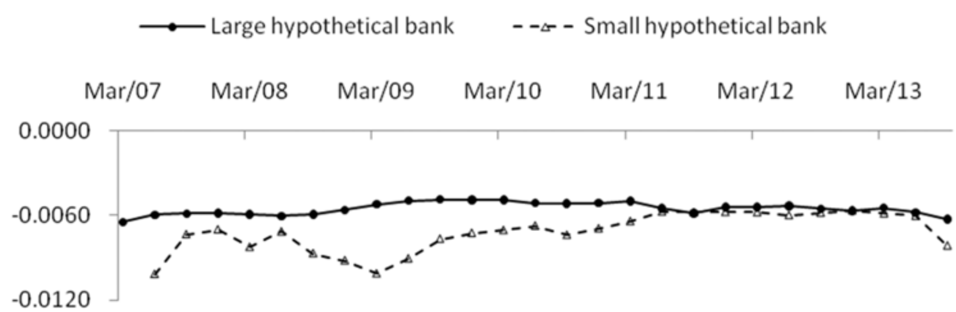

Figure 5The trend of hypothetical banks' Add-VaR at 99.9% confidence level

The vertical axis of figure 5 represents Add-VaR of hypothetical banks at 99.9% confidence level. From figure 5, we know that small bank's absolute value of Add-VaR is larger than that of large bank at 99.9% confidence level. This means that small bank's loss per asset is larger. What's more, Add-VaR of the small bank fluctuates more drastically, which caused by the massive change of business mix. For us, this implies that the total risk faced by small banks changes widely as time going.

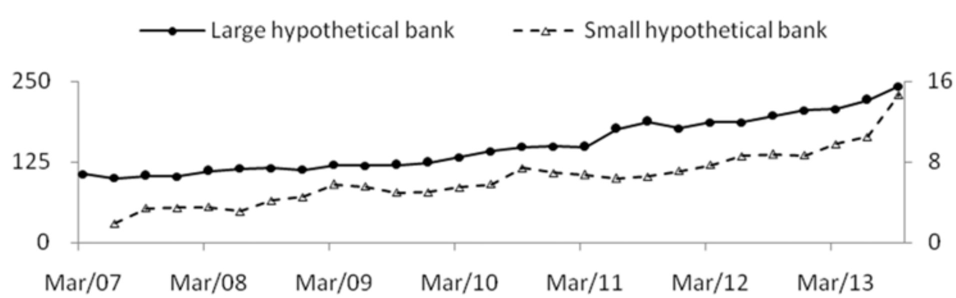

Figure 6The trend of hypothetical banks' economic capital at 99.9% confidence level

(Unit: billion CNY)

The trend of economic capital from 2007Q1 to 2013Q3 at 99.9% confidence level is shown in figure 6. The vertical axis reflects the amount of economic capital. Obviously, the economic capital for large bank is larger than that of small bank although small bank's absolute value of Add-VaR is even larger. The reason is that large bank operates in a large scale, in another words, the risk exposures are larger. This indicates that large commercial bank will face more losses if risk event triggers so that it needs more economic capital to respond to the potential losses. Similarly, small bank need less economic capital is that its operation scale, what I mean is total risk exposure, is smaller compared with the large bank.

4. Conclusion

By mapping risk types to financial statements we get risk data to model risk distributions. Uniquely, the off-balance sheet items are corresponded with risk exposures making the risk exposures more accurate and rational. For the purpose of studying the difference between large banks and small banks, two hypothetical banks of difference sizes are established.

The empirical results show that the loss per asset of small bank is larger and its Add-VaR fluctuates more drastically as time going. However, small bank needs less economic capital because it operates with a small scale compared with large bank. In addition, regardless of the off-balance sheet items will produce deviation in total risk measurement. To be specific, the total risk of large bank is overestimated while underestimated for small bank if off-sheet assets are ignored. And with the rapid growth of off-balance sheet items, the deviation of risk aggregation will be increasingly obvious. So the off-balance sheet items are of great importance in risk aggregation. As for profitability and robustness of Chinese commercial banks, large commercial bank operates more robust while with lower profitability. The overall risk return for large bank is less than that of small bank, which is due to excessive regulatory capital.

This study still has several limitations. Firstly, due to data availability, we just use part of the off-balance sheet data and this can be resolved by more standardized disclosure requirements for off-balance sheet items; Secondly, the correspondence between risk types and financial statements is kind of rough. For example, net interest income not only reflects credit risk, but also reflects market risk. And net investment income assumes market risk and liquidity risk at the same time. Besides, whether all assets are subjected to operational risk is still under question. In the future studies, the employment of other information may calibrate the corresponding relationship to some extent.

