The control variate method is a popular variance reduction technique used in Monte Carlo methods which are frequently used to price a complex derivative by calculating the expected discounted payoff of that derivative. This method is used in much financial literature to exploit information about the errors in estimates of known quantities – which are usually the prices (or the expected discount payoffs) of derivatives that can be analytically priced – to reduce the error for estimating an unknown quantity, which is usually the price of a complex derivative of interest. This paper generalizes the core idea of the control variate method in two ways: First, the idea of reducing the errors for estimating unknown (discounted) expected values can be generalized extended to a boarder class of operators, the linear operators, like the inverse Fourier transform and the convolution. Second, our method can be separately applied to reduce the error contributed by one or more numerical procedure(s) that are (repeatedly) involved in a numerical pricing method to suppress the overall pricing error. Thus our general control variate method can be applied to reduce the pricing errors of a wide classed of numerical pricing methods, such as the tree method, the characteristic-function-based pricing method, and the convolution-based pricing method. Numerical results shows that our approach can effectively increase the accuracy and the efficiency of many numerical pricing methods.

Keywords: numerical method; pricing; control variate; tree; characteristic function; convolution.

1 Introduction

Due to the booming of financial markets, complex derivative products are constructed to meet customers' need. The presences of these complex derivatives do improve the efficiency of financial markets. On the other hand, sophisticated stochastic processes are also investigated to fit the processes of market variables better. But the presence of these sophisticated products and processes also make the derivation of analytical pricing formulae intractable. Thus we must rely on many different numerical methods, such as Monte Carlo simulations, tree methods, characteristic-function-based pricing methods, convolution-based methods, and so on.

When continuous pricing models or equations are hard to be analytically evaluated, they are transferred into discrete counterparts that are suitable for numerical evaluations. Take the CRR tree model proposed by Cox et al. (1979) in Fig. 1 as an example. The time interval $[0, T]$ are discretized into several time steps, each with length Δt. The possible stock prices at each time step are also discretized; for example, there are two stock prices: S_0u and S_0d at the time step 1. The details of this figure will be discussed in later sections. Usually, the pricing results generated by a numerical method converge to the theoretical derivative price as the discretization get finer; for example, the pricing results generated by the CRR tree converge to the theoretical derivative price as Δt gets smaller (see Duffie (1996)). However, increasing the resolution of the discretization would (dramatically) increases the size of the discretization, like the number of tree nodes in Fig. 1, and hence the computational time. Financial practitioners are usually thrown into a dilemma to strike the balance between the pricing accuracy and the computational time.

To address the aforementioned dilemma, finding efficient and accurate numerical pricing methods is an important issue and is widely studied in academic literature. One possible approach is to find an efficient algorithm to speed up computation. For example, evaluating derivatives under the tree model illustrated in Fig. 1 is traditionally performed by the backward induction method. Roughly speaking, we first evaluate the derivative price at each node located in the last time step, say time step 2 in this example. This information is then used to derive the derivative price at each node in time step 1. The above procedure is repeatedly applied by using the derivative prices at time step i to derive the derivative prices at time step $i-1$ until the derivative price at the root node located at time step 0 is obtained. Lyuu (1998) and Dai et al. (2007) suggest that some calculation process of the backward induction method can be saved by taking advantage of combinatorial properties. Thus the pricing performance is improved since the combinatorial method requires less computational time to achieve the same level of accuracy than the backward induction method does.

Another approach to improve a numerical method is to improve the convergence rate of the pricing results. Take the Monte Carlo pricing method (`MC` hereafter) pioneered by Boyle (1977) as an example. It randomly samples the changes of a economic variable, say the underlying asset's price, to evaluate a derivative's price which can be expressed as the discounted expected payoff of that derivative under the so-called risk-neutral probability measure (see Harrison and Pliska (1981)). Note that the pricing result is also a random variable and a large amounts of samples (and hence a large amount of computational time) are required to obtain a satisfactory pricing result. The control variate method can improve the performance of the `MC` by reducing the variances of the pricing results. Instead of directly estimating an unknown quantity which is usually the price of a complex derivative of interest, the control variate method estimates the expected difference between the unknown quantity and the known one – which is usually the value of a simple derivatives that can be analytically evaluated. Thus the unknown quantity can be estimated as the known quantity (evaluated by the analytical formula) plus the estimated difference. The variance of the pricing result can be dramatically reduced if the sample differences are close to zero.

The control variate method is widely adopted in the financial literature. For example, the

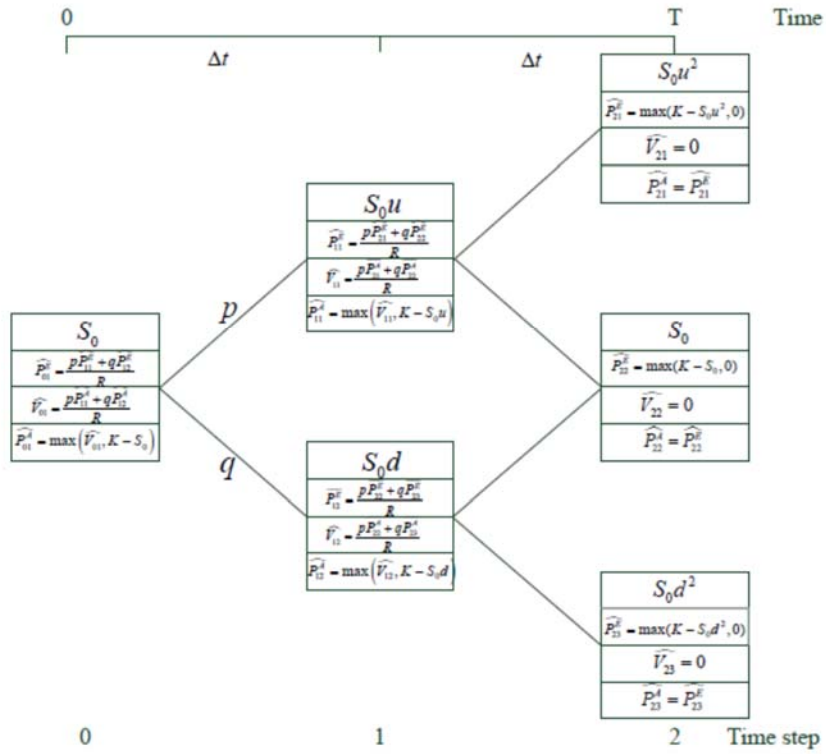

Figure 1: **Pricing American Puts on the Two-time-Step CRR Tree** S_0 denotes the underlying asset's value at time 0, K denotes the strike price, T denotes the time to maturity for the American put, Δt denotes the length of a time step, and R denotes the discount factor. p and q denote the upward and the downward branching probabilities, respectively. u and d denote the upward and the downward multiplication factors, respectively. Each node is represented by a node with four fields, which denote the price of the underlying asset, the price of the European put $\hat{P}^E_{ij}$, the continuation value $\hat{V}_{ij}$, and the price of the American put $\hat{P}^A_{ij}$ of that node. Overhead hat symbols are used to distinguish symbols involved in the traditional backward induction method in this figure from the symbols used in the general control variate method (discussed later). The subscript ij means the j-th node (counted from the uppermost node) at the i-th time step.

payoffs of arithmetic average Asian options (abbreviated to Asian options hereafter) depend on the arithmetic average price of the underlying asset. These options are popular but can not be analytically solved. Kemna and Vorst (1990) derive the analytical pricing formulae for geometric average Asian options whose payoffs depend on the geometric average price of the underlying asset. Since the magnitudes of the differences of the payoffs between these two options are relatively much smaller than the magnitudes of the option payoffs, the variance for estimating the differences of expected payoffs by `MC` is much smaller than the variance for estimating the Asian option value. Thus the pricing accuracy for evaluating an Asian option is improved by summing the value of an otherwise identical geometric average Asian option (evaluated by analytical formulae) plus the expected discounted differences of the payoffs of these two options (evaluated by `MC`). This approach is further improved by Han and Lai (2010) by using an optimal control process as a control variate to gain further variance reduction. Besides, Duan (1995) also applies the control variate method to efficiently evaluate options under the GARCH model. Dingec and Hormann (2012) price path dependent options under Lévy processes by exploiting information about the error to evaluate the same options under geometric Brownian motion.

Hull and White (1988) first generalize the core idea of the control variate method to improve the accuracy for pricing an American put on the CRR tree illustrated in Fig. 1. Specifically, they take advantage of the error for estimating the price of a European put on a CRR tree to reduce the error for estimating the price of an American put. They suggest that the American put can be evaluated as the difference between the estimates of prices of American and European puts on the CRR tree (i.e, $\hat{P}^A_{01} - \hat{P}^E_{01}$)[1] plus the European put price which can be analytically solved by Black and Scholes (1973) formula.

This paper will investigate the property of the control variate method further and examine how useful it could be to improve the performance of various numerical pricing methods. Note that most numerical pricing methods need to evaluate the result for applying a linear operator O on a certain function X. Usually $O(X)$ can not be analytically evaluated and must be estimated numerically. Our core idea is to suppress the error for estimating $O(X)$ in order to improve the overall accuracy of numerical pricing methods. To inherit the spirit of the control variate method, we first pick another function Y as a control variate – call it a control function for simplicity. That is, the control function Y is close to the function X and $O(Y)$ can be analytically solved. Then a more accurate estimation for $O(X)$ is obtained by numerically estimating $O(X - Y)$ plus the analytical result of $O(Y)$. Take pricing American puts with the CRR tree illustrated in Fig. 1 as an example. The American-put-value function of the underlying asset price at an arbitrary positive time step i plays the role of the function X. Finding the continuation-value[2] function (of the underlying asset price) at the time step $i-1$ based on the function X plays the role of the operator O. O can be numerically estimated by a 1-time-step backward induction; in other words, the continuation value of a node (illustrated in the third field) is estimated as the expected discounted option values of its two successor nodes (illustrated in the fourth fields). The European-put-value function at time step i plays the role of control function Y to suppress the error for numerically estimating $O(X)$. This is because the function Y is close to X and each point in the European-put-value function at time step $i-1$ (or $O(Y)$) can be analytically solved by the Black and Scholes (1973) formula. Note that the American put value for each node at time step $i-1$ is then evaluated as the maximum of the continuation value and the exercise value at that node as illustrated in the fourth field of that node. And the aforementioned evaluations are repeated from the last time step to the beginning of the tree to obtain the final pricing result. Note that our approach can repeatedly apply the control variate method to the 1-time-step backward induction, while Hull and White (1988) approach apply once to overall pricing result. Numerical experiments suggest that our approach outperforms their approach.

Two more examples are given to demonstrate how the general control variate method is applied to improve the performance of numerical pricing methods. First, to capture versatile behaviors of the underlying asset price, various processes, such as the jump diffusion process proposed by Merton (1976), the stochastic volatility process proposed by Heston (1993), and so on, are invented to fit real world financial markets better. Since the characteristic functions of most of these processes are simpler to derive analytically than the probability density functions of these processes, Carr and Madan (1999) and Carr and Wu (2004) take advantage of the relation between the Fourier transforms of vanilla option prices and the characteristic functions to price vanilla options. Specifically, the option prices can be evaluated as an inverse Fourier transform (or the operator O) of the function X which can be expressed in terms of the characteristic function. $O(X)$ may not be analytically solved but can be numerically evaluated by the fast Fourier transform (FFT)– which can be viewed as a numerical integration as discussed later. However, the integrand oscillates significantly, which makes a high resolution of discretization (and hence

[1] The pricing results generated by the CRR tree for European and American puts in Fig. 1 are $\hat{P}^E_{01}$ and $\hat{P}^A_{01}$, respectively.

[2] The continuation value means the value to hold an American put without exercising it immediately.

a large amount of computational time) necessary to obtain a satisfactory pricing result. To improve the pricing performance under the general control variate method, we pick a control function Y that is close to X and $O(Y)$ is required to be analytically solved to avoid introducing extra numerical errors. Again, the error for estimating $O(X)$ is significantly suppressed by numerically evaluating $O(X-Y)$ plus the analytical function $O(Y)$. Numerical results suggest that our revised method provide more accurate pricing results and can avoid the negative-price problem for pricing deep-out-of money options.

Next, the general control variate method is used to improve the performance of the convolution-based Asian option pricing method. The payoff of an Asian option depends on the average price of the underlying asset. The pricing problem is intractable since the density function of the average asset price f_A can not be analytically solved. Carverhill and Clewlow (1990) and Benhamou (2002) suggest that f_A can be numerically evaluated by alternatively applying a convolution and a Jacobian transformation[3] on density functions. Numerical errors propagate and accumulate when the aforementioned operators are alternatively applied numerically. To reduce the overall pricing error, we apply the general control variate method alternatively on each operator to suppress the numerical error introduced by that operator. Numerical results show that our revised method is more accurate and more efficient than the original pricing method.

The rest of this paper is organized as follows. In Sec. 2, we will survey the traditional control variate method and introduce the framework of our general version. Then we demonstrate how general control variate method reduce the pricing error of the the tree pricing method, the characteristic-function-based pricing method, and the convolution-based pricing method in Sec. 3, 4, and 5, respectively. A simple survey of each numerical method and the related numerical experiments will also be given in the corresponding section. Sec. 6 concludes the paper.

2 The Control Variate Method

2.1 The Traditional Version

The traditional control variate method is a variance reduction technique used in MC (see Glasserman, 2004). It uses the estimation error of a known quantity, say $\mathrm{E}(Y)$, to improve the estimation of a unknown quantity, say $\mathrm{E}(X)$, where X and Y are random variables. Specifically, $\mathrm{E}(X)$ can be estimated as

$$\begin{aligned} \mathrm{E}(X) &\approx \mathrm{E}^{\mathtt{MC}}(X) && (1)\\ &\approx \mathrm{E}^{\mathtt{MC}}(X-Y)+\mathrm{E}(Y), && (2) \end{aligned}$$

where $\mathrm{E}^{\mathtt{MC}}$ denotes an operation to estimate the expected value with MC, Eq. (1) and Eq. (2) denote that $\mathrm{E}(X)$ is estimated by directly applying MC or by applying the traditional control variate method, respectively. For convenience, let $\mathrm{Var}(X)$ and $\mathrm{Cov}(X,Y)$ denote the variance of X and the covariance of X and Y, respectively. The performances for estimating $\mathrm{E}(X)$ by above two approaches can be measured by the variances of the righthand sides of Eq. (1) and Eq. (2), which are $\mathrm{Var}(X)$ and $\mathrm{Var}(X)+\mathrm{Var}(Y)-2\mathrm{Cov}(X,Y)$, respectively. Thus, the control variate method can dramatically improve the performance for estimating $\mathrm{E}(X)$ (or reduce the variance) if we can find a proper Y that is highly correlated to X. Note that a derivative price can be expressed as the expected present value of its future payoff under the risk neutral probability measure. Thus much literature take advantage of the traditional control variate method to evaluate the value of a complex derivative with a simple derivative that can be analytically priced. For example, Kemna and Vorst (1990) price an Asian option by using a geometric

[3]It is used to find the probability density of one random variable that can be expressed in terms of more fundamental random variable(s).

average Asian option's payoff as the control variate. The pricing performance is dramatically improved since the payoff of the latter (simple) derivative is highly correlated to the former (complex) derivative.

2.2 The General Version

The core idea of traditional control variate method illustrated in Eq. (2) can be further generalized to other linear numerical methods[4] like a numerical integration. Specifically, recall that random variables X and Y can be treated as real-valued functions defined on the sample space Ω. Thus the unknown quantity $\mathrm{E}(X)$ can be estimated by numerically integrating $\int_\Omega X(\omega)dP(\omega)$, where P denotes the probability density function. The linear property of a numerical integration asserts that $\mathrm{E}(X)$ can also be estimated by

$$\mathrm{E}(X) \approx \int_\Omega (X(\omega) - Y(\omega))\, dP(\omega) + \int_\Omega (Y(\omega))\, dP(\omega), \tag{3}$$

which is analogous to Eq. (2). To improve the accuracy for estimating $\mathrm{E}(X)$ in Eq. (3), we mimic the core idea of the traditional control variate method – picking a highly correlated random variable Y to reduce the numerical error of $\mathrm{E}^{MC}(X-Y)$. Analogously, we can properly select a function Y that is close to the function X to reduce the error for numerically evaluating $\int_\Omega (X(\omega) - Y(\omega))\, dP(\omega)$. In addition, $\int_\Omega (Y(\omega))\, dP(\omega)$ (or $\mathrm{E}(Y)$) is required to be exactly solved without introducing extra numerical errors to ruin the accuracy for estimating $\mathrm{E}(X)$ by Eq. (3).

Indeed, the above idea can be further extended to reduce the error for applying any linear operator O to numerically estimate a wide class of unknown quantities, like the density function of the average underlying asset price f_A mentioned in the introduction. Specifically, the linear property assets that applying O on the input X can be evaluated as

$$O(X) \approx O^N(X-Y) + O(Y) \tag{4}$$

instead of $O^N(X)$, where N denotes the numerical evaluation of O. To suppress the error of Eq. (4), we pick a proper input Y that is close to the input X to suppress the numerical error of $O^N(X-Y)$. $O(Y)$ is required to be analytically solved to avoid introducing extra numerical errors. Since many numerical pricing methods may numerically evaluate one or many operator(s) repeatedly, the overall pricing accuracy can be improved by suppressing the numerical error for evaluating each operator with the "general version" of the control variate method. For example, in a characteristic-function-based pricing method like Carr and Madan (1999) and Carr and Wu (2004), the inverse Fourier transform and the characteristic function of the underlying asset's process play the roles of O and X, respectively. A numerical method may numerically evaluate more than one operators that can be improved by the general control variate method. In a convolution-based pricing method like Carverhill and Clewlow (1990) and Benhamou (2002), the convolution and the Jacobian transformation are alternatively applied repeatedly. The general control variate method is applied on each operator to improve the accuracy of an intermediate output rather than directly on the pricing result. In addition, the intermediate output is not necessary a value; it can be a discretized function, say a discretized density function in the convolution-based pricing method. Our numerical experiments suggest that the accumulations of these "partial" improvements would result in overall performance improvement of a numerical pricing method in terms of accuracy and computational time.

[4]Hull and White (1988) improves the pricing accuracy of American puts by generalizing the traditional control variate method to the tree method – which is not a linear numerical method. Note that the linear property (of a numerical method)is a sufficient condition, but not a necessary condition for generalizing the traditional control variate method to that numerical method.

Applying the control variate method to reduce the error for numerically estimating $O(X)$ is similar to the procedure mentioned above. First, we find a proper control function Y that makes $O(Y)$ analytically solvable and that is close to X. Then the error for estimating $O(X)$ is reduced by estimating $O(X-Y)$ numerically plus the analytical value of $O(Y)$. Note that the effectiveness of the general control variate method highly depends on how the control function Y is close to the function X. For pricing American puts on the tree, we use the European-put-price function of the underlying asset as the control function since these two options are almost identical except the right to exercise the option early. For the characteristic-function-based pricing method, we use the characteristic function of the jump diffusion process proposed in Merton (1976) to approximate the characteristic function of the underlying asset's price process. The parameters of the former process is calibrated to make the first five cumulants of the former process match the cumulants of the latter process. For the convolution-based pricing method, we use the normal density function to approximate the density function inputted to the convolution or the Jacobian transformation. Again, the parameters of the former density function are calibrated to make the first two moments of the former function match the estimated moments of the latter one.

3 Pricing American Puts under Tree Methods

3.1 Background Introduction

A put option grants a holder the right to sell the underlying asset for a predetermined strike price K. While a European put only allows the option holder to exercise the right at the maturity date T, an American put allows the holder to exercise the right at any time τ prior to maturity T. Let S_t denote the underlying asset price process at time t for convenience. The payoff of a European put at maturity is $(K-S_T)^+$, and the payoff to exercise an American put at time τ is $(K-S_\tau)$. By taking advantage of the risk neutral valuation method, the value of a European put P^E and an American put P^A can be expressed as the expected discounted payoff

$$\begin{aligned} P^E &= \mathrm{E}_Q\left[e^{-rT}(K-S_T)^+\right] && (5)\\ P^A &= \max_{\tau\in\Upsilon}\mathrm{E}_Q\left[e^{-r\tau}(K-S_\tau)\right], && (6)\end{aligned}$$

where r denotes the risk-free rate, Q denotes the risk neutral measure, and Υ denotes the set of all stopping times. Here we follow Hull and White (1988) by assuming that S_t follow the lognormal diffusion process

$$\ln(S_t/S_0) = \left(r-\sigma^2/2\right)t + \sigma W_t, \tag{7}$$

where σ denotes the volatility of the underlying asset's price, and W_t denotes a standard Brownian motion. Note that Eq. (5) can be analytically evaluated by the Black and Scholes (1973) formula, while Eq. (6) can not be analytically evaluated due to the difficulty to estimate the early exercise premium.

The evolution of a lognormal diffusion process in Eq. (7) can be discretely simulated by a tree, say the CRR tree (see Cox et al., 1979), as illustrated in Fig. 1. It divides the time interval $[0,T]$ into several equal time steps, each with length Δt. For convenience, the number xy in the subscript of $\hat{P}^E$ and $\hat{P}^A$ denote the values of the European put and the American put at node (i,j) – the j-th node (counted from the uppermost node) at the i-th time step. The underlying asset price S at an arbitrary node (i,j) would move to Su (node $(i+1,j)$) with probability p or Sd (node $(i+1,j+1)$) with probability q at the next time step, where multiplication factors u and d are set to $e^{\sigma\sqrt{\Delta t}}$ and $1/u$, respectively, and branching probabilities p and q are set to $\frac{e^{r\Delta t}-d}{u-d}$ and $1-p$, respectively, to match the first two moments of the lognormal diffusion process.

Both European and American puts can be numerically priced on a CRR tree by the backward induction method; that is, we evaluate the option values (of the nodes) from the end of the tree to its beginning. Specifically, the value of a European put for an arbitrary node prior to maturity, say $\hat{P}_{ij}^E$, is evaluated as the expected discounted value of its successor node $\hat{P}_{ij}^E = \frac{p\hat{P}_{i+1,j}^E + q\hat{P}_{i+1,j+1}^E}{R}$, where R denotes the 1-time-step discount factor $e^{-r\Delta t}$. An American put grants holder the right to exercise the put at node (i,j) for the profit $K - S(i,j)$, where $S(i,j)$ denotes the asset value at that node. The holder can also choose not to exercise the option at node (i,j) immediately and the value of the option, called the continuation value for simplicity, can be estimated by

$$\hat{V}_{ij} = \frac{p\hat{P}_{i+1,j}^A + q\hat{P}_{i+1,j+1}^A}{R}. \tag{8}$$

The holder will decide whether he/she exercises the option or not to maximize the benefit; that is, the value of American put at node (i,j) is

$$\max\left(\hat{V}_{ij}, K - S(i,j)\right). \tag{9}$$

The pricing results for European and American puts are $\hat{P}_{01}^E$ and $\hat{P}_{01}^A$, respectively. The accuracy of the pricing results can be improved as the discretization of the tree get finer.

3.2 Applying the Generalized Control Variate Method

The operator that calculates the expected discounted payoff as in Eqs. (5) and (6) can be numerically estimated by the tree method. Hull and White (1988) extend the control variate method by applying it on the tree method instead of `MC`. They take advantage of the error for estimating P^E by the tree method to reduce the error for estimating P^A. The estimation result $\hat{P}_{01}^A - \hat{P}_{01}^E + \mathrm{BS}(S_0, T)$ is much more accurate than $\hat{P}_{01}^A$ given the same discretization level (of the tree), where $\mathrm{BS}(a, b)$ denotes the Black and Scholes (1973) put option pricing formula with the underlying asset price a and the time to maturity b.

We generalize the control variate method further by applying it to improve the accuracy of certain operators in the tree method. Here we detail how the continuous pricing model in Eq. (6) is transferred into its discrete counterpart since similar concepts and notations will be used in the following sections. Recall that a n-time-step tree method discretizes the time interval $[0, T]$ into n equal-distance time steps. Thus, pricing the American put on the tree can be viewed to repeat the operator O_B, to evaluate the continuation value function of the underlying asset's value at time step $i-1$ based on the option-value function at time step i, n times from the last step back to the beginning of the tree. Take Fig. 1 as an example. Let P_i^A, V_i, and P_i^E denote the American put value function, continuation value function, and the European put value functions of the underlying asset at time step i, respectively. P_2^A can be discretely approximated by keeping the option values at certain points, say S_0u^2, S_0, and S_0d^2, in a list $\hat{\mathbb{P}}_2^{\mathbb{A}}$; that is, $\hat{\mathbb{P}}_2^{\mathbb{A}} \equiv \{\hat{P}_{21}^A, \hat{P}_{22}^A, \hat{P}_{23}^A\}$. The operator O_B is numerically evaluated by applying the 1-time-step backward induction formula like Eq. (8) on $\hat{\mathbb{P}}_2^{\mathbb{A}}$ to obtain the discretization of the continuation value function at time step 1, $\hat{\mathbb{V}}_1 \equiv \{\hat{V}_{11}, \hat{V}_{12}\}$. The above numerical estimation can be expressed as $\hat{\mathbb{V}}_1 = O_B^N(\hat{\mathbb{P}}_2^{\mathbb{A}})$, where O_B^N denotes that the operator O_B is evaluated numerically. Then the list of the American put values at time step 1, $\hat{\mathbb{P}}_1^{\mathbb{A}}$ is obtained by judging whether exercising the put is beneficial or not by Eq. (9) at each node in the time step 1. O_B^N and the early exercise judgement can be alternatively applied to obtain the final pricing result $\hat{P}_{01}^A$.

Now we improve the accuracy for estimating the continuation value function and as a consequence the American put value function by the general control variate method as illustrated in Fig. 2. The American and the European-put-value functions play the roles of the function of interest X and the control function Y, respectively. Unlike Eq. (8), the continuation value for a

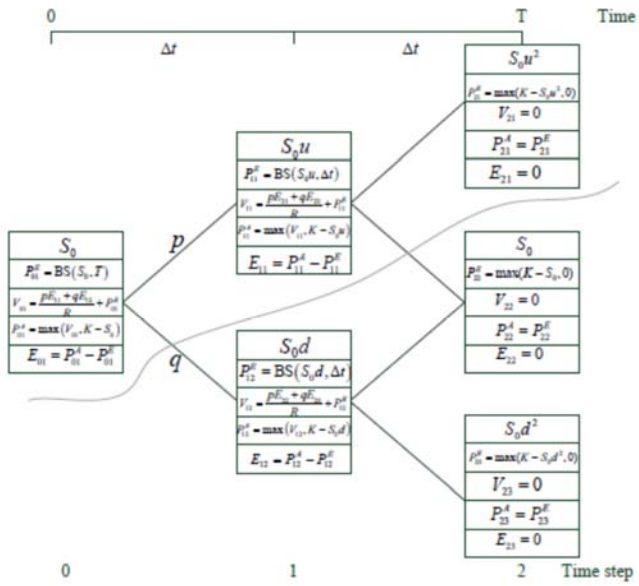

Figure 2: **Pricing American Puts with the General Control Variate Method** The meanings of S_0, u, d, p, q, and K are the same as those in Fig. 1. Each node (i,j) is represented by a rectangle with five fields, which denote the price of the underlying asset, the analytical value of the European put P_{ij}^E, the continuation value V_{ij}, the value of the American put P_{ij}^A, and the early exercise premium E_{ij}.

node (i,j) prior to maturity is now estimated as $V_{ij} \equiv \frac{pE_{i+1,j}+qE_{i+1,j+1}}{R} + P_{ij}^E$, where $E_{i,j}$ denotes the early exercise premium, or the difference of the values of the American and the European puts at node (i,j). P_{ij}^E denotes the European put value at node (i,j) that is analytically evaluated by the Black and Scholes (1973) formula[5]. The above formula for evaluating V_{ij} is applied to evaluate the value of each element in the list $\mathbb{V}_i$ that discretely approximate the function V_i. Indeed, the above approximation can be expressed in terms of the general control variate method as

$$\mathbb{V}_i = O_B^N(\mathbb{P^A}_{i+1} - \mathbb{P^E}_{i+1}) + O_B(P_{i+1}^E), \tag{10}$$

where the difference of two lists $\mathbb{P^A}_{i+1} - \mathbb{P^E}_{i+1}$ is the list of the early exercise premium or the discretization of the difference between the functions X and Y. Note that applying O_B on the European put value function at time step $i+1$, P_{i+1}^E, will obtain the function P_i^E. This can be proved by applying the tower rule on Eq. (5) as follows:

$$\begin{aligned} P_i^E(S_{i\Delta t}) &= \mathrm{E}_Q\left[e^{-r(T-i\Delta t)}(K-S_T)^+|S_{i\Delta t}\right] \\ &= \mathrm{E}_Q\left[e^{-r\Delta t}\mathrm{E}_Q\left[e^{-r(T-(i+1)\Delta t)}(K-S_T)^+|S_{(i+1)\Delta t}\right]|S_{i\Delta t}\right] \\ &= \mathrm{E}_Q\left[e^{-r\Delta t}P_{i+1}^E|S_{i\Delta t}\right]. \end{aligned}$$

By taking advantage of the general control variate method in Eq. (10), we get the list $\mathbb{V}_i$ that is more accurate than the list $\hat{\mathbb{V}}_i$ evaluated by directly applying the backward induction. The list of American put values $\mathbb{P^A}_i$ is then obtained by substituting $\mathbb{V}_i$ into Eq. (9). Note that $\mathbb{P^A}_i$ tends to be more accurate than $\hat{\mathbb{P}}_i^{\mathbb{A}}$ since $\mathbb{V}_i$ is more accurate than $\hat{\mathbb{V}}_i$ Our accurate pricing method for American put is constructed by repeatedly applying the above procedure as

[5]Note that P_{ij}^E and P_i^E are different symbols distinguished by the number of elements in the subscript. The latter symbol denotes the European put value function at the time step i.

described in Algorithm 1. Note that other numerical methods in the following sections will also be described in this format without giving a specificized example like Fig. 2 for brevity.

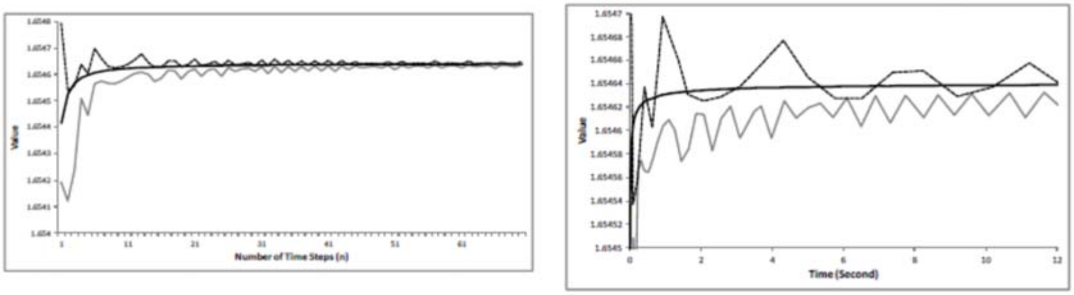
Algorithm 1 The General Control Variate Method for Pricing American Puts on a n-Time-Step Tree.

1: Evaluate the list of the early exercise premium $\mathbb{E}_n(\equiv \mathbb{P}^{\mathbb{A}}{}_n - P_n^E)$.
2: **for** $i = n-1$ down to 0 **do**
3: Evaluate the list of the continuation value $\mathbb{V}_i$ by substituting $\mathbb{E}_{i+1}$ into Eq. (10).
4: Evaluate the list of the American put value $\mathbb{P}^{\mathbb{A}}{}_i$ by substituting $\mathbb{V}_i$ into Eq. (9).
5: Evaluate the list of the early exercise premium $\mathbb{E}_i(\equiv \mathbb{P}^{\mathbb{A}}{}_i - P_i^E)$.
6: **end for**
7: The pricing result is the American put value at the beginning node of the tree; i.e, P_{01}^A.

3.3 Numerical Experiments

Recall that the pricing results of a tree method converge to the theoretical value (about 1.64563 in this example) as the number of time steps n increases. Compared to the results generated by directly applying the backward induction method to the tree model (denoted by the gray dotted line), the Hull and White (1988) method applies the control variate method once on the overall pricing results (denoted by black dashed line) and slightly improve the accuracy for pricing American puts as illustrated in Fig. 3 (a). That is, given the same number of time steps (of the tree method), the pricing result generated by the Hull and White (1988) method tends to be closer to 1.65463 than the result generated by the direct backward induction. In addition, our approach repeatedly applies the general control variate method and the pricing results (denoted by the black solid line) significantly improve the accuracy and reduce the oscillation problem.

Note that a sophisticated pricing method like our approach would require extra computations (like evaluating the Black-Scholes pricing formula many times) and hence long computational time. Thus evaluating the performances among different pricing methods should compare the convergence rates of these methods in terms of computational time as illustrated in Fig. 3 (b). Indeed, most of extra computations in Algorithm 1 can be skipped by taking advantage of the property of the early exercise boundary (see Curran, 1994). For convenience, we call a node (i,j) an "early-exercise node" if the option holder decides to exercise the American put immediately at that node (i.e, $V_{ij} < K - S(i,j)$); otherwise, we call it a "non-early-exercise node". There exists a default boundary, like the gray curve in Fig. 2, that divide the tree nodes into two groups: the group of non-early-exercise nodes in the upper part of the tree and the group of early-exercise nodes in the lower part. We mimic the Curran (1994) method to estimate the default boundary and use the general control variate method to improve the estimation. For each non-early-exercise node (i,j), we directly evaluate the early exercise premium E_{ij} without calculating P_{ij}^A; that is, we evaluate E_{ij} as $\frac{pE_{i+1,j}+qE_{i+1,j+1}}{R}$ without involving the Black-Scholes pricing formula. For early-exercise nodes, we only calculate the values for the node right below the default boundary. The evaluation for other early-exercise nodes can be skipped without influencing the pricing results as mentioned in Curran (1994). Indeed, the above concept can be used to improve all tree-based pricing algorithms analyzed in this numerical experiment. The experiment suggests that our method still converges much faster than the other two methods in terms of the computational time as in Fig. 3 (b).



(a) (b)

Figure 3: Convergence Comparisons for Pricing American Puts

The x axes in panel (a) and (b) denote the number of time steps (in thousands) and the computational time, respectively. The y axes in both panels denote the American put prices generated by different numerical methods. The gray dotted lines denote the results generated by directly applying the backward induction method on the CRR tree. The black dashed lines denote the results generated by Hull and White (1988) method. The black solid lines denote the results generated by our method. The initial underlying asset's price S_0 is 40, the time to maturity T is 3 year, the strike price K is 35, the risk-free rate r is 0.05, and the volatility σ is 0.2.

4 Characteristic-Function-Based Pricing Methods

4.1 Background Introduction

A plenty of empirical studies suggest that many assets' prices have certain features like "high peak" and "heavy tail" that can not be properly modeled by the aforementioned lognormal diffusion process (see e.g. Eberlein et al. (1998) ,Hosking et al. (2000), and Koedijk et al. (1998)). To capture these features better, many financial experts develop complex processes like the variance gamma process (see Madan et al. (1998)) and the stochastic volatility process (see Heston (1993)) to model the evolution of an asset price process. However, pricing derivatives on these complicated processes under the risk neutral variation method could become mathematical intractable. This is because the density of the asset price can not be analytically solved, which make the closed-form pricing formulae for even the simplest vanilla options unavailable. Fortunately, the analytical formulae of return characteristic functions for a vast class of price processes are available, and can be applied to price derivatives as mentioned in Bakshi and Chen (1997), Bates (1996), and Chen and Scott (1992). The following discussions focus on the approach proposed by Carr and Madan (1999) since it seems to be the most efficient one due to the use of FFT to improve the performance. Our general control variate method can be applied to improve the accuracy of their pricing method by finding a proper control function that approximates the target characteristic function. The information about the difference between the control function and the target function is then exploited to reduce the pricing error.

Assume that the underlying asset price process S_t follows a stochastic process G. Carr and Madan (1999) propose that the value of a European call option can be expressed as a function $C_G^{\mathrm{E}}(e^k)$ of the strike price e^k as follows:

$$C_G^{\mathrm{E}}(e^k) = E_Q\left[e^{-rT}(S_T - e^k)^+\right] = \int_k^{\infty} (e^s - e^k) q(s)\, ds = \frac{e^{-dk}}{\pi} \int_0^{\infty} \mathrm{Re}[e^{-ivk}\psi_G(v)]\, dv, \tag{11}$$

where q denotes the density function of $\ln S_T$, and $\mathrm{Re}[x]$ denotes the real part of a complex number x. ψ_G is the Fourier transform of $e^{dk}C_G^{\mathrm{E}}(e^k)$, where $d > 0$ denotes an exogenously given damping constant[6]. Thus ψ_G can be expressed as

$$\psi_G(v) \;=\; \frac{e^{-rT}\,\phi_G(v-(d+1)i)}{d^2+d-v^2+i(2d+1)v},$$

where ϕ_G denotes the characteristic function of q; that is, $\phi_G(v) \equiv \int_{-\infty}^{\infty} e^{ivs}q(s)\,ds$.

The call option value in Eq. (11) can be approximately evaluated by a numerical integration method like the Trapezoid rule as follows:

$$\begin{aligned} C_G^{\mathrm{E}}(e^k) &= \frac{e^{-dk}}{\pi}\int_0^{\infty} \mathrm{Re}[e^{-ivk}\psi_G(v)]\,dv && (12)\\ &= \frac{e^{-dk}}{\pi}\int_0^{\eta N} \mathrm{Re}[e^{-ivk}\psi_G(v)]\,dv + \text{truncation error} && (13)\\ &= \frac{e^{-dk}}{\pi}\sum_{j=0}^{N-1}\frac{\eta}{2}\mathrm{Re}\left[e^{-i\eta jk}\psi_G(j\eta)+e^{-i\eta(j+1)k}\psi_G((j+1)\eta)\right] + \text{truncation error} + \text{sampling error}, && (14) \end{aligned}$$

where η denotes the distance between quadrature points, and N denotes the number of quadrature points. The improper integral in Eq. (12) can be approximated by truncating the upper limit and using the definite integral in Eq. (13) since $|e^{-ivk}\psi_G(v)|$ converges to zero as $v \to \infty$. The error incurred due to the truncation is called the truncation error which is negligible when $N\eta$ becomes larger (see Lee, 2004). The sampling error in Eq. (14) is the error contributed by approximating a definite integral with the Trapezoid rule and is equal to

$$\frac{1}{12}\eta^3\left(\frac{d^2}{dv^2}\mathrm{Re}\left[e^{iv_0k}\psi_G(v_0)\right]\right) \tag{15}$$

for some $v_0 \in [0, N\eta]$.

4.2 Applying the General Control Variate Method to Improve a Characteristic-Function-Based Pricing Method

In the aforementioned characteristic-function-based pricing method, the values of the function ψ_G are discretely sampled to store in a list $\psi_{\mathbb{G}} \equiv \{\psi_G(0), \psi_G(\eta), \cdots, \psi_G(N\eta)\}$, then the inverse Fourier transform is applied numerically on the list $\psi_{\mathbb{G}}$ as in Eq. (14). That is, the call option value $C_G^{\mathrm{E}}(e^k)$ is numerically estimated as

$$C_G^{\mathrm{E}}(e^k) \approx O_{\mathrm{IF}}^N(\psi_{\mathbb{G}}),$$

where the operator O_{IF} denotes the inverse Fourier transform, and the superscript N denotes that the operator is numerically evaluated. To apply our general control variate method to suppress the pricing error contributed by the numerical evaluation, we first find a control price process, say the jump diffusion process in this paper. Let ψ_{CTRL} be the Fourier transform of the call value function $C_{\mathrm{CTRL}}^{\mathrm{E}}(e^k)$ (on the control process) multiplied by e^{dk}, and $\psi_{\mathbb{CTRL}}$ be a list of discrete samples of ψ_{CTRL}: $\{\psi_{\mathrm{CTRL}}(0), \psi_{\mathrm{CTRL}}(\eta), \cdots, \psi_{\mathrm{CTRL}}(N\eta)\}$. Then our general control variate method exploits the information of $\psi_{\mathbb{G}} - \psi_{\mathbb{CTRL}}$ to reduce the numerical error for applying O_{IF}^N and improve the accuracy for estimating $C_G^{\mathrm{E}}(e^k)$ as follows:

$$C_G^{\mathrm{E}}(e^k) = O_{\mathrm{IF}}(\psi_{\mathrm{CTRL}}) + O_{\mathrm{IF}}^N(\psi_{\mathbb{G}} - \psi_{\mathbb{CTRL}}). \tag{16}$$

Obviously, the performance of error reduction depends on how ψ_{CTRL} is close to ψ_G. In addition, $O_{\mathrm{IF}}(\psi_{\mathrm{CTRL}})$ must be analytically solvable to avoid the introduction of other numerical errors.

[6]Note that the Fourier transform of $C_G^{\mathrm{E}}(e^k)$ doesn't exist since it is not a square integrable function– note that it tends to S_0 as k tends to $-\infty$. Carr and Madan (1999) employ a proper damping constant d to make the Fourier transform of $e^{dk}C_G^{\mathrm{E}}(e^k)$ well defined.

Therefore, Eq. (16) entails that the call value function C_G^{E} in Eq. (11) under our general control variate method is evaluated as follows:

$$\begin{aligned} C_G^{\mathrm{E}}(e^k) &= \frac{e^{-dk}}{\pi}\int_0^\infty \mathrm{Re}\left[e^{-ivk}\psi_G(v)\right]\,dv \\ &= \frac{e^{-dk}}{\pi}\int_0^\infty \mathrm{Re}\left[e^{-ivk}[\psi_{\mathrm{CTRL}}(v)+\psi_{\mathrm{RESIDUAL}}(v)]\right]\,dv \\ &\equiv C_{\mathrm{CTRL}}^{\mathrm{E}}(e^k)+C_{\mathrm{RESIDUAL}}^{\mathrm{E}}(e^k), \end{aligned} \tag{17}$$

where $\psi_{\mathrm{RESIDUAL}}(v) \equiv \psi_G(v) - \psi_{\mathrm{CTRL}}(v)$ be the difference between ψ_G and ψ_{CTRL}, $C_{\mathrm{CTRL}}^{\mathrm{E}}(e^k)$ (or $O_{\mathrm{IF}}(\psi_{\mathrm{CTRL}})$) should be analytically evaluated to avoid extra numerical errors.