□ □ □ □ □ □ IMPACT OF THE TRANS-PACIFIC PARTNERSHIP NEGOTIATIONS AND SUSTAINABLE EXPORT DEVELOPMENT FOR VIETNAM'S ENTERPRISES

Ton That Hoang Hai
Saigon Technology University, Vietnam

haiton.ip@gmail.com

Abstract

The Trans-Pacific Partnership (TPP) agreement seems to have reached a crossroads: it could either be a building block toward achieving economic integration in Asia and the Pacific, or trigger the formation of two large trade blocs which will work independently of one another. When the Government of Japan announced its participation in the TPP negotiations in March 2013, the partnership began to attract greater interest from other East Asian countries.

Members may be interested in understanding the potential economic impact and significance of TPP and the economic characteristics of the other TPP countries as they evaluate the potential impact of the proposed TPP on the U.S. economy and the commercial opportunities for expansion into TPP markets.

This report analyzes the opportunities and challenges of the TPP will impact the economic of Vietnam, as well as the opportunity to export goods from Vietnam into the TPP countries and analyze strategies sustainable exports development for Vietnam's enterprises

Keywords: Trans-Pacific Partnership, TPP, free trade agreement , Sustainable Export , Vietnam imports-exports, economic relations,…

1. Introduction

The Trans-Pacific Partnership (TPP) is a potential Free Trade Agreement (FTA) among 12 countries and perhaps more. The United States (US) and 11 other countries of the Asia-Pacific region Australia, Brunei, Canada, Chile, Japan, Malaysia, Mexico, New Zealand, Peru, Singapore, and Vietnam are negotiating the text of the FTA. With over 20 chapters under negotiation, the TPP partners envision the agreement to be "comprehensive and high-standard," in that they seek to eliminate tariffs and nontariff barriers to trade in goods, services, and agriculture, and to establish or expand rules on a wide range of issues including intellectual property rights, foreign direct investment, and other trade-related issues. They also strive to create a "21st-century agreement" that addresses new and cross-cutting issues presented by an increasingly globalized economy.

Its intention to negate the "spaghetti bowl" effect is however doubted by many (Ravenhill John, 2009). For example, the existing complex Rules of Origin (ROO) for textiles and apparel are expected to be incorporated unchanged into the TPP agreement, and will not be replaced by a single, over-arching ROO (Ian F. Fergusson, 2014). In all previous FTAs, the US had used the "yarn forward" rule which requires that the material (cotton or synthetic fiber) for a textile product be sourced within the FTA area, and representatives of the US textile industry have argued for an even tighter "yard forward" rule to be included in the TPP (Ian F. Fergusson, 2014). In contrast, some TPP countries, including Vietnam, seek a less restrictive "cut and sew" rule which will allow its products manufactured from materials of non-TPP origin to benefit from the TPP. Therefore, if compromise positions are not reached eventually, the ROOs of TPP will fail to be liberal, effective and simple rules and may become just one more strand of noodle in the bowl (Shiro Patrick Armstrong, 2011).

The proposed TPP and its potential expansion are important due to the economic significance of the Asia-Pacific region for both the US and the world. The region is home to 40% of the world's population, produces over 50% of global Gross Domestic Product (GDP), and includes some of the fastestgrowing economies in the world. With the addition of Canada and Mexico, TPP negotiating partners made up 31% of US goods and services trade in 2011, and the Asia-Pacific economies as a whole made up over 56%. The TPP would be the largest US FTA to date by trade value (Brock R. Williams, 2013).

2. Some characteristics of TPP

Agreement negotiation in the scale and ambition as TPP Agreement is a complicated and time-consuming task. However, high level ranking officials of the negotiation participating countries feel confident the successful formation of the description of the main negotiating areas of the agreement will provide the basis and essential driving force for the success of the agreement. The characteristics making this historic agreement include:

(1) Comprehensive market access in all sectors, including the elimination of tariffs and other barriers to trade and investment between the member states, as well as job generation for people. The agreement aims at promoting the mutual market access for goods of members

countries in a comprehensive way with free-tax, eliminating service restrictions simultaneously in order to create new opportunities for employees and enterprises as well as immediate benefits to consumers.

(2) As a regional agreement, TPP participating countries agree to build a unified tariff as well as a general rule of origin so that enterprises can take advantage of the agreement more easily. This regional approach will boost regional trade network, thereby enhance competitive capacity of enterprises and encourage the use of TPP input products.