In this paper, we demonstrate our idea by choosing the jump-diffusion process proposed by Merton (1976) as the control process. Then we tune the parameters of the control process to reduce the amplitude of $\psi_{\mathrm{RESIDUAL}}(v)$ and hence the pricing error. Specifically, a jump-diffusion process follows the stochastic differential equation:

$$dS_t = \left(\mu + \frac{\sigma^2}{2}\right) S_t\,dt + \sigma S_t\,dW_t + (e^{J_t}-1)S_t\,dM_t,$$

where μ and σ^2 denote respectively the drift and the volatility of the diffusion component of the asset price, and W_t denotes a standard Brownian motion. The jump component is governed by a Poisson process M_t with intensity λ, and it is independent of W_t. The jump size is governed by a sequence of independent normal random variables J_t with mean μ_J and standard derivation σ_J. The characteristic function of $\ln S_T$ can be expressed as an infinite series:

$$\phi_{\mathrm{MJD}}(v) = \exp\left(-\lambda T + iv(\mu T + \ln S_0) - \frac{1}{2}\sigma^2 T v^2\right)\sum_{h=0}^{\infty}\frac{(\lambda T \exp(iv\mu_J - \frac{\sigma_J^2 v^2}{2}))^h}{h!}.$$

To avoid the truncation error caused by the truncation of the infinite summation, we consider a modified jump-diffusion process with at most $H-1$ jumps during the option life; that is, the characteristic function of $\ln S_T$ of this modified process, denoted as $\phi_{\mathrm{MJD}_H}(v)$, is the sum of the first H terms of $\phi_{\mathrm{MJD}}(v)$ expressed as follows:

$$\phi_{\mathrm{MJD}_H}(v) \equiv \exp\left(-\lambda T + iv(\mu T + \ln S_0) - \frac{1}{2}\sigma^2 T v^2\right)\sum_{h=0}^{H-1}\frac{(\lambda T \exp(iv\mu_J - \frac{\sigma_J^2 v^2}{2}))^h}{h!}. \tag{18}$$

The call price formula for this modified process will play the role of $C_{\mathrm{CTRL}}^{\mathrm{E}}(e^k)$ in Eq. (17) and can be expressed as a summation of the following finite sequence:

$$C_{\mathrm{CTRL}}^{\mathrm{E}}(e^k) = \sum_{h=0}^{H-1}\frac{e^{-\lambda' T}(\lambda' T)^h}{h!}\mathrm{BS}_C(S_0, e^k, T, \sigma_h, r_h) \quad \text{for} \quad u = 0, 1, \ldots, m-1, \tag{19}$$

where $\lambda' \equiv \lambda e^{\mu_J + \frac{\sigma_J^2}{2}}$. $\mathrm{BS}_C(S_0, e^k, T, \sigma_h, r_h)$ denotes the Black-Scholes call option pricing formula on the lognormal diffusion process (see Black and Scholes, 1973) with the initial underlying asset's price S_0, the strike price e^k, the time to maturity T, the risk-free rate $r_h \equiv \mu + \frac{\sigma^2}{2} + \frac{h(\mu_J + \frac{\sigma_J^2}{2})}{T}$, and the volatility rate $\sigma_h \equiv \sqrt{\sigma^2 + \frac{h\sigma_J^2}{T}}$. The Fourier transform of $e^{dk}C_{\mathrm{CTRL}}^{\mathrm{E}}(e^k)$, denoted as ψ_{CTRL}, can be expressed as

$$\psi_{\mathrm{CTRL}}(v) \equiv \frac{e^{-(\mu + \frac{\sigma^2}{2} + \lambda(e^{\mu_J + \frac{\sigma_J^2}{2}} - 1))T}\,\phi_{\mathrm{MJD}_H}(v - (d+1)i)}{d^2 + d - v^2 + i(2d+1)v}. \tag{20}$$

Thus the residual part call price $C^{\mathrm{E}}_{\mathrm{RESIDUAL}}(e^k)$ in Eq. (17) can be numerically estimated as follows:

$$\begin{aligned} C^{\mathrm{E}}_{\mathrm{RESIDUAL}}(e^k) &= \frac{e^{-dk}}{\pi}\int_0^\infty \mathrm{Re}\left[e^{-ivk}\psi_{\mathrm{RESIDUAL}}(v)\right] dv \\ &\approx \frac{e^{-dk}}{\pi}\sum_{j=0}^{N-1}\frac{\eta}{2}\mathrm{Re}\left[e^{-i\eta jk}\psi_{\mathrm{RESIDUAL}}(j\eta) + e^{-i\eta(j+1)k}\psi_{\mathrm{RESIDUAL}}((j+1)\eta)\right] \\ &= O^N_{\mathrm{IF}}(\psi_{\mathrm{G}} - \psi_{\mathrm{CTRL}}). \end{aligned} \tag{21}$$

Next we calibrate the parameters for the jump diffusion process to make ψ_{CTRL} close to ψ_G through the cumulant matching method. Assume that the first five cumulants of $\ln S_T$ under the process of interest G exist and are equal to m_1, m_2, m_3, m_4, and m_5, respectively. Matching these five cumulants to the first five cumulants of $\ln S_T$ under the jump-diffusion process yields the following equations:

$$(\mu + \lambda\mu_J)\,T + \ln S_0 = m_1, \tag{22}$$
$$\left(\sigma^2 + \lambda\left(\mu_J^2 + \sigma_J^2\right)\right)T = m_2, \tag{23}$$
$$\lambda(\mu_J^3 + 3\mu_J\sigma_J^2)T = m_3, \tag{24}$$
$$\lambda(\mu_J^4 + 6\mu_J^2\sigma_J^2 + 3\sigma_J^4)T = m_4, \tag{25}$$
$$\lambda(\mu_J^5 + 10\mu_J^3\sigma_J^2 + 15\mu_J\sigma_J^4)T = m_5. \tag{26}$$

Note that the left hand sides of the above equations are the first five cumulants of $\ln S_T$ under the jump-diffusion process.[7]

The parameters for jump diffusion process are calibrated by solving Eqs. (22)$\sim$(26). We first rewrite Eq. (24) as

$$\sigma_J^2 = \frac{m_3 - \lambda\mu_J^3 T}{3\lambda\mu_J T}. \tag{27}$$

By substituting Eq. (27) for all σ_J^2 in Eq. (25) and Eq. (26), we have

$$\begin{aligned} &-2\mu_J^6T^2\lambda^2 + (4m_3\mu_J^3T - 3\mu_J^2m_4T)\lambda + m_3^2 = 0, \\ &-2\mu_J^6T^2\lambda^2 - 3\mu_Jm_5T\lambda + 5m_3^2 = 0. \end{aligned}$$

By equating the above two equations, we get

$$\lambda = \frac{4m_3^2}{\left(3m_5\mu_J - 3m_4\mu_J^2 + 4m_3\mu_J^3\right)T}. \tag{28}$$

Substituting σ_J^2 in Eq. (27) and λ in Eq. (28) into Eq. (24) would yield a quartic polynomial equation of μ_J as follows:

$$48m_3^4\mu_J^4 - 120m_3^3m_4\mu_J^3 + 9m_3^2\left(8m_3m_5 + 5m_4^2\right)\mu_J^2 - 54m_3^2m_4m_5\mu_J + 9m_3^2m_5^2 = 0. \tag{29}$$

The above equation can be solved by the root finding method provided by mathematical softwares like Mathematica. If there are multiple real roots for μ_J, we will first substitute each root into Eq. (28) to find its corresponding jump intensity λ. The root with the smallest λ will be chosen to make ϕ_{MJD_H} – constructed based on the the modified jump-diffusion process with finite jumps

[7]Although we use the modified jump-diffusion process (with at most $H-1$ jumps) instead of the jump-diffusion process to calculate the control process ψ_{CTRL} as in Eq. (20), the calibration error will be absorbed by the evaluation of Eq. (21). That is, the use of the modified jump-diffusion process does not generate additional errors.

as in Eq. (18)– more close to ϕ_{MJD_G}. This is because we calibrate the parameters of the jump diffusion with infinite jumps to match the cumulants of the process of interest G by Eqs. (22)$\sim$(26) to make ϕ_{MJD} approximate ϕ_{MJD_G}. Thus we should pick a lowest jump intensity λ to minimize the difference between ϕ_{MJD} and ϕ_{MJD_H}. On the other hand, it is possible that Eq. (29) does not have any real root. Then we simply pick a proper μ_J which minimizes the absolute value of the left hand side of Eq. (29). Once μ_J is determined, the other 4 parameters, λ, σ_J, μ, and σ, can be determined by substituting μ_J into Eqs. (28), (27), (22), and (23), respectively. Algorithm 2 summarizes the core idea for applying our general control variate method to improve Carr and Madan's characteristic-function-based pricing method.

Algorithm 2 Applying the General Control Variate Method to Improve the Characteristic-Function-Based Method.

1: Find ψ_G, the Fourier transform of the call price $c_G^{\mathrm{E}}(e^k)$ on the process G multiplied by e^k.
2: Determine the parameters of the jump diffusion process to make ψ_{CTRL} approximate to ψ_G by Eqs. (22) $\sim$ (29).
3: Evaluate $O_{\mathrm{IF}}^N(\psi_{\mathrm{G}} - \psi_{\mathrm{CTRL}})$ numerically to get $C_{\mathrm{RESIDUAL}}^{\mathrm{E}}(e^k)$ (see Eq. (21)).
4: Evaluate $O_{\mathrm{IF}}(\psi_{\mathrm{CTRL}})$ to get $C_{\mathrm{CTRL}}^{\mathrm{E}}(e^k)$ by the analytical formula in Eq. (19).
5: $C_G^{\mathrm{E}}(e^k)$ is estimated as the sum of $C_{\mathrm{RESIDUAL}}^{\mathrm{E}}(e^k)$ and $C_{\mathrm{CTRL}}^{\mathrm{E}}(e^k)$ as in Eq. (17).

4.3 Numerical Results

The accuracy of the characteristic-function-based pricing methods highly depends on the magnitude of the sampling error introduced by applying the numerical integral like the Trapezoid rule as illustrated in Eq. (15). Under our general control variate method, the sampling error is suppressed by substituting the numerical integral with the integrand ψ_{RESIDUAL} in Eq. (21) for the integral with the integrand ψ_G in Eq. (14). Since a control function ψ_{CTRL} is properly selected to closely approximates ψ_G, the amplitude of ψ_{RESIDUAL} becomes smaller and smoother than ψ_G. Thus the amplitude of the second order derivative of ψ_{RESIDUAL} will have a better chance to be smaller than the derivative of ψ_G as illustrated in Fig. 4. Since the sampling error is bounded above by the supremum of the second order derivative of the integrand as in Eq. (15), a lower amplitude of the second order derivative would imply a lower pricing error as illustrated in Fig. 5. Fig. 4 demonstrates the amplitude of $\frac{d^2}{dv^2}\mathrm{Re}\left[e^{ivk}\psi_G(v)\right]$ (plotted in thin dashed curves) and $\frac{d^2}{dv^2}\mathrm{Re}\left[e^{ivk}\psi_{\mathrm{RESIDUAL}}(v)\right]$ (plotted in thick solid curves) for three popular price processes: the variance gamma model in panel (a) (see Madan et al., 1998), the stochastic volatility model in panel (b) (see Heston, 1993), and the double exponential model in panel (c) (see Kou, 2002). It can be observed that the amplitudes of $\frac{d^2}{dv^2}\mathrm{Re}\left[e^{ivk}\psi_{\mathrm{RESIDUAL}}(v)\right]$ in all three models are significantly smaller than the amplitudes of $\frac{d^2}{dv^2}\mathrm{Re}\left[e^{ivk}\psi_G(v)\right]$. Fig. 5 uses the same numerical settings for the aforementioned three processes as the settings in Fig. 4 and show that our general control variate method (plotted in thick solid curves) is more efficient and more accurate than the characteristic-function-based method studied by Carr and Madan (1999) (plotted in thin dashed curves). Specifically, the upper limit ηN of the integral in Eq. (13) is fixed to be a very large constant 2^{10} to ensure that the truncation error is negligible. Then we can analyze how the change of the distance between the quadrature points η and hence the number of quadrature points N influence the computational efficiency and the accuracy. Note that the y-axes in all six panels denote the logarithm of the absolute pricing error. The x-axes in panel (a), (c), and (e) denote the computational time. It can be observed that our general control variate method is more efficient since the computational time required by our method to achieve any certain precision level is lower than the computational time required by the Carr and Madan (1999) method. On the other hand, the x-axes in panel (b), (d), and (f) denote the logarithm of the distance between the quadrature points η. It can also be observed that our method is more accurate since the pricing error produced by our method is much smaller than the error produced by the Carr and Madan (1999) method given the same η.

5 Convolution-Based Asian Option Pricing Method

5.1 Background Introduction

The payoff of an Asian option depends on the average of discrete samples of the underlying asset price over a pre-specified time interval. Pricing Asian options is an intractable problem since the analytical formula for the average underlying asset's price density does not exist. Let A be the average of the underlying asset's price sampled at times $t_0, t_1, t_2, \ldots, t_n$, where $0 = t_0 < t_1 < t_2 < \cdots < t_n = T$ as follows:

$$A \equiv \frac{1}{n+1}\sum_{i=0}^{n} S_{t_i}. \tag{30}$$

The value of an Asian call option can be expressed as the expectation of the discounted payoff under the risk-neutral variation method (see Harrison and Pliska, 1981) as follows:

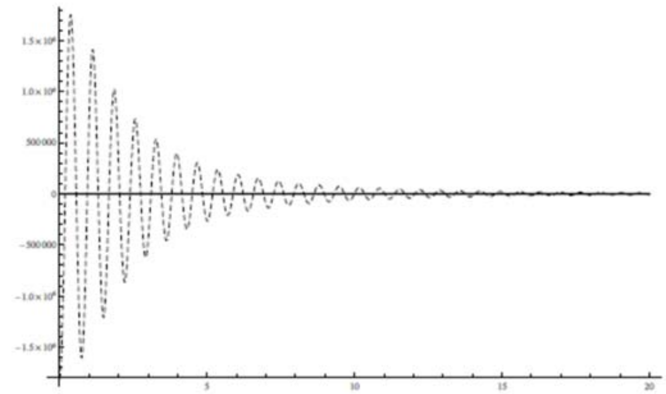
$$C^{\text{Asian}} = E_Q\left[e^{-rT}(A-K)^+\right]. \tag{31}$$

Carverhill and Clewlow (1990) propose a convolution-based pricing method to estimate the probability density of A in order to price C^{Asian}, and their method is then improved by Benhamou (2002). Our general control variate method can improve both pricing methods and the following discussion will focus on the latter one for simplicity. Denote the underlying asset's return from time t_{i-1} to time t_i as $R_i \equiv \ln(S_{t_i}/S_{t_{i-1}})$. Since $S_{t_i} = S_{t_0}e^{R_1+R_2+\cdots R_i}$, Eq. (30) can be rewritten as:

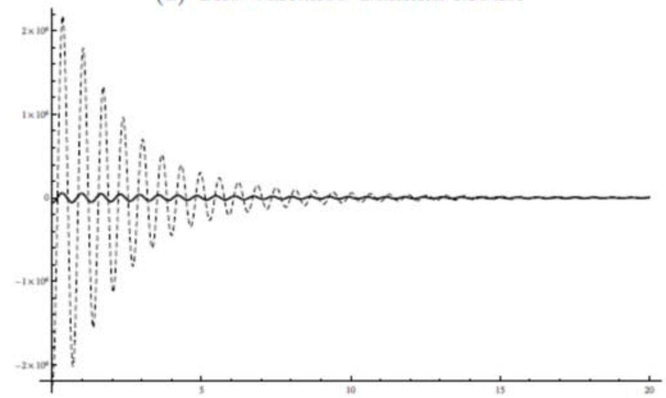
$$\begin{aligned} A &= \frac{1}{n+1}\sum_{i=0}^{n} S_{t_i} = \frac{S_{t_0}}{n+1}\left(1+e^{R_1}+e^{R_1+R_2}+\cdots+e^{R_1+R_2+\cdots R_n}\right) \\ &= \frac{S_{t_0}}{n+1}\left(1+e^{R_1}\left(1+e^{R_2}\left(1+\cdots e^{R_{n-1}}\left(1+e^{R_n}\right)\right)\right)\right) \\ &= \frac{S_{t_0}}{n+1}\left(1+e^{R_1+\ln(1+\exp(R_2+\ln(1+\cdots+\exp(R_{n-2}+\ln(1+\exp(R_{n-1}+\ln(1+\exp(R_n))))))))}\right) \end{aligned} \tag{32}$$

Under the premise that S_t follows a Levy process, the stationary and the independent increment properties entail that the returns $R_1, R_2, R_3, \ldots$ are independent. This useful property allow us to recursively apply the numerical convolution method to evaluate the densities of the exponential terms in Eq. (32). Specifically, Benhamou (2002) expresses the exponential term in Eq. (32) as a recursive sequence $\{D_i\}$ as follows:

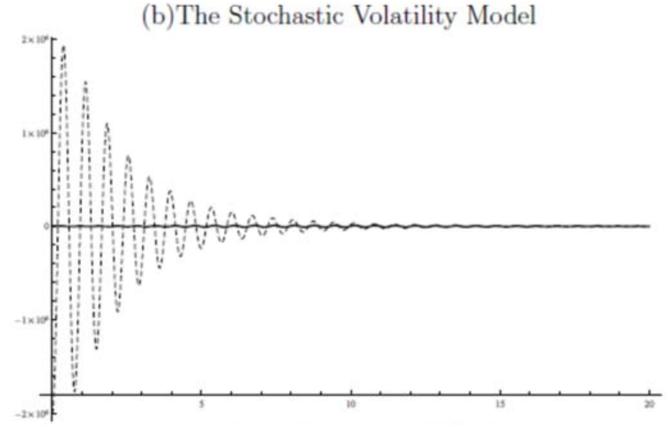
$$\begin{aligned} D_{n-1} &= R_n - E[R_n] = R_n - \mu_{n-1}, \\ D_{n-2} &= R_{n-1} + \ln\left(1+e^{R_n}\right) - E[R_{n-1}] - \ln\left(1+e^{E[R_n]}\right) \\ &= R_{n-1} + \ln\left(1+e^{D_{n-1}+\mu_{n-1}}\right) - \mu_{n-2}, \\ D_{n-3} &= R_{n-2} + \ln\left(1+e^{R_{n-1}+\ln\left(1+e^{R_n}\right)}\right) - E[R_{n-2}] - \ln\left(1+e^{E[R_{n-1}]+\ln\left(1+e^{E[R_n]}\right)}\right) \\ &= R_{n-2} + \ln\left(1+e^{D_{n-2}+\mu_{n-2}}\right) - \mu_{n-3}, \\ &\vdots \\ D_0 &= R_1 + \ln\left(1+e^{R_2\left(\cdots+\ln\left(1+e^{R_n}\right)\right)}\right) - E[R_1] - \ln\left(1+e^{E[R_2]\left(\cdots+\ln\left(1+e^{E[R_n]}\right)\right)}\right) \\ &= R_1 + \ln\left(1+e^{D_1+\mu_1}\right) - \mu_0, \end{aligned} \tag{33}$$



(a) The Variance Gamma Model



(b)The Stochastic Volatility Model



(c) The Double Exponential Model

Figure 4: Comparison of the Second Order Derivatives for Estimating Sampling Errors.

The x-axes denote the variable v, the thin dashed lines denote $\frac{d^2}{dv^2}\mathrm{Re}\left[e^{ivk}\psi_G(v)\right]$, and the thick solid lines denote $\frac{d^2}{dv^2}\mathrm{Re}\left[e^{ivk}\psi_{\mathrm{Residual}}(v)\right]$. Panel (a) is generated from the variance gamma model with $S_0 = 100$, $K = 100$, $r = 0$, T =4 months, the drift rate of the Brownian motion -0.1436, the variance rate of the Brownian motion 0.1213, and the variance rate of the gamma process 0.1686. Panel (b) is generated from the stochastic volatility model with $S_0 = 100$, $K = 100$, $r = 0$, $T = 4$ months, the mean reversion speed 1.49, the long-run variance 0.0671, the volatility of the underlying asset price volatility 0.742, the correlation -0.0571, and the current variance 0.0262. Panel (c) is generated from the double exponential model with $S_0 = 100$, $K = 98$, $r = 0.05$, $T = 6$ months, the rate of upward jumps 10, the rate of downward jumps 5, the upward probability 0.4, the downward probability 0.6, and the intensity of the Poisson process 1.

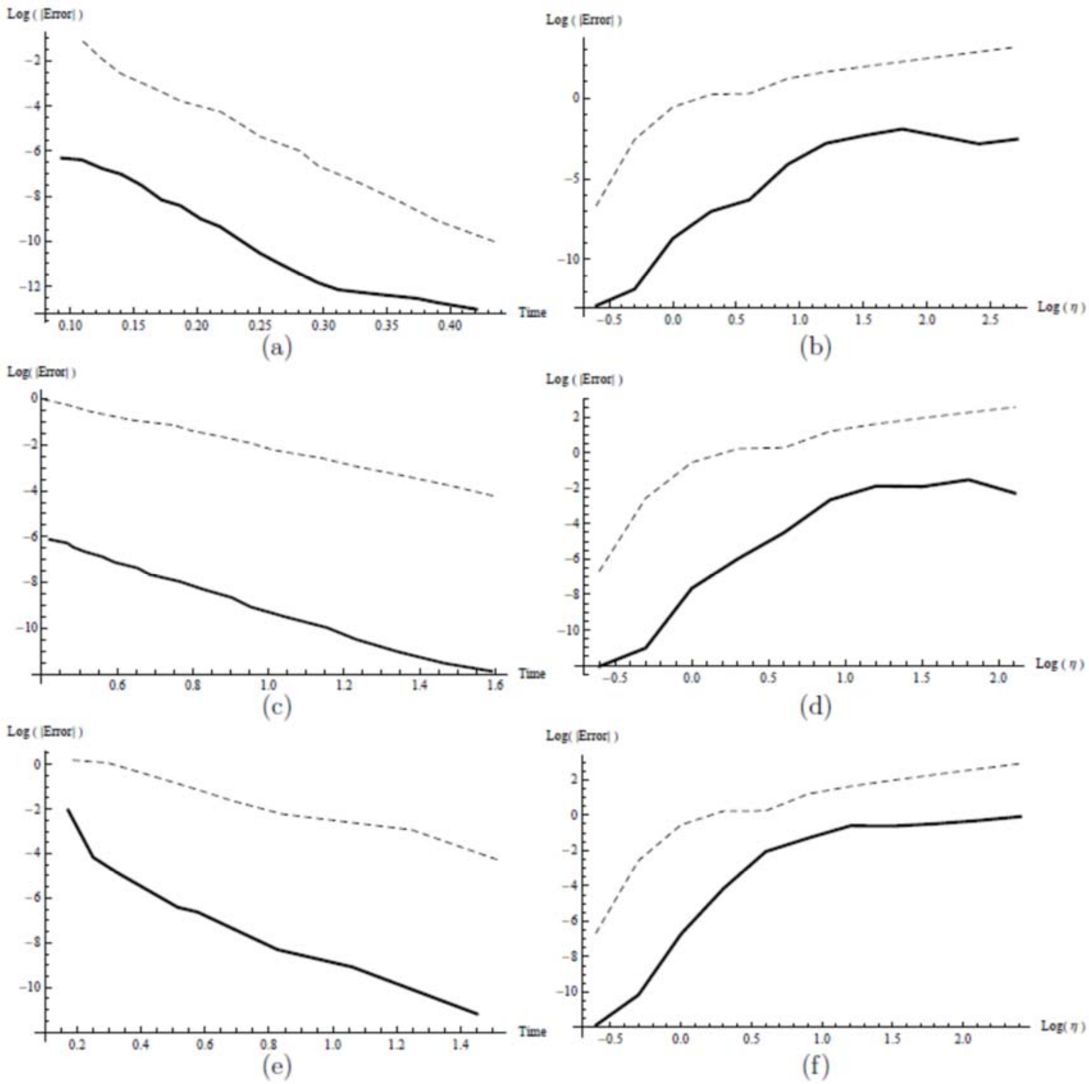


Figure 5: Convergence of pricing results.

The pricing errors for the variance gamma model, the stochastic volatility model, and the double exponential model are shown in panel (a) and (b), (c) and (d), and (e) and (f), respectively. Panels (a), (c), and (e) plot the relations between the computational time and the logarithm of the absolute pricing errors. Panels (b), (d), and (f) plot the relations between the logarithm of the distance between the quadrature points η and the logarithm of the absolute pricing errors. The thin dashed curves and the thick solid curves denote the pricing error generated by the Carr and Madan (1999) method and our general control variate method with $H = 9$, respectively. The damping coefficient d is set as 1.5. We use the pricing results generated by the Carr and Madan (1999) method with $N = 2^{20}$ and $\eta = 2^{-10}$ as the benchmarks. All parameter values for the variance gamma model, the stochastic volatility model, and the double exponential model are the same as those in Fig. 4.

where the sequence $\{\mu_i\}$ denotes the approximately expected values for $\{D_i\}$ as follows:

$$\begin{aligned}
\mu_{n-1} &= E[R_n], \\
\mu_{n-2} &= E[R_{n-1}] + \ln\left(1 + e^{E[R_n]}\right) = E[R_{n-1}] + \ln\left(1 + e^{\mu_{n-1}}\right), \\
\mu_{n-3} &= E[R_{n-2}] + \ln\left(1 + e^{E[R_{n-1}] + \ln\left(1+e^{E[R_n]}\right)}\right) = E[R_{n-2}] + \ln\left(1 + e^{\mu_{n-2}}\right), \\
&\vdots \\
\mu_0 &= E[R_1] + \ln\left(1 + e^{E[R_2] + \ln\left(1 + \cdots + \ln\left(1+e^{E[R_n]}\right)\right)}\right) = E[R_1] + \ln\left(1 + e^{\mu_1}\right).
\end{aligned}$$

Therefore, the average underlying asset's price A can be expressed as $\frac{S_{t_0}}{n+1}\left(1 + e^{D_0+\mu_0}\right)$ and the Asian call option price defined in Eq. (31) can be reexpressed as

$$C^{\text{Asian}} = E_Q\left[e^{-rT}(A-K)^+\right] = E_Q\left[e^{-rT}\left(\frac{S_{t_0}}{n+1}\left(1 + e^{D_0+\mu_0}\right) - K\right)^+\right]. \tag{34}$$

Eq. (34) can be evaluated by the numerical integration method if the density of D_0 is available. For convenience, let f_U represent the density function of a random variable U. Benhamou (2002) numerically evaluates f_{D_0} by repeatedly apply the numerical convolution method and the Jacobian transformation method discussed as follows. First, define Z_i to satisfy the equation $D_{i-1} = R_i + Z_i$. Then $f_{D_{i-1}}$ can be evaluated as the convolution O_{C} of the density functions f_{R_i} and f_{Z_i}, which can be expressed as

$$f_{D_{i-1}} = O_{\text{C}}(f_{R_i}, f_{Z_i}). \tag{35}$$

Substituting the aforementioned equation into Eq. (33) would suggest that Z_i can be expressed as a increasing function of D_i as follows:

$$Z_i = \ln\left(1 + e^{D_i+\mu_i}\right) - \mu_{i-1},$$

This entails that f_{Z_i} can be expressed in terms of f_{D_i} by the Jacobian transformation method as follows:

$$f_{Z_i}(x) = \begin{cases} f_{D_i}(\ln(e^{x+\mu_{i-1}} - 1) - \mu_i)\frac{e^{x+\mu_{i-1}}}{e^{x+\mu_{i-1}}-1} & \text{if } x > -\mu_{n-i-1}, \\ 0 & \text{otherwise.} \end{cases} \tag{36}$$

Thus we can solve $f_{Z_{n-1}}$ by applying Eq. (36) on $f_{D_{n-1}}$. Then apply the convolution method on $f_{Z_{n-1}}$ and $f_{R_{n-1}}$ to solve $f_{D_{n-2}}$. By repeating the procedures, we will eventually obtain f_{D_0} and solve the option value by Eq. (34).

Since the above operators can not be analytically applied, thus each density function involved in above calculations is approximated by a list of density values. Specifically, a window $[-b, b]$ is chosen to contain the bulk of the probability mass of all involved densities. Then $2m+1$ grid points $-b = x_{-m} < \cdots < x_0 = 0 < \cdots < x_m = b$ are selected with equal grid spacing b/m. For example, the density $f_{D_{n-1}}$ is approximated by the grid list $\mathbb{D}_{n-1} = \{f_{D_{n-1}}(x_{-m}), f_{D_{n-1}}(x_{-m+1}), \cdots, f_{D_{n-1}}(x_m)\}$. To estimate $\mathbb{Z}_{n-1}$ – the grid list to approximate the density $f_{Z_{n-1}}$ – with $\mathbb{D}_{n-1}$, we first apply numerical interpolations on the list $\mathbb{D}_{n-1}$ to estimate the list $\{f_{D_{n-1}}(\ln(e^{x+\mu_{n-2}} - 1)) - \mu_{n-1}\}_{x=x_{-m}}^{x_m}$, then apply the Jacobian transformation formula in Eq.(36) on the latter list to evaluate $\mathbb{Z}_{n-1}$. We use the symbol O_{J} to denote the density conversion operator by the Jacobian transformation and the superscript N to denote that the operator is evaluated numerically. Then each grid list $\mathbb{Z}_i$ $(1 \le i \le n-1)$ can be evaluated by applying numerical transformation on $\mathbb{D}_i$ as follows:

$$\mathbb{Z}_i = O_{\text{J}}^N(\mathbb{D}_i). \tag{37}$$

In addition, the convolution mentioned used to evaluate $f_{D_{i-1}}$ in Eq. (35) is numerically approximated by applying the numerical convolution O_{C}^{N} on the grid lists $\mathbb{R}_i$ and $\mathbb{Z}_i$ to obtain the $\mathbb{D}_{i-1}$ as follows:

$$\mathbb{D}_{i-1} = O_{\mathrm{C}}^{N}(\mathbb{R}_i, \mathbb{Z}_i), \tag{38}$$

The Benhamou (2002) pricing method is summarized in Algorithm 3.

Algorithm 3 Benhamou Pricing Method.

1: Evaluate the densities values in the list $\mathbb{D}_{n-1}$.
2: **for** $i = n-1$ down to 1 **do**
3: Calculate $\mathbb{Z}_i$ by applying numerical Jacobian transformation method on $\mathbb{D}_i$ (see Eqs. (36) and (37)).
4: Calculate $\mathbb{D}_{i-1}$ by applying the numerical convolution on $\mathbb{R}_i$ and $\mathbb{Z}_i$ (see Eq. (38)).
5: **end for**
6: The Asian option value C^{Asian} is evaluated as the expectation in Eq.(34) with the grid list $\mathbb{D}_0$.

5.2 Using the General Control Variate Method to Improve the Convolution-Based Pricing Method

In Benhamou (2002) pricing method, the numerical Jacobian transformation (see Eq. (37)) and the numerical convolution (see Eq. (38)) are alternatively applied to construct two series of grid lists $\{\mathbb{Z}_i\}$ and $\{\mathbb{D}_i\}$ in order to estimate the density of the average underlying asset's price A and hence the value of the Asian option as illustrated in Eq. (34). The general control variate method is used to improve the accuracy for estimating $\{\mathbb{Z}_i\}$ and $\{\mathbb{D}_i\}$ and hence the overall pricing result.

To improve the accuracy for estimating the grid list $\mathbb{Z}_i$ by applying the Jacobian transformation on $\mathbb{D}_i$, we first find an analytical control function $f_{D_i}^{\mathrm{ctrl}}$ that closely approximate $\mathbb{D}_i$. Let $\mathbb{D}_i^{\mathrm{ctrl}} \equiv \{f_{D_i}^{\mathrm{ctrl}}(x_{-m+1}),\ f_{D_i}^{\mathrm{ctrl}}(x_{-m}),\ \cdots,\ f_{D_i}^{\mathrm{ctrl}}(x_m)\}$ denote the grid list of $f_{D_i}^{\mathrm{ctrl}}$. Thus, we decompose $\mathbb{D}_i$ into two parts $\mathbb{D}_i = \mathbb{D}_i^{\mathrm{ctrl}} + (\mathbb{D}_i - \mathbb{D}_i^{\mathrm{ctrl}})$, and then apply the Jacobian transformations to these two parts separately. Since $f_{D_i}^{\mathrm{ctrl}}$ is analytically known, $O_{\mathrm{J}}\left(f_{D_i}^{\mathrm{ctrl}}\right)$ can be analytically solved without incurring numerical errors (due to the interpolation). The grid list contributed by this part is

$$\{f_{D_i}^{\mathrm{ctrl}}\left(\ln(e^{x_{-m}+\mu_{i-1}}-1)-\mu_i\right)\frac{e^{x_{-m}+\mu_{i-1}}}{e^{x_{-m}+\mu_{i-1}}-1}, f_{D_i}^{\mathrm{ctrl}}\left(\ln(e^{x_{-m+1}+\mu_{i-1}}-1)-\mu_i\right)\frac{e^{x_{-m+1}+\mu_{i-1}}}{e^{x_{-m+1}+\mu_{i-1}}-1},$$
$$\cdots, f_{D_i}^{\mathrm{ctrl}}\left(\ln(e^{x_m+\mu_{i-1}}-1)-\mu_i\right)\frac{e^{x_m+\mu_{i-1}}}{e^{x_m+\mu_{i-1}}-1}\}.$$

On the other hand, applying the Jacobian transform on $\left(\mathbb{D}_i - \mathbb{D}_i^{\mathrm{ctrl}}\right)$ is estimated numerically. That is, the estimation of $\mathbb{Z}_i$ mentioned in the third step of Algorithm 3 is improved as follows:

$$\mathbb{Z}_i = O_{\mathrm{J}}^{N}\left(\mathbb{D}_i - \mathbb{D}_i^{\mathrm{ctrl}}\right) + O_{\mathrm{J}}\left(f_{D_i}^{\mathrm{ctrl}}\right). \tag{39}$$

The numerical error incurred in Eq. (39) is less than the error incurred in Eq. (37) since the magnitude of the grid list $\mathbb{D}_i - \mathbb{D}_i^{\mathrm{ctrl}}$ would be less than the magnitude of $\mathbb{D}_i$ due to the premise that $f_{D_i}^{\mathrm{ctrl}}$ is close to $\mathbb{D}_i$.

Similarly, the numerical error incurred for estimating the grid list $\mathbb{D}_{i-1}$ mentioned in the fourth step of Algorithm 3 (or Eq. (38)) can also be suppressed by our general control variate method. We find an analytical function $f_{Z_i}^{\mathrm{ctrl}}$ that possesses the following two critical properties to play the role of a control variate for estimating $\mathbb{D}_{i-1}$: First, $f_{Z_i}^{\text{ctrl}}$ should closely approximate f_{Z_i}. Second, the convolution of f_{R_i} and $f_{Z_i}^{\text{ctrl}}$ (i.e, $O_C(f_{R_i}, f_{Z_i}^{\text{ctrl}})$) can be analytically solved to avoid the introduction of numerical errors. Let $\mathbb{Z}_i^{\text{ctrl}}$ denote the grid list $\{f_{Z_i}^{\text{ctrl}}(x_{-m}), f_{Z_i}^{\text{ctrl}}(x_{-m+1}), \cdots, f_{Z_i}^{\text{ctrl}}(x_m)\}$ for the density function $f_{Z_i}^{\text{ctrl}}$. To improve the accuracy for estimating $\mathbb{D}_{i-1}$, we first decompose $\mathbb{Z}_i$ into the following two parts: $\mathbb{Z}_i = \mathbb{Z}_i^{\text{ctrl}} + \left(\mathbb{Z}_i - \mathbb{Z}_i^{\text{ctrl}}\right)$. The linear property of the convolution operator entails that the convolution of $\mathbb{R}_i$ and $\mathbb{Z}_i$ evaluated in Eq. (38) can be decomposed into the convolution of $\mathbb{R}_i$ and $\mathbb{Z}_i - \mathbb{Z}_i^{\text{ctrl}}$ plus the convolution of $\mathbb{R}_i$ and $\mathbb{Z}_i^{\text{ctrl}}$. Note that the latter convolution can be analytically solved to avoid introducing extra numerical errors. Thus the accuracy of the fourth step of Algorithm 3 (or Eq. (38)) can be improved as follows:

$$\mathbb{D}_{i-1} = O_{\mathrm{C}}^{N}\left(\mathbb{R}_i, \mathbb{Z}_i - \mathbb{Z}_i^{\text{ctrl}}\right) + O_{\mathrm{C}}\left(f_{R_i}, f_{Z_i}^{\text{ctrl}}\right). \tag{40}$$

For simplicity, our following discussions and experiments are demonstrated by assuming that the underlying assets price process follows the geometric Brownian motion and that the control functions $f_{Z_i}^{\text{ctrl}}$ and $f_{D_i}^{\text{ctrl}}$ follow the normal distributions. To ensure that $f_{D_i}^{\text{ctrl}}$ and $f_{Z_i}^{\text{ctrl}}$ are close to f_{D_i} and f_{Z_i} respectively, the parameters of $f_{D_i}^{\text{ctrl}}$ and $f_{Z_i}^{\text{ctrl}}$ are calibrated by the moment matching method. Since the first few moments of D_i and Z_i are hard to be derived, we first derive the moments of e^{D_i} and e^{Z_i} instead. Note that e^{D_i} and e^{Z_i} can be expressed as

$$\begin{aligned} e^{D_i} &= e^{R_{i+1}}(1+e^{R_{i+2}}(1+e^{R_{i+3}}(\ldots e^{R_{n-2}}(1+e^{R_{n-1}}(1+e^{R_n})))))e^{-\mu_i}, \\ e^{Z_i} &= 1+e^{R_{i+1}}(1+e^{R_{i+2}}(1+e^{R_{i+3}}(\ldots e^{R_{n-2}}(1+e^{R_{n-1}}(1+e^{R_n})))))e^{-\mu_i}. \end{aligned}$$

The above formulas imply two recursive formulae: $e^{D_{i-1}} = e^{R_i}e^{Z_i}$ and $e^{Z_i} = 1 + e^{D_i}$. Since the random variables R_i and Z_i are independent due to the independent increment property of the Levy process (which is followed by the underlying asset price process), the first two moments of e^{D_i} and e^{Z_i} can be iteratively determined by alternatively applying the following three rules provided in Turnbull and Wakeman (1991): First, if the n^{th} moments (n=1 or 2) of two independent random variables U_1 and U_2 are equal to $m_1(n)$ and $m_2(n)$ respectively, then the n^{th} moment of U_1U_2 equals $m_1(n)m_2(n)$. Second, the first moment of $1+U_1$ is equal to $1+m_1(1)$. Third, the second moment of $1+U_1$ is equal to $1+2m_1(1)+m_2(2)$. Let a normal random variable D_i^{ctrl} follow the density function $f_{D_i}^{\text{ctrl}}$. The first two moments of D_i^{ctrl} can be solved by requiring the first two moments of $e^{D_i^{\text{ctrl}}}$ to match the first two moments of e^{D_i} as follows:

$$\begin{aligned} \mathrm{E}(e^{D_i}) &\equiv \mathrm{E}\left(e^{D_i^{\text{ctrl}}}\right) = e^{\mathrm{E}(D_i^{\text{ctrl}})+\mathrm{Var}(D_i^{\text{ctrl}})/2}, \\ \mathrm{Var}(e^{D_i}) &\equiv \mathrm{Var}(e^{D_i^{\text{ctrl}}}) = \left(e^{\mathrm{Var}(D_i^{\text{ctrl}})}-1\right)e^{2\mathrm{E}(D_i^{\text{ctrl}})+\mathrm{Var}(D_i^{\text{ctrl}})}, \end{aligned}$$

where $\mathrm{E}(U)$ and $\mathrm{Var}(U)$ denote the expected value and the variance of a random variable U, respectively. Therefore, the first two moments of $f_{D_i}^{\text{ctrl}}$ are solved to be

$$\begin{aligned} \mathrm{E}(D_i^{\text{ctrl}}) &= \ln \frac{\left(\mathrm{E}(e^{D_i})\right)^2}{\sqrt{\mathrm{Var}(e^{D_i}) + \left(\mathrm{E}(e^{D_i})\right)^2}}, \\ \mathrm{Var}(D_i^{\text{ctrl}}) &= \ln\left(1 + \frac{\mathrm{Var}(e^{D_i})}{\left(\mathrm{E}(e^{D_i})\right)^2}\right). \end{aligned}$$

Similarly, the first two moments of $f_{Z_i}^{\text{ctrl}}$ can also be determined by the same method as above.

The Asian call option value evaluated in the sixth step of Algorithm 3 (or Eq. (34)) by the numerical integration can also be improved by decomposing f_{D_0} into a normal density $f_{D_0}^{\text{ctrl}}$ plus a residual function $f_{D_0}^{\text{RESIDUAL}}$ as follows:

$$\begin{aligned} C^{\text{Asian}} &= e^{-rT} E\left[\left(\frac{S_{t_0}}{n+1}\left(1+e^{D_0+\mu_0}\right)-K\right)^+\right] \\ &= e^{-rT}\int_{-\infty}^{\infty}\left(\frac{S_{t_0}}{n+1}\left(1+e^{x+\mu_0}\right)-K\right)^+ f_{D_0}(x)dx \\ &= e^{-rT}\int_{-\infty}^{\infty}\left(\frac{S_{t_0}}{n+1}\left(1+e^{x+\mu_0}\right)-K\right)^+ \left(f_{D_0}^{\text{ctrl}}(x)+f_{D_0}^{\text{RESIDUAL}}(x)\right)dx \\ &\equiv C_{\text{ctrl}}^{\text{Asian}}+C_{\text{RESIDUAL}}^{\text{Asian}}, \end{aligned} \tag{41}$$

where $C_{\text{ctrl}}^{\text{Asian}}$ and $C_{\text{RESIDUAL}}^{\text{Asian}}$ denote the option values contributed by $f_{D_0}^{\text{ctrl}}$ and $f_{D_0}^{\text{RESIDUAL}}$, respectively. Since $f_{D_0}^{\text{ctrl}}(x)$ is a normal density function, $C_{\text{ctrl}}^{\text{Asian}}$ can be evaluated analytically by modifying Black and Scholes (1973) option pricing formula as follows:

$$C_{\text{ctrl}}^{\text{Asian}} = \frac{S_{t_0}e^{-rT+\mu_0+\mu_{D_0}+\frac{\sigma_{D_0}^2}{2}}}{(n+1)}\Phi\left(\frac{\mu_{D_0}+\sigma_{D_0}^2-\xi}{\sigma_{D_0}}\right)+\left(\frac{S_{t_0}}{n+1}-K\right)e^{-rT}\Phi\left(\frac{\mu_{D_0}-\xi}{\sigma_{D_0}}\right), \tag{42}$$

where $\Phi(\cdot)$ denotes the standard normal distribution function, and μ_{D_0} and $\sigma_{D_0}^2$ denote the first two moments of the density function $f_{D_0}^{\text{ctrl}}$, respectively. ξ denotes $\ln\left(K(n+1)/(S_{t_0})-1\right)-\mu_0$, which is the solution of $\frac{S_{t_0}}{n+1}\left(1+e^{x+\mu_0}\right)-K=0$. Since only $C_{\text{RESIDUAL}}^{\text{Asian}}$ needs to be evaluated numerically, numerical errors can be further suppressed. Note that Eq. (42) can be viewed as an application of our general control variate method as well. Our revised version for the Benhamou (2002) pricing method is summarized in Algorithm 4.