(3) Cross-cutting trade issues by building on work being done in Asia-Pacific Economic Cooperation (APEC) and other fora by incorporating four new cross-cutting issues in the TPP, namely:

- Regulatory coherence: Binding specific policy environment between countries;

- Competitiveness and business facilitation of each member country's economy;

- Small and medium sized enterprises (SMEs): Commitment of addressing concerns of SMEs so that these enterprises can look for advantages within TPP and trade internationally;

- Development: directing trade policy toward poverty reduction, strengthening social responsibilities of enterprises.

(4) On one hand, new technology will create new opportunities for trade and investment between the Member States, but also raise potential issues to be addressed in the agreement to boost trade, goods and services and to ensure mutual benefits of the economies of all TPP members, on the other hand.

(5) TPP performs opening mechanism, accordingly, in the future, the country concerned may participate the negotiation for the participation. In other words, TPP aims at ultimate goal of expanding to other countries in the Asia - Pacific.

Negotiating groups have been consulting countries which express their interests of joining the agreement in joining the agreement, in order to help these countries realize objectives agreed by TPP. Currently, many countries and territories have expressed their interest in participating in the negotiations including: South Korea, Taiwan, Philippines, Laos, Thailand, Colombia, Costa Rica. It is worth noting that although TPP is a Trans-Pacific FTA; China, the world second largest economy still stands outside, while the US is the most active nation to promote the negotiations.

The TPP opening shows an advantage that only with TPP negotiation each country can get FTA with many partner countries. However, this advantage also creates difficulty as the more countries participate, the more difficult to reach final agreement as well as the more prolonged negotiating time.

3. Vietnam's Merchandise trade with FTA and TPP partners

3.1. *Vietnam's FTA*

With rapid increase of FTA for Free Trade Area, Vietnam has actively launched FTA establishment process. Results are:

♦ Signed:

1. Association of South East Asian Nations (ASEAN)-FTA: Signed in 1996. most of commitments have been implemented

2. ASEAN-Australia/New Zealand FTA: Signed in 2009; Effective from 2010

3. ASEAN-India FTA: Signed in 2009; Effective from 2010

4. ASEAN-Korea FTA: Effective from 2007

5. ASEAN-Japan FTA: Signed in 2008 within ASEAN-Japan Comprehensive Economic Partnership Agreement (AJCEPA)

6. ASEAN-China FTA: Signed in 2004; Effective from 2010

♦ Under examination

. Vietnam-Canada FTA

♦ FTA Commitments

Vietnam pledges to open market and to tax reductions, focus on investment environment, intellectual property, sustainable development accordingly to FTA

- Regarding the liberalization level: Basically, it is higher than commitments to World Trade Organization (WTO) accession. Of these, approximately 90% of tariff lines (accounting tariff lines of import tax) with the time frame of cutting down to 0% within 10 years, of which some tariff lines are flexible in the range of extended period from 2 to 6 years. Of which, the degree of liberalization in ASEAN Free Trade Area (AFTA)/ Common Effective Preferential Tariff (CEPT) / ASEAN Trade in Goods Agreement (ATIGTA) commitments is highest (99% of 8-digit tariff lines), the lowest is in the ASEAN-India Free Trade Association (AIFTA)/ ASEAN-India Trade in Goods (AITIG) commitments (80% of 6-digit tariff lines) and the commitment ASEAN-Japan Comprehensive Economic Partnership (AJCEP) (88,6% of 10-digit tariff lines).

- On tax cuts roadmap: With AFTA, ASEAN–China Free Trade Area (ACFTA) and ASEAN-Korea Free Trade Area (AKFTA) tax cuts will be implemented according to the schedule prescribed for the annual reduction step (AFTA: 1996 to 2006 - from 2015 to 2018, AKFTA: 2007 - 2016 to 2018). Road map for reduction of the remaining FTA: AJCEP, AIFTA, ASEAN-Australia-New Zealand Free Trade Agreement (AANZFTA), Vietnam-Japan Economic Partnership Agreement (VJEPA); will be gradually reduced each year to reach the final tariff commitments. (AJCEP: 2008-2018-2024; VJEPA: 2009-2019 2025; AANZFTA: 2010 – 2018 -2020 and AIFTA: 2010 – 2018 - 2021).

- Tariff Commitments of Vietnam in Vietnam-Chile FTA: Vietnam committed to eliminate tariffs on 87.8% of tariff lines in the current import tariff (accounting for 91.22% of imports from Chile to Vietnam in 2007) in 15 years. In 12.2% of the remaining tariff lines, 4.08% of the tariff lines under the exclusion list (no reduction and elimination), 3.37% of tariff lines remain the same tax base and 4.75% of tariff lines are partially tax reduction.

3.2. *Vietnam's Merchandise trade with TPP partners*