Algorithm 4 Applying the General Control Variate Method to Improve the Convolution-Based Pricing Algorithm

1: Evaluate the densities values in the list $\mathbb{D}_{n-1}$;
2: **for** $i = n-1$ **downto** 1 **do**
3: Decompose $\mathbb{D}_i$ into two parts: $\mathbb{D}_i = \mathbb{D}_i^{\text{ctrl}} + \left(\mathbb{D}_i - \mathbb{D}_i^{\text{ctrl}}\right)$;
4: Calculate $\mathbb{Z}_i$ by applying the Jacobian transformation to $\mathbb{D}_i - \mathbb{D}_i^{\text{ctrl}}$ and $f_{D_i}^{\text{ctrl}}$ respectively (see Eq. (39));
5: Decompose $\mathbb{Z}_i$ into two parts: $\mathbb{Z}_i = \mathbb{Z}_i^{\text{ctrl}} + \left(\mathbb{Z}_i - \mathbb{Z}_i^{\text{ctrl}}\right)$;
6: Calculate $\mathbb{D}_{i-1}$ by applying the numerical convolution on $\mathbb{Z}_i - \mathbb{Z}_i^{\text{ctrl}}$ and $\mathbb{R}_i$ and the analytical convolution on $f_{Z_i}^{\text{ctrl}}$ and f_{R_i} (see Eq. (40)).
7: **end for**
8: Evaluate the Asian option value C^{Asian} by Eqs. (41) and (42).

5.3 Numerical Results

We demonstrate how our general control variate method (plotted in solid curves) improve the accuracy and the efficiency of the convolution-based Asian option pricing method proposed by Benhamou (2002) (plotted in dashed curves) as illustrated in Fig. 6. Panel (a) denotes the relationship between the logarithm of the absolute pricing error and the grid spacing b/m. Note that the magnitude of the errors introduced by the numerical Jacobian transform and the numerical convolution would reduce with the decrement of the grid spacing. This can be confirmed by observing that the pricing errors decrease with the decrement of grid spacing. It can also be observed that our method does improve the accuracy since the pricing error produced by our method is much smaller than that produced by the Benhamou (2002) method given an

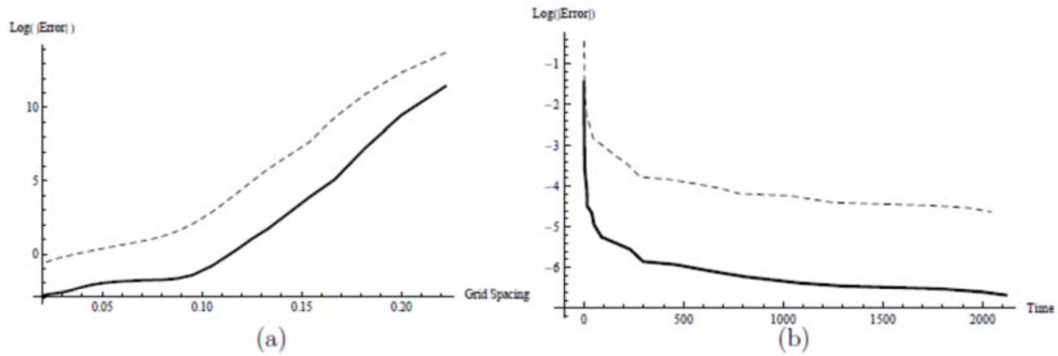

Figure 6: Convergence Comparisons for Pricing Asian Options.

The x-axes in panel (a) and (b) denote the grid spacing b/m and the computational time, respectively. The y-axes in both panels denote the logarithm of the absolute pricing errors. The dashed curves denote pricing errors generated by Benhamou (2002) method illustrated in Algorithm 3. The solid curves denote pricing errors generated by our improvement method illustrated in Algorithm 4. The initial underlying asset's price S_0 and the strike price K are 40, the volatility of the asset price is 0.3, the time to maturity T is 1 year, the risk-free rate r is 0.1, the window size is [-2,2], and the number of samples n (to evaluate the average price A) is 50.

arbitrary level of grid spacing. Note that the decrement of grid spacing would also increase the number of grid points and hence the computational time. In addition, our improvement method requires extra calculations and thus more computational time than the Benhamou (2002) method. To make the comparison fair, we compare the error convergence speeds in terms of computational time for both methods in panel (b). It can be observed that our method is more efficient since the computational time required by our method to achieve any certain precision level is lower than the time required by Benhamou (2002) method.

6 Conclusions

This paper extends the core idea of the control variate method, a popular variance reduction method used in Monte Carlo simulations, to reduce the errors for numerically evaluating linear operators, like the fast Fourier transform and the convolution. These numerical operators usually repeatedly occur in a numerical pricing method so we can drastically reduce the overall pricing error by reducing the error introduced by each operator. Specifically, we find a control function Y that is close to the function X inputted to the operator O and that $O(Y)$ can be analytically evaluated without introducing extra numerical errors. The overall numerical error is greatly suppressed since it is only contributed by numerically evaluating $O(X-Y)$– note that the residual function $X-Y$ is close to a zero function. We show that how our idea can be applied to tree methods, characteristic-function-based pricing methods, and convolution-based pricing methods. Numerical results verify the superiority of our approach.

This paper makes an attempt to estimate the corporate social responsibility (CSR) of a social enterprise in Singapore. Following the literature, we measure CSR based on a set of standard questions to gauge how the public values CSR according to these standard questions.

The social enterprise being studied is NTUC Fairprice. NTUC is Singapore's labour movement which is a macro-focused union that works well with the government to achieve growth with equity (see Yao and Chew (2014) for the theory of the macro-focused union). In this study, we also measure the CSR of Giant, another supermarket which is a commercial firm. A comparative analysis of the estimate of the CSR of these two firms is then made.

The main finding is that, based on a field survey, Singaporeans value the CSR of NTUC Fairprice more highly than that of Giant. Our regression analysis reveals that the CSR valuation of NTUC Fairprice is basically determined by how people perceive NTUC Fairprice in terms of their sentiments. On the other hand, the only variable that is statistically significant in explaining changes in the CSR valuation of Giant is Malay respondents.

The study also finds that, based on the second field survey, almost 85% of respondents chose to become members of NTUC because of non-collective bargaining benefits and only 10% joined the union because of sentiment.

The main conclusion is that union members are always supportive of the social effort of NTUC Fairprice and other cooperatives. The main policy implication is that NTUC is far-sighted in making non-collective bargaining benefits available to the general public provided that they become union members.

1. A Selective Literature Review

Corporate Social Responsibility (CSR) has gained much significance in recent years with the increasing awareness of the benefits that CSR brings forth. This section provides an insight into the workings of CSR.

Many different definitions for CSR have been applied in the existing literature, many of which revolve around Carroll‘s pyramid of CSR, which embraces four aspects - economic, legal, ethical and philanthropic - in defining social responsibilities (Carroll, 1991). The definition of CSR becomes more problematic when researchers seek to elucidate whether CSR is a commitment (WBCSD, 1999) or a voluntary investment (Benabout & Tirolet, 2009) made by firms. Since this paper studies CSR from an economic perspective, we define CSR as an investment in line with other studies such as Reinhardt & Stavins (2010). Moreover, in Singapore’s context, CSR is a hand-out as it is not mandatory for companies to engage in CSR.

Empirical research provides strong support for the linkage between CSR and financial performance (Orlitzky et al., 2003; Chong & Tan, 2010). Surveys carried out reveal that branding, value maximization, stakeholdership and profit maximization are the main reasons that motivate managers to engage in CSR (Kan, 2012). Raza et al. (2013) and Naqvi, Ishtiaq, Kanwal, Ali, & Inderyas (2013) show that CSR helps to create a positive image of the company.

In our study we distinguish between the benefits to private firms from engaging in CSR from the benefits to social enterprises. Private firms engage in socially responsible business practices, either in the form of discretionary activities or investments to support social causes in order to improve community well-being and protect the environment. These activities are expected to produce brand preference, build brand positioning, improve product quality, as well as build relationships with external partners and even decrease operating costs and improve employees’ productivity (Biovna, 2010). Leedy (2009) studies how non-profit firms help to address important social issues that contribute to negative externalities by engaging in CSR. This paper focuses on the marginal benefits (MB) attained in acts of CSR.

Investment in CSR is not without costs. The costs involved when engaging in CSR can be categorized into 3 main types – sunk cost, recurrent cost and opportunity cost,[1] according to a report done by the Sino-German Project (giz, 2012). Profits forgone (Carroll & Shabana, 2010), labour and capital maintenance are examples of such costs. Therefore, as with all economic goods, CSR is costly and hence must be justifiable. Hence this paper focuses on determining the marginal costs (MC) of engaging in CSR in a bid to find the optimal level of CSR.

Many studies have been made on the effectiveness of CSR on raising the profitability of companies to determine whether engaging in CSR can be justified. Methods employed include cost and benefit analysis (CBA) (Asatryan, 2013), qualitative evaluation (Aravossis, Panayiotou, & Tsousi, 2006), and linear additive model (Sweeney, 2009).

[1] Sunk costs would include investment in capital such as equipment and infrastructure, while recurrent costs would involve the maintenance of such equipment. The opportunity costs would then be the wealth invested or the labour hours involved in CSR when it could have been used to generate additional revenue for firms.

In quantifying CSR, Sweeney (2009) argues that CSR involves 4 dimensions – (A) Environment, (B) Customer, (C) Community and (D) Employees. CSR essentially implies good externalities enjoyed by the society at large. The public perception and evaluation of these four dimensions by the firm are therefore regarded as external benefits. Sweeney also argues that there are other benefits from engaging in CSR, specifically (i) employee attraction, motivation and retention, (ii) customer attraction and loyalty, (iii) reputation, and (iv) access to capital, which are accrue solely to the firms themselves. These benefits may be referred to as private benefits.

This paper aims to investigate the public perception and evaluation of external benefits and private benefits for NTUC FairPrice and Giant using the Sweeney model.

2. Methodology and Hypotheses

This paper uses Sweeney's model of estimating CSR on the basis of external benefits, private benefits and total benefits,which is the sum of external benefits and private benefits for NTUC FairPrice and Giant. To evaluate the performance of the respective supermarket's CSR, online surveys and face-to-face interviews were conducted from 20 January 2014 to 23 February 2014. The objective of the survey is to capture the subjective personal valuation of total benefits, external benefits, and private benefits for NTUC FairPrice and Giant. Respondents were requested to state whether they agree or disagree with a given statement regarding each organisation on a scale of 1 to 7, with a higher number indicating stronger agreement. (See Appendix A for the survey questionnaire. For a brief background on NTUC FairPrice and Giant, please visit the respective websites:

http://www.fairprice.com.sg/webapp/wcs/stores/servlet/StoreLocatorCmd?langId=1&storeId=90001&catalogId=10051&storesView=ContentView&Corporate=Y&strType=Cheers

http://www.dairyfarmgroup.com/companies/overview.htm)

The survey covers a random sample of 198 observations, with 128 females and 70 males (see Appendix B for the profile of the respondents), with the majority aged between 21 to 25 years. 162 of the respondents are Chinese, 62% are single, and 59% are professionals. 56% of the respondents attained tertiary education. The average household size is 4.2, with 94 respondents having household income of more than $5,000. The average weekly visits to supermarkets stands at 1.82, with FairPrice being the main choice of visit. 41% of the respondents are NTUC members. As NTUCFP is owned by NTUC, the average score for Sentiments towards NTUC is 4.5 among the respondents.

As NTUC FairPrice is a social enterprise and is a co-operative of the labour movement in Singapore, and Giant is a private enterprise, the following hypotheses are proposed:

Hypothesis 1: FairPrice's CSR on the account of total benefits is greater than Giant's CSR.

Hypothesis 2: NTUC FairPrice's external benefits is greater than Giant's external benefits.

Hypothesis 3: NTUC FairPrice's private benefits is smaller than Giant's private benefits.

The total benefits, external benefits and private benefits for NTUC Fairprice and Giant are given in Table 1. Not surprisingly, the total benefits and external benefits are higher for

NTUC Fairprice than for Giant. But it can also be seen that the private benefits for NTUC FairPrice are also higher than for Giant. This goes to show that it pays to be perceived to perform a public good.

Table 1: FairPrice and Giant Performance

	FairPrice (F)	Giant (G)
Total Benefit (TB/CSR)	4.4	4.2
External Benefit (EB)	4.5	4.3
Private Benefit (PB)	4.3	4.2

3. Regression model

The model of regressions is as follow:

$$y = \beta_0 + \beta_1 Gender + \beta_2 Age + \beta_3 Race + \beta_4 Marital + \beta_5 Education + \beta_6 Professionals + \beta_7 Income + \beta_8 Household\ Size + \beta_9 Frequency + \beta_{10} Member + \beta_{11} Choice + \beta_{12} Sentiments$$

Where	Y	=	Total Benefit (NTUC/Giant) or External Benefit (NTUC/Giant) or Private Benefit (NTUC/Giant)
	Gender	=	Dummy variable of gender, with 0=female and 1=male
	Age	=	Age (in years) of respondents
	Race	=	Race, further segregated to 3 dummy variables to represent the three majority races in Singapore – Chinese, Indian, Malay.
	Marital	=	Dummy variable of marital status, with 0=married and 1=single/divorced/widowed
	Education	=	Education level of respondents
	Profession	=	Dummy variable of profession, with 0=non-professionals and 1=professionals
	Income	=	Household income (in dollars) of respondents
	Household size	=	Household size (number of people) of respondents
	Frequency of visit	=	Number of weekly visits to supermarkets
	Member	=	Dummy variable of NTUC membership, with 0=non-member and 1=member
	Choice	=	Dummy variable of frequent choice of supermarket, with 0=Giant and1=NTUC FairPrice
	Sentiments	=	Sentiments for NTUC as a union on a scale of 1-7, with 1being Strongly Negative and 7 being Strongly Positive
	β_0	=	Constant term
	β_1	=	Coefficient of Gender
	β_2	=	Coefficient of Age
	β_3	=	Coefficient of Race
	β_4	=	Coefficient of Marital
	β_5	=	Coefficient of Education
	β_6	=	Coefficient of Profession
	β_7	=	Coefficient of Income
	β_8	=	Coefficient of Household size
	β_9	=	Coefficient of Frequency of visit
	β_{10}	=	Coefficient of NTUC member

β_{11}	=	Coefficient of Choice of supermarket
β_{12}	=	Coefficient of Sentiments for NTUC Union, for NTUC FairPrice analysis only

3.1. *Stage I Analysis*

To test for significance, a regression analysis is done on all three components – CSR/TB, PB and EB. The results are given in Tables 2-5. Table 2 shows that, for NTUCFP, all variables are insignificant except sentiments. In other words, respondents who score high in terms of sentiments also give higher score for total benefits for NTUCFP. All variables for Giant are insignificant except the variable Malay respondents. This shows that respondents who are Malay give a high score for total benefits for Giant.

Table 2: Total Benefit (TB) as the Independent Variable

TB = f(Independent variables)

Dependent Variable	**(1)** **NTUCFP_TB**	**(2)** **Giant_TB**
gender_male	-0.0547 (0.628)	-0.0876 (0.44)

Sentiments	0.241** (0)	-
N	198	198
adj R^2	0.146	0.131

Table 3 shows that all variables for NTUCFP are insignificant except sentiments. In other words, respondents who score high in terms of sentiments also give a higher score for external benefits for NTUCFP. All variables for Giant are insignificant except the variable Malay respondents. This shows that respondents who are Malay give a high score for total benefits for Giant.

Table 3: External Benefit as the Independent Variable for NTUCFP and Giant

EB = f (Independent variables)

Dependent Variable	(1) NTUCFP_EB	(2) Giant_EB
gender_male	-0.0406 (0.681)	-0.0738 (0.462)
Age	-0.0525 (0.136)	-0.0387 (0.28)

Sentiments	0.221** (0.001)	-
N	198	198
adj R^2	0.0801	0.0469

Hence for NTUCFP, sentiments is a variable consistently able to explain TB, EB and PB of NTUCFP. This positive ideology towards NTUC would generate a host of benefits for FairPrice as well. Firstly, if consumers generally feel better towards the corporation, they are more likely to be biased. Secondly, consumers are more likely to feel that the supermarket has done more than what is required or has met its objective. Thirdly, the services offered by the supermarket will be better appreciated by consumers as opposed to the same services offered by other supermarkets. All this adds up to imply that good sentiments may lead to an increase in patronage of the supermarket. Subsequently, we will examine the determinants of sentiments towards NTUC.

In the case of Giant, the dummy variable for Malay respondents has been consistently significant in the equations of TB, EB and PB of Giant. Hence, we conducted another survey to ascertain the views of Malay residents regarding the choice of Giant as a supermarket (the profile of the Malay respondents is given in Annex C). As Table 5 shows, on a scale of 1 to 7, the statement that prices at Giant are lower registers a value of 5.31, followed by Giant as a familiar brand among Malay population receiving a value of 5.28. Our findings imply that Giant has been very successful in building a brand loyalty among the Malay residents in Singapore.

Table 5: Reasons for choosing Giant over other supermarkets

Giant has a wider variety of goods	4.72/7.00
Prices of goods in Giant are lower	5.31/7.00
Giant is located near my house	4.83/7.00
Giant is a familiar barnd among the Malay community as Giant is a key sponsor for social events such as concerts for the Malay community	5.28/7.00

Note: 1 = Very Strongly Disagree, 5 = Neither Agree nor Disagree, 7 = Very Strongly Agree

3.2. *Stage II Analysis*

Conceptualising sentiments towards NTUC

The earlier sections reveal a key observation regarding FairPrice and its affiliation to NTUC, as well as how sentiments towards the latter can play a critical role in CSR benefits, alongside both PB and EB. Therefore, this section investigates the factors affecting consumers' sentiments. As seen in the regression results presented below, at the 5% significance level, all variables are insignificant except NTUC Membership and the Choice of visit, as given in Table 6.

The regression model is as follow:

$$y = \beta_0 + \beta_1 Gender + \beta_2 Age + \beta_3 Race + \beta_4 Marital + \beta_5 Education + \beta_6 Professionals + \beta_7 Income + \beta_8 Household\ Size + \beta_9 Frequency + \beta_{10} Member + \beta_{11} Choice$$

where Y = Sentiments towards NTUC.

Table 6 shows that NTUC union membership is the only significant variable in the Sentiments equation. It shows that an increase in choice of visit by 1 would lead to an increase in sentiments by only 0.671.

One of the reasons for consumers' positive attitude towards FairPrice can be understood by the higher level of CSR engaged in by the supermarket, proven by the findings above. This is also consistent with the expected norm as with increased visits to the same supermarket, the consumer is better able to be aware of their CSR activities and services offered. Therefore, this can be translated into a better understanding of the good intention of the supermarket, generating positive feelings towards FairPrice and hence in turn, NTUC.

Table 6: The Sentiments Equation

Dependent Variable	(1) sentiments
gender_male	-0.15826 (0.384)
Age	0.002354 (0.971)
race_Chinese	0.755016 (0.212)
race_Malay	1.045583 (0.117)
race_Indian	0.501306 (0.499)
maritalstatus_Single	0.075762 (0.781)
edu_lvl	-0.08089 (0.582)
occupation_professional	0.346851 (0.093)
income_lvl	-0.11706 (0.051)
household_size	-0.08698 (0.244)
Frequency	0.092097 (0.164)
ntuc_member	0.399247** (0.035)
choice_visit	0.671191** (0.004)
N	198
adj R^2	0.0715

Similarly, there exists a positive relationship between sentiments and NTUC membership, where the latter would offer member consumers exclusive privileges that may increase the good feeling consumers have towards the supermarket. This indirect link between sentiments and membership can be proven through the findings attained from a pilot test[2] conducted, which aims at establishing the rationale for joining NTUC. Out of the 50

NTUC members surveyed, 84% of the respondents joined NTUC because of the benefits offered by being a union member rather than because of sentiments.

Therefore, the empirical results and analysis presented in this section prove a crucial finding – Sentiments are affected by NTUC membership, where the latter is in turn affected by NTUC benefits only.

[2] Refer to Annex D for thesurvey questionnaire and findings of NTUC members.

4. Conclusion

This paper studies the benefits arising from CSR activities engaged by supermarkets in Singapore as perceived by their customers. The private benefits arising from engaging in CSR activities are different for a social enterprise compared to a private firm, and our findings reveal that the private benefits for FairPrice are higher than that for Giant. Given the assumption that both FairPrice and Giant engage in the same CSR level, our study indicates that FairPrice as a social enterprise has achieve higher private benefits than Giant from its CSR activities. Our results imply that is a good strategy to be perceived to be a social enterprise.

Annex A: Survey Questionnaire

SECTION 1 – RESPONDENT'S PROFILE

(Please ✔ where appropriate)

1.1. What is your gender?

☐ Male ☐ Female

1.2. What is your age?

☐ 21-25 years old ☐ 26-30 years old ☐ 31-35 years old ☐ 36-40 years old
☐ 41-45 years old ☐ 46-50 years old ☐ 51-55 years old ☐ 56-60 years old
☐ 61-65 years old ☐ >65 years old

1.3. What is your race?

☐ Chinese ☐ Malay ☐ Indian ☐ Eurasian ☐ Others, please specify: ________

1.4. Marital status

☐ Single ☐ Married ☐ Divorced ☐ Widowed

1.5. What is your highest attained education level?

☐ 'O' Level & below ☐ 'A' Level/Diploma/IB ☐ Degree ☐ Masters & above

1.6. Which category best classifies your occupation?

☐ Legislators, Senior Officials & Managers
☐ Associate Professionals & Technicians
☐ Agricultural & Fishery Workers
☐ Service & Sales Workers
☐ Plant and Machine Operators & Assemblers
☐ Others
☐ Professionals
☐ Clerical Support Workers
☐ Student
☐ Craftsmen & Related Trades Workers
☐ Cleaners, Laborers & Related Workers
☐ Not working

1.7. How many people are there in your household?

____

1.8. What is your monthly household income level?

☐ \$0 - \$1000 ☐ \$1001 - \$2000 ☐ \$2001 - \$3000
☐ \$3001 - \$4000 ☐ \$4001 - \$5000 ☐ \$5001 & above

1.9. How many times do you visit a supermarket in 1 week?

☐ 0 ☐ 1 ☐ 2 ☐ 3 ☐ 4 ☐ 5 ☐ >5

1.10. Are you currently a NTUC member?

☐ Yes ☐ No

1.11. Please rank the supermarkets according to the frequency you visit:

Supermarket	Rank (1=most frequent)
FairPrice Supermarket	
Giant Supermarket	

Page 1

SECTION 2

Scale: 1 = Very Strongly Disagree; 7 = Very Strongly Agree (Please ✔ where appropriate)	FairPrice Supermarket								Giant Supermarket						
	1	2	3	4	5	6	7		1	2	3	4	5	6	7
Section 2.1: Responsible Retailing															
To what extent has the respective supermarket met the objective of:															
1. Promoting a healthy lifestyle of consumers through providing quality products															
2. Taking into account consumers' feedback and act on it promptly															
3. Placing customers concerns and satisfaction above its goal of profit making															
4. Ensuring consistency in its pricing policies (i.e. same price across outlets)															
5. Ensuring that the prices of products are reasonably priced and value-for-money															
Section 2.2: Community Care															
To what extent has the respective supermarket met the objective of:															
1. Creating more employment opportunities for the public															
2. Initiating new and/or support existing training opportunities															
3. Promoting the setting up of local businesses (e.g. by assisting investment programmes)															
4. Being involved in voluntary activities that would benefit society (e.g. distributing daily necessities to the low-privileged/low income groups)															
5. Prioritizing societal issues above profit maximising goals															
Section 2.3: Sustainable Environment															
To what extent has the respective supermarket met the objective of:															
1. Reducing environmental impacts of its business operations (e.g. adopting green technology)															
2. Implementing new green initiatives (e.g. set up eco-friendly outlets)															
3. Actively participating and/or encouraging the public to take part in environmentally – friendly activities (e.g. campaigns and products)															
4. Constantly monitoring and regulating environmental impacts from operations (e.g. set target on waste reduction)															
5. Prioritizing environmental considerations before its profit maximising goal.															
Section 2.4: Workplace															
To what extent has the respective supermarket met the objective of:															
1. Providing a nurturing and safe workplace environment to attract and retain employees.															
2. Minimizing conflicts at work and promote staff bonding (e.g. staff retreat).															
3. Paying employees according to industry standards.															
4. Ensuring welfare of employees (in terms of training, work life balance, flexible employment).															
5. Providing ample equal opportunities to all employees regardless of gender and race.															

Scale: 1 = Very Strongly Disagree; 7 = Very Strongly Agree (Please ✓ where appropriate)	FairPrice Supermarket								Giant Supermarket						
	1	2	3	4	5	6	7		1	2	3	4	5	6	7
Section 2.5: Contribution															
1. I am willing to donate money to the supermarket if they are CSR friendly.															
2. I am willing to donate in-kind (e.g. non-monetary donations) for the respective supermarket if they are CSR friendly.															
3. The respective supermarket should pay fully for their CSR activities.															

SECTION 3

Scale: 1 = Very Strongly Disagree; 7 = Very Strongly Agree (Please ✓ where appropriate)	FairPrice Supermarket								Giant Supermarket						
	1	2	3	4	5	6	7		1	2	3	4	5	6	7
Section 3.1: Customer Attraction & Retention															
1. I will choose to purchase an item from the respective supermarket because it engages in CSR (i.e. more contribution to the community and providing adequate rewards to its employees).															
2. I will encourage my friends to shop at the supermarket which engages in CSR.															
3. I will buy from this supermarket that provides CSR to the society (even at a higher price), even if another supermarket offers a lower price.															
4. I am willing to volunteer my services to the supermarket because it engages in CSR (e.g. willing to help out in the supermarket without receiving a salary)															

SECTION 4

Scale: 1 = Strongly Negative; 7 = Strongly Positive (Please ✓ where appropriate)	1	2	3	4	5	6	7
1. What are your sentiments towards NTUC (as a union)?							

Annex B: General Profile of Respondents of the Main Survey

1. *Gender*

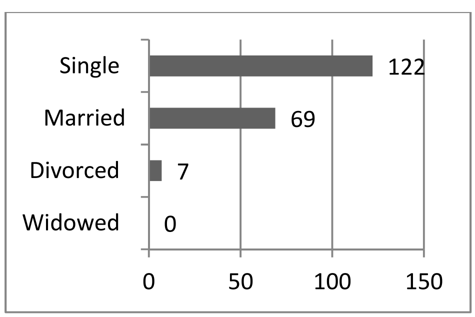
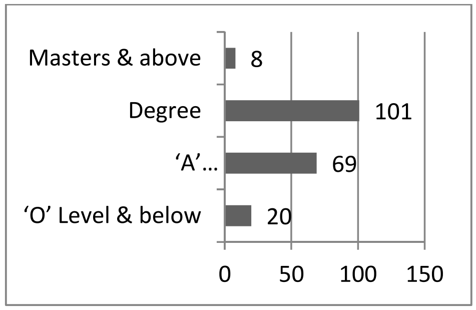
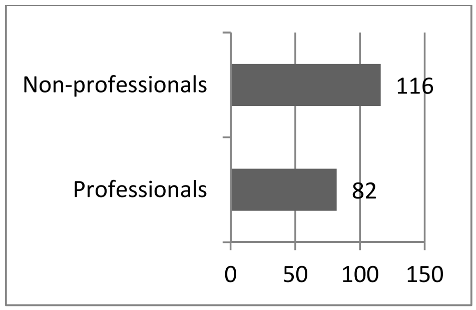
4. *Marital Status*



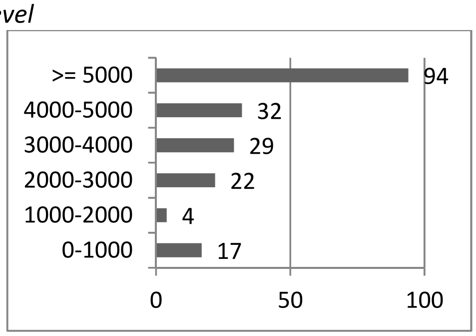
5. *Education Level*



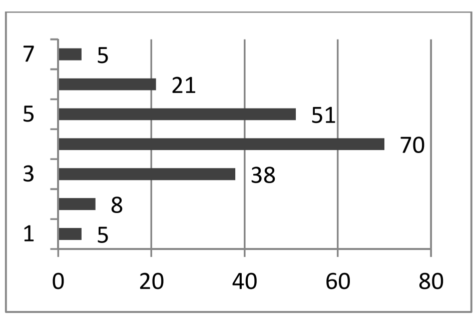
6. *Occupation*



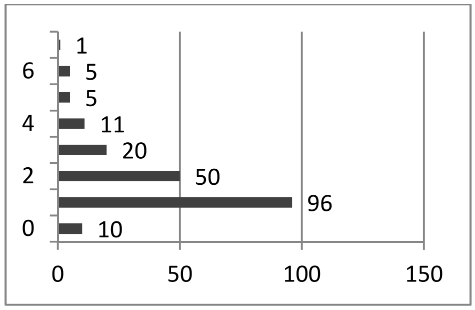
7. *Household Income Level*



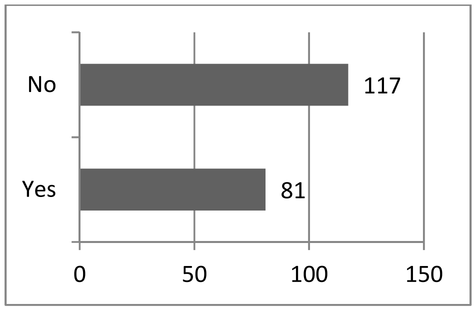
8. *Household Size*



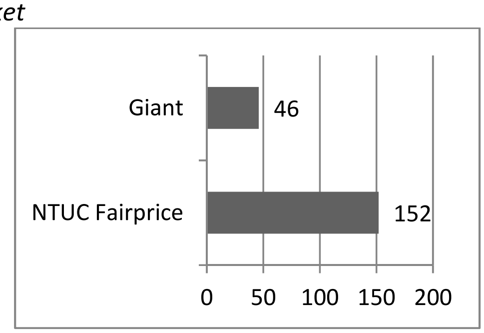
9. *Number of visits to supermarket per week*



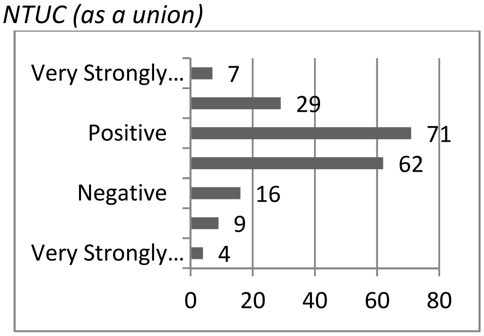
10. NTUC Member



11. Choice of supermarket



12. Sentiments towards NTUC (as a union)



Annex C: Survey Questionnaire for Giant

This pilot survey was conducted from 1 May 2014 to 19 May 2014. The purpose of the survey was to establish the primary reason of Malays choosing Giant as the choice of supermarket. A total of 47 respondents were surveyed but only responses of 36 were taken into consideration because 11 respondents did not choose Giant as the choice of visit.

Questions

(Please ✔ where appropriate)

1.1. Is Giant supermarket the most frequent choice of supermarket?

☐ Yes ☐ No

1.2. Marital status

☐ Single ☐ Married ☐ Divorced ☐ Widowed

1.3. What is your household income level?

☐ $0 - $1000 ☐ $1001 - $2000 ☐ $2001 - $3000 ☐ $1001 - $2000
☐ $3001 - $4000 ☐ $4001 - $5000 ☐ $4001 - $5000 ☐ $5001 & above

1.4. Please rate (from 1 to 7) the following reasons for choosing Giant supermarket over other supermarkets (e.g. FairPrice, Sheng Siong)?

Scale: 1 = Very Strongly Disagree; 7 = Very Strongly Agree (Please ✔ where appropriate)	1	2	3	4	5	6	7
I choose Giant supermarket because:							
1. Giant has a wider variety of goods							
2. Prices of goods in Giant is lower							
3. Giant is located near my house							
4. Giant is a familiar brand among the Malay community as Giant is a key sponsor for social events such as concerts for the Malay community							
5. Other reasons, pls specify: ______________________							

Results of pilot survey

1.1 Is Giant supermarket the most frequent choice of supermarket?

Yes	36	100%
No	0	0%

1.2 What is your marital status?

Single	9	25%
Married	24	67%
Divorced	1	3%
Widowed	2	6%

1.3 What is your household income level?

$0 - 1000	0	0%
$1001 - $2000	6	17%
$20001 - $3000	7	19%
$3001 - $4000	4	11%
$4001 - $5000	15	42%
$5001 & above	4	11%

1.4. Please rate the following reasons for choosing Giant supermarket over other supermarkets (e.g. FairPrice, Sheng Siong)

	Very Strongly Disagree	Strongly Disagree	Disagree	Neither Agree nor Disagree	Agree	Strongly Agree	Very Strongly Agree	Mean
Giant has a wider variety of goods	1	1	5	6	14	5	4	4.72

Annex D: Survey Questionnaire for NTUC members

This pilot survey was conducted from 12 March 2014 to 23 March 2014. The purpose of the survey was to establish the primary reason for being a NTUC member. A total of 54 respondents were surveyed but only responses of 50 NTUC members were taken into consideration because 4 respondents were non-NTUC members.

Questions

(Please ✔ where appropriate)

1.1. Are you currently a NTUC member?

☐ Yes ☐ No

1.2. Marital status

☐ Single ☐ Married ☐ Divorced ☐ Widowed

1.3. How many people are there in your household?

____

1.4. What is the primary reason for being an NTUC member?

☐ I feel good towards NTUC

☐ I want to enjoy the benefits of being a member (e.g. discounts, LINKPoints)

☐ Other reasons, please specify: ________________________________

Results of pilot survey

1.1 Are you currently a NTUC member?

Yes	50	100%
No	0	0%

1.2 What is your marital status?

Single	16	32%
Married	33	66%
Divorced	0	0%
Widowed	1	2%

1.3 How many people are there in your household?

	Min Value	Max Value	Average Value	Standard Deviation	Responses
Household size	2.00	8.00	4.60	1.34	50

1.4 What is the primary reason for being a NTUC member?

I feel good towards NTUC.	5	10%
I want to enjoy the benefits of being a member (e.g. discounts, LINKPoints).	43	86%
Others	2	4%

□ □ □ □ □ □ Are Multiple Directorships Beneficial in East Asia?

We posit that the benefits and costs of multiple directorships are conditional on firm characteristics. We find firm valuation is positively associated with multiple directorships in (i) firms with high advising needs and (ii) firms with high external financing needs. These beneficial effects of multiple directorships are generally stronger in countries with weak shareholder rights and in firms that are widely-held. However, when controlling shareholder hold high voting-rights to cash-flow rights, multiple directorships reduce firm valuation, especially in countries with weak shareholder rights and in closely-held firms. As multiple directorships increases, cash holdings (capital expenditures) contribute less to shareholder value. The negative association between value of cash (capital expenditure) and busy boards is mitigated in firms with (i) high advising needs, (ii) high external financing needs, and (iii) less entrenched ownership structures.

Keywords: Multiple directorships; Ownership structure; Firm performance.

JEL classifications: G30, G32, G34

1. Introduction

Prior studies suggest two competing hypotheses on the association between firm performance and multiple directorships held by outside directors. According to the reputation hypothesis, the market for outside directorships provides incentives for outside directors to develop a reputation as monitoring specialists (Fama and Jensen (1983)). Thus, firm performance is positively associated with external directorships held by outside directors because directors with more outside board seats are likely to be more experienced, provide better advice, and offer better monitoring. Consistent with the reputation hypothesis, prior studies find that the number of outside directorships is related to firm performance for financially distressed firms (Gilson (1990)), for firms that cut dividends (Kaplan and Reishus (1990)), and for firms that opt out of stringent anti-takeover provisions (Coles and Hoi (2003)).

On the other hand, the busyness hypothesis posits that as the number of outside directors sitting on multiple board increases, the directors are likely to be over-stretched. Hence, the busyness hypothesis predicts firm performance is negatively associated with external directorships held by outside directors because of diminished board oversight. Consistent with the busyness hypothesis, prior studies find that firms with busy boards exhibit lower firm valuation ((Fich and Shivdasani (2006)) and lower announcement period abnormal returns in corporate acquisitions (Ahn, Jiraporn and Kim (2010)).

In summary, prior studies provide mixed evidence on the association between multiple external directorships and firm performance. A possible reason for this mixed evidence is that different firms have different optimal board structures (Adams, Hermalin and Weisbach (2010)). Recent governance literature emphasizes the importance of firm characteristics in the design of optimal board structures (Boone, Field, Karpoff and Raheja (2007), Coles, Daniel and Naveen (2008) and Linck, Netter and Yang (2008)). Thus, a one-size fits all recommendation for board structure is not appropriate for all firms because a uniform board structure does not explicitly consider the heterogeneity in firm characteristics. In this study, we posit that the benefits and costs of multiple directorships are conditional on firm characteristics. Our objectives are twofold. First, we examine how the association between multiple directorships and firm performance vary systematically with firm characteristics. This investigation helps to shed light on the conditions under which the benefits of multiple directorships outweigh the costs of having busy directors or vice-versa. Second, we examine specific channels through which multiple directorships affect firm performance.

We examine our research questions on multiple board appointments with a large sample of listed firms in East Asia. We focus on East Asia for several reasons. First, in a survey of the literature on the board of directors, Adams, Hermalin and Weisbach (2010, page 101) find that "the vast majority of the literature focuses on United States firms and comparisons of boards across countries outside United States is, in contrast, an under-explored". Our examination on the board structure in East Asia attempts to fill this void. Second, in emerging economies such as East Asia, higher information asymmetry allows managers and large shareholders to expropriate corporate resources for their personal benefits. These opportunities for expropriation are exacerbated when the legal protection is weak; when enforcement of contracts is poor; and when shareholders have weaker rights (LaPorta, Lopez and Shleifer (1999), Claessens, Djankov, Fan and Lang (2002) and Lee, Lee and Yeo

(2009)). Third, the prevalence of multiple directorships in East Asia is much higher compared to United States. For example, in United States, the percentage of busy outside directors[1] is 21% ((Fich and Shivdasani (2006)) whereas in our sample of East Asia countries, the percentage of busy outside directors is 43%.

In this study, we posit three firm characteristics that affect the association between external board appointments held by outside directors and firm performance: (i) firm's advising needs, (ii) firm's external financing needs, and (iii) corporate ownership structure. Coles, Daniel and Naveen (2008) argue that complex firms such as those that are diversified, those that are large and those with large intangible assets, have greater advising requirements. Prior studies suggest outside directors can provide good advice and expertise to the firm. Hermalin and Weisbach (1988) argue that firms can choose "an outside director who will give good advice and counsel, who can bring valuable experience and expertise to the board.'' Agarwal and Knoeber (2001) find that the proportion of outside directors with political expertise on the board is positively related to firms' need for political advice. Building on these arguments, if outside directors who hold multiple external board seats bring more experience and knowledge and offer better advice, complex firms with high advising requirements can benefit from having such directors. Thus, our first hypothesis is that in firms with high advising needs, firm performance is positively associated with outside directors' external board appointments.

Prior studies find that firms that have stronger external financing needs have stronger corporate governance structures (Durnev and Kim (2005), Fan and Wong (2005), Dahya, Dimitrov and McConnell (2008)). Durnev and Kim (2005) find that corporate governance and disclosure practices are positively associated with the firms' external financing needs, especially in countries with weak investor protection. Fan and Wong (2005) find that firms that frequently raise equity capital are more likely to appoint high-quality auditors. Dahya, Dimitrov and McConnell (2008) find a positive association between the proportion of the board composed of directors not affiliated with the dominant shareholder and the likelihood of the firm issuing equity. Building on these studies, we predict that firms with high external financing needs are likely to benefit from having directors with multiple external board seats. The rationale is as follows. Firms with higher external financing needs are subjected to more scrutiny by capital market participants. Thus, in such firms, there is heightened awareness in outside directors that their reputation is sensitive to the intense monitoring by capital market participants (Fama and Jensen (1983)). Hence, in firms with high external financing needs, outside directors who fail to monitor are more likely to lose their external board seats due to personal reputational losses in the managerial labour market. Thus, our second hypothesis predicts that in firms with high external financing needs, firm performance is positively associated with outside directors' external board appointments.

In East Asia, corporate ownership is concentrated and many firms are controlled by a large dominant shareholder. Prior studies find that firm valuation is negatively associated with the separation of control rights and cash flow rights of the controlling shareholder (LaPorta et al (1998), Claessens et al (2002) and Lins (2003)). Multiple board appointments

[1] Following prior studies (Ferris et, al (2003) and Fich and Shivdasani (2006)), we classify a director as busy if he holds three or more directorships.

by outside directors can be beneficial or detrimental in firms with high separation of control rights and cash flow rights of the controlling shareholder. On one hand, if outside directors with multiple board seats play an effective corporate governance role, then the negative association between firm performance and the separation of control rights and cash flow rights of the controlling shareholders will be reduced by the proportion of outside directors with multiple board appointments. On the other hand, the directors' busyness hypothesis suggests that lower monitoring by busy outside directors increases the potential expropriation of minority shareholders by the controlling shareholders. Thus, our third hypothesis predicts that if busy directors are ineffective (effective) monitors, the negative association between firm performance and the wedge between the control rights and cash flow rights in the controlling shareholder will be more (less) pronounced in firms with higher proportion of outside directors with multiple board appointments.

In our first set of tests, we examine the association between firm performance and outside directors' external directorships. Using a sample of listed firms in East Asia, we find that firms in which outside directors hold multiple directorships have lower firm valuation. Our result suggests that for the average firm in our sample, the directors' busyness hypothesis dominates the reputation hypothesis.

More importantly, we find that the association between multiple directorships and firm valuation is conditional on firm characteristics. First, we find that in firms with high advising needs, firm valuation is positively associated with the proportion of outside directors with multiple external directorships. This result suggests that in firms with high advising needs, there is a net benefit from having directors with multiple external board seats who can provide more experience, advice and expertise to the firms. Second, we find that in firms with high external financing needs, firm valuation is positively associated with outside directors' external board appointments. The intuition is that as firms with high external financing needs are subjected to disciplinary forces when they return to the capital market, outside directors who fail to monitor are more likely to lose their external board seats due to reputational losses. Third, we document that in firms in which the controlling shareholder holds disproportionately high voting rights relative to cash flow rights, the negative association between firm valuation and multiple directorships is more pronounced.

Additional analysis indicates that our results vary systematically with the governance and institutional features of the East Asian countries. First, in developing countries and in countries with weak shareholder rights, we find that the negative association between busy boards and firm value is more pronounced in firms with high separation of control rights and cash flow rights. Thus, in countries with weak investor protection, poor monitoring associated with busy boards combined with agency problems associated with concentrated ownership structure, results in further declines in firm value. Second, in developed countries and countries with strong shareholder rights, the beneficial effect of multiple directorships is more positive in firms with high external financing needs. We conjecture the strong country-level governance institutions improve the effectiveness of board monitoring in firms that frequently raise external finance. Third, we find that combination of high percentage of busy outside directors and high separation of voting rights and cash flow rights in the controlling shareholder increase agency problems in closely held firms relative to widely-held firms.

Fourth, we provide some evidence that the beneficial effect of multiple board appointments in firms with high advising needs is stronger in widely held firms.

In our second set of tests, we examine two possible channels through which busy boards affect firm performance. First, we find that as multiple directorships increases, corporate cash holdings are worth less to outside shareholders. We find that the negative association between the marginal value of cash and busy boards is mitigated in firms with (i) higher advising needs, (ii) higher external financing needs, and (iii) lower separation of voting rights and cash flow rights of the controlling shareholder. Additional analysis suggests that these results are generally stronger in countries with stronger shareholder rights, developed countries and in widely-held firms. Second, in firms with busy boards, corporate capital expenditures contribute more to shareholder value in firms with (i) higher advising needs, (ii) higher external financing needs, and (iii) lower separation of voting rights and cash flow rights of the controlling shareholder. Moreover, these results are more pronounced in countries with stronger shareholder rights, developed countries and in widely-held firms.

Our results contribute to the literature of board structure in at least two ways. First, we contribute to the literature on multiple directorships (Ferris et al (2003), Fich and Shivdasani (2006)) by providing evidence that the association between firm performance and busy boards is conditional on firm characteristics. We shed light on the conditions under which the benefits of multiple directorships outweigh the costs of having busy directors. Our result on the positive association between multiple directorships and firm performance for complex firms with high advising needs is new. Similarly, our finding of the positive association between multiple directorships and firm performance in firms with high external financing needs is novel. Our results cast doubt on the suggestion that busy boards are detrimental for all firms. More broadly, our results add to the recent governance literature that underscores the importance of taking into account the heterogeneity in firm characteristics in the design of optimal board structures (Boone, Field, Karpoff and Raheja (2007), Coles, Daniel and Naveen (2008) and Linck, Netter and Yang (2008)).

Second, we shed light on two channels through which busy boards reduce firm valuation by providing evidence that as multiple directorships increases, corporate cash holdings are worth less to outside shareholders, and capital expenditures contribute less to shareholder value. Our results highlight the contextual nature of the association between multiple directorships and the valuation of cash holdings (capital expenditure) that varies systematically with firm characteristics, country-level shareholder rights and corporate ownership structure.

The rest of the paper is organized as follows. Section 2 describes the sample and method. Section 3 presents our results on the association between multiple directorships and firm performance conditional on firm characteristics. Section 4 presents evidence on the specific channels through which multiple directorships affect firm performance. Section 5 concludes.

2. Sample and Method

2.1. *Sample*

We begin with the Worldscope database to identify listed firms in six East Asian countries comprising Hong Kong, Indonesia, Malaysia, Philippines, Singapore and Thailand and during the period 2001 to 2007. We exclude financial institutions because of their unique financial structure and regulatory requirements. We eliminate observations with extreme values of control variables such as sales growth and firm size. We obtain the annual reports from the Global Report database and company websites. Our final sample consists of 1,482 firms for 6,536 firm-year observations during the period 2001 to 2007 in six East Asian countries (Hong Kong, Indonesia, Malaysia, Philippines, Singapore and Thailand). We collect data on the board characteristics and corporate ownership from the annual report.

2.2. *Code of Corporate Governance*

An important issue is how the corporate governance rules differ across the different countries because these rules may contain guidance on the level of outside (non-executive) directors and the incidence of multiple directorships. We briefly review the Code of Corporate Governance of each country in our sample to better understand the effect of country-specific corporate governance rules on our results, in particular the guidelines on the composition of the level of outside (non-executive) directors and the incidence of multiple directorships.

The Malaysian Code Corporate Governance, the Code of Corporate Governance in Singapore, Hong Kong Code on Corporate Governance Practices and the Principles of Good Corporate Governance For Listed Companies in Thailand recommend that there should be a strong and independent element on the Board, with independent directors making up at least one-third of the Board. The Code of Corporate Governance in these countries typically define an "independent" director as one who has no relationship with the company, its related companies or its officers that could interfere, or be reasonably perceived to interfere, with the exercise of the director's independent business judgment. The Philippines Code Corporate Governance recommends that Public Companies shall have at least two independent directors or such independent directors shall constitute at least twenty percent of the members of such Board, whichever is the lesser. In contrast, the Indonesia Code Corporate Governance recommends that there should be ample board independence without stipulating the minimum number of independent directors or the proportion of board independence.

Under the stock exchange listing rules for the countries in our sample, public companies describe in the annual reports their corporate governance practices with specific reference to the principles of the Code Corporate Governance, as well as disclose and explain any deviation from any guideline of the Code. Companies are also encouraged to make a positive confirmation at the start of the corporate governance section of the annual report that they have adhered to the principles and guidelines of the Code, or specify areas of non-compliance.

In terms on multiple directorships, the code of corporate governance in Hong Kong, Indonesia, Malaysia, Singapore, Philippines and Thailand do not explicitly provide a maximum cap on the number of external board seats per director. The common theme in the code of corporate governance in these countries is that when a director has multiple board representations, he must ensure that sufficient time and attention is given to the affairs of each company. In other words, although the codes of corporate governance in these countries do not explicitly stipulate a formal limit on maximum number of board representations, the guidelines generally recommend that boards should carefully consider the competing time commitments that are faced when directors serve on multiple boards.

2.3. *Measures of Directors' Busyness*

In this study, we employ three measures of directors' busyness. Following prior studies (Fich and Shivdasani (2006) and Ahn, Jiraporn and Kim (2010)), our basic premise is that if outside directors are central to effective board monitoring, a measure of busy director computed only for outside directors will be more relevant. Our first measure of directors' busyness is the average number of external directorships per outside director (DIRCOOUT), which is computed as the total number of external directorships held by outside directors divided by the number of outside directors. Outside directors are directors who directors who are not classified as inside or grey directors, where grey directors include former employees or persons who have related party transactions with the firm. Our second measure of director's busyness is the percentage of busy outside directors (BUSYOUT). As in Ferris et. al (2003) and Fich and Shivdasani (2006), we consider a director as busy if he holds three or more directorships. Our third measure of director's busyness is a dummy variable that equals one if 50% or more of the outside directors are busy, and zero otherwise (D_BUSY) where we classify a director as busy if he holds three or more directorships.

2.4. *Model Specification*

Following Fich and Shivdasani (2006), to test the association between firm valuation and external directorships held by the board, we employ the following firm-fixed effects model[2]:

$$\begin{aligned}\text{TOBINQ}_{i,t} = {} & \beta_0 + \beta_1 \text{BUSYDIR}_{i,t-1} + \beta_2 \text{BUSYDIR}_{i,t-1}{*}\text{ADVICE}_{i,t-1} \\ & + \beta_3 \text{BUSYDIR}_{i,t-1}{*}\text{EXTFIN}_{i,t-1} + \beta 4 \text{ BUSYDIR}_{i,t-1}{*}\text{WEDGE}_{i,t-1} \\ & + \beta_5 \text{ADVICE}_{i,t-1} + \beta_6 \text{EXTFIN}_{i,t-1} + \beta_7 \text{WEDGE}_{i,t-1} + \beta_8 \text{OUTDIR}_{i,t-1} \\ & + \beta_9 \text{BDSIZE}_{i,t-1} + \beta_{10} \text{BDOWN}_{i,t-1} + \beta_{11} \text{INTLOCK}_{i,t-1} + \beta_{12} \text{NOMIN}_{i,t-1} \\ & + \beta_{13} \text{INSTI}_{i,t-1} + \beta_{14} \text{LNASSET}_{i,t-1} + \beta_{15} \text{ROA}_{i,t-1} + \beta_{16} \text{SALECHG}_{i,t-1} \\ & + \beta_{17} \text{DEBT}_{i,t-1} + \beta_{18} \text{GAAPDIF}_{i,t-1} + \text{Firm-fixed effects} + \text{Country Dummies} \\ & + \text{Industry Dummies} + \text{Year Dummies} \qquad (1)\end{aligned}$$

Our proxy for firm valuation is TOBINQ, computed as market value of equity plus book value of total liabilities divided by total assets. Our test variable of interest is BUSYDIR, which is one of the three measures of directors' busyness: (i) average directorships per outside director (DIRCOOUT) (ii) percentage of busy outside directors where a director is classified is busy if he hold three or more directorships (BUSYOUT); and (iii) a dummy variable that equals one if more than 50% of outside directors are busy, and zero otherwise (D_BUSY).

---

[2] Fitch and Shivdasani (2006, page 694) explain that "the fixed effects approach is robust to the presence of omitted firm-specific variables that would lead to biased estimates in an ordinary least squares (OLS) framework. Given the high correlation between the market-to-book ratio and corporate governance variables with numerous other company attributes, the fixed effects framework offer more reliable estimates than OLS regressions".

Our first hypothesis predicts that in firms with high advising needs, firm performance is positively associated with outside directors' external board appointments. Coles, Daniel and Naveen (2008) argue that the need for advising increases with organizational complexity. Thus, we use a firm's organizational complexity as a proxy for its advising needs. We measure the firm's intensity of advising needs based on a common factor analysis of three widely-used measures of organizational complexity: (i) number of business segments, (ii) firm size and (iii) proportion of intangible assets to total assets. As expected, this common factor score (i.e. firm's intensity of advising needs) increases with corporate diversification, firm size and intangible assets. We create a dummy variable (ADVICE) that equals one if this common factor score is greater than the median value and zero otherwise. As per Hypothesis 1, both β_2 and $\beta_1 + \beta_2$ should be positive.

The second hypothesis predicts that in firms with high external financing needs, firm performance is positively associated with outside directors' external board appointments. Following Rajan and Zingales (1998), we define a firm's external finance needs as its capital expenditures minus cash flow from operations divided by capital expenditures. Then, we compute the firm's average external finance needs ratio in the prior five years to smooth temporal fluctuations and to remove the effect of outliers. We create a dummy variable (EXTFIN) that equals one if the external finance needs ratio is greater than the median value and zero otherwise. As per Hypothesis 2, both β_3 and $\beta_1 + \beta_3$ should be positive.

The third hypothesis predicts that if the directors busyness hypothesis dominates the reputation hypothesis, then in firms in which the controlling shareholder holds high control rights relative to cash flow rights, firm performance is negatively associated with outside directors' external board appointments. We follow the procedures in La Porta et al. (1999) to compute the separation of control rights and cash flow rights of the controlling shareholder (WEDGE)[3]. To test the incremental effect of the controlling shareholder's ownership on the association between busy boards and firm valuation, we interact busy boards (BUSYDIR) and the control rights minus cash flow rights of the largest controlling shareholder (WEDGE). If the directors' busyness hypothesis dominates the reputation hypothesis, we expect the interaction term between BUSYDIR and WEDGE to be negative. Appendix A contains the variable definitions.

Our control variables are as follows. The governance literature generally suggests that as boards become increasingly independent of managers, their monitoring effectiveness increases, thereby decreasing managerial opportunism and enhancing firm performance (Shivdasani (1993) and Perry and Peyer (2005)). Thus, we include the proportion of outside directors on the board (OUTDIR) in our tests. Yermack (1996) finds that smaller boards are associated with higher firm value because they are more efficient. Hence, we include board size at the end of the preceding fiscal year (BDSIZE). Linck, Netter and Yang (2008) find

---

[3] Specifically, we consider the shareholder of Company X to be the controlling shareholder when the shareholder is an individual or a family, a privately held company, a privately held financial firm, or a government. A controlling shareholder is defined as the shareholder who has the determining voting rights of the company and who is not controlled by anyone else. If a company does not have a controlling shareholder, it is classified as widely held. For example, if the controlling shareholder is the family M that owns 50% of the shares in Company B and Company B owns 30% of the shares in Company A, we designate family M as controlling 30% of the control rights of Company A and owning 15% (= 50% x 30%) of the cash flow rights.

that higher common equity ownership by outside directors increases board monitoring incentives. We control for percentage of common shares held by outside directors (BDOWN). Bizjak, Lemmon and Whitby (2009) argue that board interlocks can be beneficial if they facilitate the efficient transfer of information or knowledge, or if they facilitate learning about best corporate practices. Alternatively, board interlocks and close relations between firms through director ties potentially reduce the independence of board members and can exacerbate agency problems. Following Bizjak, Lemmon and Whitby (2009), our measure of board interlock is a dummy variable (INTLOCK) that is set to one if two firms in the sample share a common board member in that year. We also include a dummy variable for the presence of a board nominating committee (NOMIN). We also control for the proportion of common equity held by institutional shareholders (INSTI) because prior studies (Lins (2003) and Durnev and Kim (2005)) find that large institutional shareholders are associated with more effective monitoring of managers.

Following Jian and Lee (2011), we control for firm size by including the natural logarithm of book assets (LNASSET) and profitability (ROA). To control for growth opportunities (Smith and Watts (1992)), we include prior year's sales growth (SALECHG). Jensen (1986) argues that debt can mitigate the agency costs of free cash flow. Thus, we include the ratio of long-term debt to total assets (DEBT).

One concern is that differences in accounting standards across countries will affect the levels of conservatism across countries. To address this concern, we follow the approach in Nobes (2001) and Bae, Tan, Welker (2008) to control for differences between domestic accounting standards (local GAAP) and International Financial Reporting Standards (IFRS). Specifically, for each country, we compute a measure of the number of differences between domestic accounting standards and International Financial Reporting Standards (GAAPDIF)[4]. In our model, we also include country dummy variables to control for country effects, industry dummy variables to control for country effects, and year dummy variables to control for time effects.

3. Results

3.1. *Descriptive statistics*

Table 1 shows the descriptive statistics by country. Several results are noteworthy. There is considerable variation in the sample. Firms in Malaysia have the highest percentage of busy outside directors (mean BUSYOUT is 48%) whereas firms in Indonesia have the lowest percentage of busy outside directors (mean BUSYOUT is 26%). About 29% of the firms in Hong Kong and 18% of the firms in Indonesia have more than 50% of their outside directors

---

[4] Nobes (2001) and Bae, Tan, Welker (2008) employ a comprehensive survey to benchmark how domestic accounting standards against International Financial Reporting Standards. In the survey, partners in large accountancy firms from more than 60 countries benchmarked the local accounting standards in their country against International Financial Reporting Standards. The survey contains information on how local GAAP differs from Financial Reporting Standards on 80 key accounting issues, issues incorporating recognition, measurement, and disclosure rules. Some examples of the accounting issues include deferred tax accounting, segment reporting, capitalization of leases, accounting for employee benefit obligations, impairment testing of intangibles, accounting for financial instruments, disclosure of the fair value of financial assets, treatment of discontinued operations, treatment of discontinued operations and consolidation of special purpose entities.

(D_BUSY) classified as busy (i.e. holding three or more directorships). At the other extreme, the proportion firms with more than 50% of their outside directors (D_BUSY) classified as busy are 41% and 43%, in Malaysia and Singapore respectively. Consistent with prior studies (Claessens, Djankov, Fan and Lang (2002), Lins (2003) and Lee (2007)) that documented concentrated ownership in East Asia, our sample average separation of voting rights and cash flow rights in the controlling shareholder (WEDGE) is 21%.

Table 2 presents the Spearman correlation between the variables. Several points are noteworthy. First, firm valuation is negatively associated with multiple directorships, indicating that busy boards are associated with lower firm performance. Second, firms with busy boards have lower operating profitability. Third, consistent with prior studies (Claessens, Djankov and Lang (2002)), firm valuation is negatively associated with the separation of voting rights and cash flow rights of the controlling shareholder. Fourth, firms with higher advising needs are more likely to have boards with multiple directorships. Fifth, firm-level external financing need is positively associated with multiple directorships.

3.2. *Market-to-book ratio tests*

Our first set of tests examines the association between market-to-book ratio (TOBINQ) and busy board. Table 3 presents the following firm-fixed effects regression results of market-to-book ratio (TOBINQ) on busy boards. In all specifications, to alleviate concern about potential cross-sectional and time-series dependence in the data, we report t-values on an adjusted basis using robust standard errors corrected for double (firm and year) clustering (Petersen (2009)). In model (1), the estimated coefficient on DIRCOOUT (average directorships per outside director) is negative and statistically significant. The results indicate that firm valuation is negatively associated with the multiple external directorships held by outside directors. Thus, in our sample, the busyness hypothesis dominates the reputation hypothesis.

The estimated coefficient on the interaction term, DIRCOOUT x ADVICE, is positive and statistically significant. The result suggests that the negative effect of busy board on Tobin's Q for firms with low advising needs is more than offset for firms with high advising needs ($\beta_1 + \beta_2 = 0.028$, $p<0.01$). This result is consistent with our hypothesis that firms with high advising needs benefit from having more outside directors with multiple external board appointments. In terms of economic significance, if the average directorships per outside director increase by one standard deviation, Tobin's Q for firms with external financing needs increases by 2.2% relative to the sample mean.

The estimated coefficient on the interaction term, DIRCOOUT x EXTFIN, is positive and statistically significant at the 1% level. The result suggests that the negative effect of busy board on Tobin's Q for firms with low external financing needs is more than offset for firms with high external financing needs ($\beta_1 + \beta_3 = 0.013$, $p<0.01$). Thus, in firms with high external financing needs, firm value is positively associated with outside directors' external board appointments. In terms of economic significance, if the average directorships per outside director increase by one standard deviation, Tobin's Q for firms with external financing needs increases by 1.1% relative to the sample mean.

The estimated coefficient on the interaction term, DIRCOOUT*WEDGE, is negative and statistically significant at the 1% level. This result suggests that in firms with higher separation of voting rights and cash flow rights of the controlling shareholder, the negative association between firm valuation and multiple directorships is more pronounced. In terms of economic significance, holding constant the wedge between control rights and cash flow rights at the sample median, a standard deviation increase in the average directorships per outside director reduces Tobin's Q by 3.9% relative to the sample mean.

In model (2), we measure directors' busyness with the percentage of busy outside directors (BUSYOUT). Following Fich and Shivdasani (2006), we classify director as busy if he holds three or more directorships. In model (3), we measure directors' busyness with a dummy variable (D_BUSY) that equals one if more than 50% of outside directors are busy, and zero otherwise. Our inferences are qualitatively similar. Specifically, we continue to document the positive association between firm valuation and multiple directorships is more pronounced in firms with (i) high external financing, (ii) high advising needs and (iii) low wedge of voting rights and cash flow rights of the controlling shareholder[5].

It is possible that differences in accounting conservatism across countries affect the dependent variable which is the market-to-book ratio. Following the approach in Claessens, Djankov, Fan and Lang (2002), we perform the market-to-book test at the country level to examine the sensitivity of our results to accounting differences. The intuition is that if country-level accounting conservatism is related to country-level accounting rules, then all firms in the same country (subjected to the same country-level accounting rules) should have the same country-level accounting conservatism. Table 4 presents the regression analysis for each country in our sample. There is no evidence that results are driven by specific countries.

3.3. *Developed countries versus developing countries*

This section examines how our results differ between developed countries and developing countries. Following La Porta, Lopez, Shleifer and Vishny (2002), we classify Hong Kong, and Singapore as developed countries, and Indonesia, Malaysia, Philippines and Thailand as developing countries. Table 5 presents the results for developed countries (column 1) and developing countries (column 2). Although the results are directionally similar in both developed countries and developing countries, there are two main differences. First, the coefficient on BUSYOUT*WEDGE is more negative in developing countries[6]. Thus, in firms with high separation of control rights and cash flow rights, the negative association between busy boards and firm value is more pronounced in developing countries. Second, the coefficient on BUSYOUT*EXTFIN is more positive and statistically significant in the

---

[5] As an alternative measure of firm performance, we examine the association between busy boards and return-on-assets (ROA). Our results (not tabulated) are qualitatively similar. Firms with higher proportion of busy outside directors have lower ROA. The negative association between ROA and busy boards is stronger in firms with higher wedge of voting rights and cash flow rights of the controlling shareholder. In firms with high advising needs and those with high external financing needs, ROA is positively associated with outside directors' external board appointments.

[6] The F-statistic of the difference between developed countries and developing countries for the coefficient on BUSYOUT*WEDGE is significant at the 5% level.

developed countries[7]. Thus, in firms with high external financing needs, outside director perform more effective monitoring in developed countries.

3.4. *Strong versus weak shareholder right*

Our sample consists of countries with different country-level shareholder protection. Hence, we examine whether board composition has a differential effect in countries with strong versus weak levels of legal shareholder protection. On one hand, if strong board monitoring substitutes weak country-level shareholder protection, a strong board is likely to be more valuable in a country with weak shareholder protection. On the other hand, it is possible that a strong board would have little effect in a country with weak shareholder protection because the board may be dominated by entrenched managers without a protective legal environment.

Based on La Porta, Lopez, Shleifer and Vishny (1998) measure of country-level shareholder right, we partition our sample into countries with strong and weak shareholder right based on the sample median. Specifically, we classify Hong Kong, Malaysia and Singapore as countries with strong shareholder right and Indonesia, Phillipines and Thailand as countries with weak shareholder right. Table 5 presents the results for countries with strong shareholder right (column 3) and countries with weak shareholder right (column 4). There are several interesting results. First, the coefficient on BUSYOUT*WEDGE is more negative in countries with weak shareholder right[8]. Thus, in firms with high separation of control rights and cash flow rights, the negative association between busy boards and firm value is more pronounced in countries with weak shareholder right. This result indicates that in countries with weak shareholder right, poor monitoring associated with busy boards combined with agency problems associated with concentrated ownership structure, results in further declines in firm value. Second, the coefficient on BUSYOUT*EXTFIN is more positive and statistically significant in the countries with strong shareholder right. Thus, in firms with high external financing needs, outside director perform more effective monitoring in countries with strong shareholder right[9] This result is consistent with notion that stronger country-level investor protection facilitates corporate monitoring by outside directors whose reputational capital is tied to external board appointments.

Another important aspect of shareholder protection is whether shareholder rights are effectively enforced. To measure the degree of enforcement, we employ quantitative assessments of the rule of law (the extent to which agents have confidence in the law and abide by the rules of the society), regulatory quality (the ability of government to formulate and implement effective policies for the regulation of business) and the control of corruption from Kaufmann, Kraay and Mastruzzi (2003). The results (not tabulated) based on partitioning the sample by enforcement of the rule of law are qualitatively similar to the results based on partitioning the sample by shareholder rights.

---

[7] The F-statistic of the difference between developed countries and developing countries for the coefficient on BUSYOUT*EXTFIN is significant at the 5% level.

[8] The F-test of the difference in BUSYOUT*WEDGE between into countries with strong and weak shareholder right is significant at the 5% level.

[9] The F-test of the difference in BUSYOUT*EXTFIN between into countries with strong and weak shareholder right is significant at the 5% level.

3.5. *Closely-held versus widely-held firms*

Outside United States, corporate ownership is concentrated with many firms being controlled by a large shareholder (La Porta, Lopez, Shleifer and Vishny (1998, 2002). Thus, we investigate whether our results differ between closely-held firms and widely-held firms. Following Claessens, Djankov, Fan and Lang (2002), we classify a firm as closely held if it is controlled by a single largest shareholder at the 20% ownership cut-off level. Otherwise, we classify the firm as widely held. Table 5 presents the results for closely-held firms (column 5) and widely-held firms (column 6). There are two main differences between closely-held firms and widely-held firms. First, the coefficient on the interaction term BUSYOUT*WEDGE is negative and statistically significant in closely held firms. The result suggests that the combination of high percentage of busy outside directors and high separation of voting rights and cash flow rights in the controlling shareholder increase agency problems in closely held firms. Our result is consistent with the finding in Claessens, Djankov, Fan and Lang (2002) that managers at closely-held firms are more likely than widely-held firms to divert private benefits of control for themselves[10]. Second, the coefficient on the interaction term BUSYOUT*ADVICE is positive and statistically significant (at the 5% significance level) in widely held firms but it is positive and marginally significant (at the 10% significance level) in closely-held firms. This result suggests that the beneficial effect of multiple board appointments in firms with high advising needs is stronger in widely-held firms. Further analysis (not tabulated) indicates that in our sample, the widely-held firms have more business segments and higher intangibles than do closely-held firms. In other words, the widely-held firms have higher organizational complexity (and hence higher advising needs) than closely-held firms.

4. Channels Through Which Multiple Directorships Affect Firm Performance

This section provides evidence on the channels through which busy boards affect shareholder value. Specifically, we examine how busy boards affect the market valuation of corporate cash holdings and market valuation of corporate capital expenditures[11].

4.1. *Market Valuation of Corporate Cash Holdings*

To examine how busy boards affect the contribution of cash to firm value, we extend the framework developed by Faulkender and Wang (2006), who study the relation between the marginal value of cash and corporate financial policies. We augment their model by introducing the busy board measure. Specifically, our regression equation is specified as follows:

---

[10] By construction, WEDGE measures the control rights minus cash flow rights of the largest controlling shareholder. Thus, WEDGE equals zero for widely-held firms.

[11] Prior studies provide evidence on the association between busy boards and specific corporate outcomes. Fich and Shivdasani (2006) find that firms with busy boards exhibit lower sensitivity of CEO turnover to firm performance. Ahn, Jiraporn and Kim (2010) find that acquiring firms, where directors hold more outside board seats, are more likely to undertake value-destroying mergers. We extend these studies by examining other channels (corporate cash holdings and capital expenditures) thorough which busy boards can affect firm valuation.

$$R_{it} - R^{B}_{it} = \beta_0 + \beta_1 \Delta CASH_{it} + \beta_2 \Delta CASH_{it}*BUSYOUT_{it-1} + \beta_3 \Delta CASH_{it}*BUSYOUT_{it-1}*ADVICE_{it-1} + \beta_4 \Delta CASH_{it}*BUSYOUT_{it-1}*EXTFIN_{it-1} + \beta_5 \Delta CASH_{it}*BUSYOUT_{it-1}*WEDGE_{it-1} + \text{control variables} \quad (2)$$

The dependent variable in equation (2) is the industry-adjusted returns of the firm's common stock over fiscal year t. On the right-hand side of equation (2), $\Delta CASH_{it}$ is a firm's unexpected change in cash from year t-1 to t, with the firm's cash position at the end of year t-1 taken to be its expected cash level in year t. Since $\Delta CASH_{it}$ is scaled by the market value of equity at the end of year t-1, its coefficient β_1 measures the dollar change in shareholder wealth for a one-dollar change in corporate cash holdings. Following Faulkender and Wang (2006), the control variables are net financing over year t-1 to t, changes in net income after tax, changes in total assets net of cash, changes in research and development, changes in interest expense, and changes in dividends. Similar to the change in cash, these variables are also scaled by the firm's market capitalization at the start of the fiscal year. All variables are defined in Appendix A.

We merge the sample of firms with board information with Datastream to obtain daily stock return information. The final sample consists of 4,723 firm-year observations from 2001 to 2007 with the necessary variables to construct the variables in equation (2)[12]. Table 5 presents the market valuation of corporate cash holdings.

In column (1), the interaction between the unexpected change in cash and the proportion of busy directors on the board, $\Delta CASH_{it}*BUSYOUT_{it-1}$, is negative and significant at the 1% level. This result suggests that in firms with higher proportion of busy directors on the board, there are fewer constraints on managers over the diversion of corporate cash holdings for personal benefit and thus results in lower valuation of cash holdings. The interaction term, $\Delta CASH_{it}*BUSYOUT_{it-1}*ADVICE_{it-1}$, is positive and significant at the 1% level, suggesting that in firms with busy boards, cash is worth more in the sub-sample of firms with high advising needs. The interaction term, $\Delta CASH_{it}*BUSYOUT_{it-1}*EXTFIN_{it-1}$, is positive and significant at the 5% level. Simply put, in firms with busy boards, cash is worth more in the sub-sample of firms with high external financing needs. We find the interaction term, $\Delta CASH_{it}*BUSYOUT_{it-1}*WEDGE_{it-1}$, to be negative, suggesting that the negative valuation of cash in firms with more busy boards is more pronounced in those firms with higher ratio of voting rights to cash flow rights in the hands of the controlling shareholder.

Columns (2) and (3) present the analysis for developed countries and developing countries respectively. Columns (4) and (5) present the analysis for countries with strong shareholder rights and weak shareholder rights, respectively. In developing countries and countries with weak shareholder rights, cash is worth less in firms with busy board. However, in developed countries and countries with strong shareholder rights, cash is worth more in firms with busy boards, especially in the sub-sample of firms with high external financing needs. Columns (6) and (7) present the analysis for closely-held firms and widely-held firms, respectively. In closely-held firms, cash is worth less in firms with busy boards and high wedge between voting and cash-flow rights.

[12] The additional requirement of stock returns data in the analysis of the market valuation of corporate cash holdings reduces the sample size.

4.2. *Market Valuation of Corporate Capital Expenditures*

To examine how the contribution of capital expenditures to shareholder value depends on the proportion of busy outside directors on the board, we employ the same general framework we used for the analysis of the market value of cash holdings. We employ the following regression equation:

$$R_{it} - R^B_{it} = \beta_0 + \beta_1\, \Delta CAPEX_{it} + \beta_2\, \Delta CAPEX_{it}{*}BUSYOUT_{it-1} + \beta_3\, \Delta CAPEX_{it}{*}BUSYOUT_{it-1}{*}ADVICE_{it-1} + \beta_4\, \Delta CAPEX_{it}{*}BUSYOUT_{it-1}{*}EXTFIN_{it-1} + \beta_5\, \Delta CAPEX_{it}{*}BUSYOUT_{it-1}{*}WEDGE_{it-1} + \text{control variables} \quad (3)$$

The only difference between this model (equation 3) and that used in the value-of-cash analysis (equation 2) is that we replace $\Delta CASH_{it}$ with $\Delta CAPEX_{it}$, the change in a firm's capital expenditures from fiscal year t-1 to fiscal year t. Since $\Delta CAPEX_{it}$ is scaled by the market value of equity at the end of year t-1, its coefficient β_1 measures the dollar change in shareholder wealth for a one-dollar increase in capital expenditures.

Table 7 presents the regression results of the capital expenditures analysis. In column (1), we find that the scaled change in capital expenditures has a significantly positive effect on excess stock returns, indicating that on average capital investments add to shareholder value. The coefficient of the interaction term between busy boards and the change in capital expenditures ($CAPEX_{it}{*}BUSYOUT_{it-1}$) is negative and significant, indicating that busy boards reduce the contribution of capital expenditures to shareholder value. The interaction term, $\Delta CAPEX_{it}{*}\ BUSYOUT_{it-1}{*}ADVICE_{it-1}$, is positive and significant, indicating in firms with busy boards, capital investments are worth more in the sub-sample of firms with high advising needs. The interaction term, $\Delta CAPEX_{it}{*}BUSYOUT_{it-1}{*}EXTFIN_{it-1}$, is positive and significant, suggesting that in firms with busy boards, corporate capital investments are worth more in the sub-sample of firms with high external financing needs. We find that the interaction term, $\Delta CAPEX_{it}{*}BUSYOUT_{it-1}{*}WEDGE_{it-1}$, is negative and significant, suggesting that in firms with busy boards, corporate capital expenditures are less valuable in the sub-sample of firms with high ratio of voting rights to cash flow rights in the hands of the controlling shareholder.

Columns (2) and (3) present the analysis for developed countries and developing countries respectively. Columns (4) and (5) present the analysis for countries with strong shareholder rights and weak shareholder rights, respectively. In developed countries and countries with strong shareholder rights, capital expenditure is worth more in firms with busy boards, especially in the sub-sample of firms with high external financing needs. Columns (6) and (7) present the analysis for closely-held firms and widely-held firms, respectively. In closely-held firms, capital expenditure is worth less in firms with busy boards and high wedge between voting and cash-flow rights.

4.3. *Additional Tests*

4.3.1. *Endogeneity*

It is possible that firm valuation, the proportion of busy outside directors on the board and corporate ownership are jointly determined. To correct for this potential endogeneity problem, we estimate a simultaneous equation model similar to Harvey, Lins and Roper (2004). In this approach, we simultaneously estimate a three-stage least squares regression model, with three structural equations consisting of a (i) firm valuation equation, (ii) a busy board equation and (iii) a corporate ownership equation.

Table 8 reports the results of the three-stage least squares regressions. In model (1), the estimated coefficient on BUSYOUT is negative and significant, indicating that an increase in the proportion of busy outside directors on the board is negatively associated with firm valuation. The interaction term BUSYOUT*ADVICE is positive and significant, indicating that firms with high advising needs benefit from having more outside directors with multiple board appointments. The interaction term BUSYOUT*EXTFIN is positive and significant, indicating that if the proportion of busy outside directors on the board in firms increases, the valuation of firms with high external financing needs also increases. The interaction term BUSYOUT*WEDGE is negative and significant, indicating that the monitoring problems associated with busy boards coupled with entrenched ownership structure reduces firm value.

In model (2), we find that firm size, the stock's market risk (beta) and stock return volatility are negatively associated with the wedge between voting rights and cash flow rights. Consistent with Harvey, Lins and Roper (2004), we also find that the separation between voting rights and cash flow rights is positively associated with leverage. However, Tobin's Q, percentage of tangible assets and sales growth rate are not significant in this equation.

In model (3), we find that the proportion of busy directors on the board is positively associated with firm size and firm age. The industry-adjusted stock return of the firm is not significantly associated with proportion of busy directors on the board. This result casts doubt that poor firm performance makes the appointment of busy boards more likely, consistent with the results in Fich and Shivdasani (2006). Furthermore, there is no association between the wedge of voting rights and cash flow rights in the hands of the controlling shareholder and the proportion of busy directors on the board. Thus, there is little evidence that controlling shareholders appoint busy outside directors to reduce monitoring of corporate insiders.

As an additional test, following prior studies (Laeven and Levine (2007) and John, Litov, and Yeung (2008)), we use the average proportion of busy outside directors in the firm's industry based on two-digit securities industry classification (SIC) codes as instruments for the proportion of busy board of a given firm. Similarly, we employ the average wedge of voting rights and cash flow rights of the firm's industry based on two-digit SIC codes as instruments for a given firm's wedge of voting rights and cash flow rights. The economic assumption behind this model is that the industry's average proportion of busy outside directors on the board (average wedge of voting rights and cash flow rights) affects the firm valuation only through its effect on that firm's busy board (wedge of voting rights and cash flow rights) and not otherwise. Our three-stage estimation results based on this instrument (not tabulated) are qualitatively similar. Taken together with the results in Table 8, it is unlikely that our results are driven by endogeneity issues[13].

4.3.2. *Other Robustness Tests*

As a sensitivity test, we also repeat our tests year by year. The year-by-year analysis is qualitatively similar to our main results. Thus, there is no evidence that our results are clustered in specific years. As a robustness test, we exclude firms with board interlock to address the concern that interlocks could reduce the perceived independence of outside directors. In this sub-sample that exclude firms with board interlock, our results (not tabulated) are qualitatively similar.

5. Conclusions

This paper examines the benefits and costs associated with multiple directorships held by outside directors. Using a sample of listed firms in East Asia, we find that firms in which outside directors hold multiple directorships have lower firm valuation. Our result suggests that for the average firm in our sample, the directors' busyness hypothesis dominates the reputation hypothesis. More importantly, we find that the association between multiple directorships and firm performance is conditional on firm characteristics. Firm valuation is positively associated with the proportion of outside directors with multiple external directorships in firms with high advising needs and those with high external financing needs. These beneficial effects of multiple directorships are generally stronger in developed countries, countries with stronger shareholder rights and widely-held firms. In firms in which the controlling shareholder hold disproportionately high voting rights relative to cash flow rights, the negative association between firm valuation and multiple directorships by outside directors is more pronounced. The detrimental effects of busy boards are stronger in countries with weaker shareholder rights and closely-held firms.

As multiple directorships increases, corporate cash holdings (capital expenditures) are worth less to outside shareholders. We find that the negative association between the marginal value of cash (capital expenditures) and busy boards is mitigated in firms with (i) higher advising needs, (ii) higher external financing needs, and (iii) lower separation of voting rights and cash flow rights of the controlling shareholder. Additional analysis suggests that these results are generally stronger in countries with stronger shareholder rights, developed countries and in widely-held firms.

---

[13] We acknowledge that it is difficult to identify ideal exogenous variables that affect firm value or board structure or ownership, but not all three. At the minimum, to the extent that our three-stage least squares estimation method controls for endogeneity among corporate valuation, busy boards and corporate ownership structure, our results are consistent with the notion that the association between multiple directorships and firm valuation is conditional on firm characteristics.

Table 3

Firm valuation and busy outside directors

This table presents the firm-fixed effects regression results of firm valuation. The sample consists of 6,536 firm-year observations during the period 2001 to 2007 in six East Asian countries (Hong Kong, Indonesia, Malaysia, Philippines, Singapore and Thailand). The dependent variable is market value of equity plus book value of total liabilities divided by total assets (TOBINQ). All variables are defined in Appendix A. All models include firm fixed effects and dummy variables for country effects, industry effects and years effects (not tabulated). The parentheses contain the t-statistics on an adjusted basis using robust standard errors corrected for double (firm and year) clustering (Petersen (2009)). ***, **, and * denote statistical significance at the 1%, 5%, and 10% levels, respectively.

Table 6

Regression results of the market valuation of corporate cash holdings.

This table presents the regression results of the market valuation of corporate cash holdings. The sample consists of 4,723 firm-year observations during the period 2001 to 2007 in six East Asian countries (Hong Kong, Indonesia, Malaysia, Philippines, Singapore and Thailand). The dependent variable is the industry-adjusted excess returns of the firms during the fiscal year. All variables are defined in Appendix A. All models include dummy variables for country effects, industry effects and years effects (not tabulated). The parentheses contain the t-statistics based standard errors corrected for heteroscedasticity and firm-level clustering. ***, **, and * denote statistical significance at the 1%, 5%, and 10% levels, respectively.

Table 7

Regression results of the market valuation of large capital expenditure increases.

This table presents the regression results of the market valuation of corporate capital expenditure. The sample consists of 2,106 firm-year observations during the period 2001 to 2007 in six East Asian countries (Hong Kong, Indonesia, Malaysia, Philippines, Singapore and Thailand). The dependent variable is the industry-adjusted excess returns of the firms during the fiscal year. All variables are defined in Appendix A. All models include dummy variables for country effects, industry effects and years effects (not tabulated). The parentheses contain the t-statistics based standard errors corrected for heteroscedasticity and firm-level clustering. ***, **, and * denote statistical significance at the 1%, 5%, and 10% levels, respectively.

Table 8

Joint determination of firm valuation, corporate ownership and busy boards

This table presents the three-stage least squares regression results of firm valuation, corporate ownership and busy boards. The sample consists of 6,536 firm-year observations during the period 2001 to 2007 in six East Asian countries (Hong Kong, Indonesia, Malaysia, Philippines, Singapore and Thailand). In model (1), the dependent variable is market value of equity plus book value of total liabilities divided by book value of total assets (TOBINQ). In model (2), the dependent variable is the separation of voting rights and cash flow rights of the controlling shareholder (WEDGE). In model (3), the dependent variable is the percentage of busy outside directors on the board where a director is classified is busy if he holds three or more directorships (BUSYOUT). All models include dummy variables for country effects, industry effects and years effects (not tabulated). The parentheses contain the t-statistics based standard errors corrected for heteroscedasticity and firm-level clustering. ***, **, and * denote statistical significance at the 1%, 5%, and 10% levels, respectively.

Appendix A - Variable definitions

Variable	Definition
Analysis of firm performance	
TOBINQ	Market value of equity plus book value of total liabilities divided by total assets.
DIRCOOUT	Average directorships per outside directors.
BUSYOUT	Percentage of busy outside directors where a director is classified is busy if he holds three or more directorships.
D_BUSY	A dummy variable that equals one if more than 50% of outside directors are busy, and zero otherwise. We consider a director as busy if he holds three or more directorships.
ADVICE	The firm's intensity of advising needs based on a common factor analysis of three widely-used measures of organizational complexity: (i) number of business segments, (ii) firm size and (iii) proportion of intangible assets to total assets. ADVICE is a dummy variable that equals one if this common factor score is greater than the median value and zero otherwise.
EXTFIN	We define a firm's external finance needs as its capital expenditures minus cash flow from operations divided by capital expenditures. Then, we compute the firm's average external finance needs ratio in the prior five years to smooth temporal fluctuations. EXTFIN is a dummy variable that equals one if the external finance needs ratio is greater than the median value and zero otherwise.
WEDGE	Control rights minus cash flow rights of the largest controlling shareholder.
OUTDIR	Proportion of outside directors on the board. Outside directors are directors who directors who are not classified as inside or grey directors, where grey directors include former employees or persons who have related party transactions with the firm.
BDSIZE	Number of directors on the board.
BDOWN	The percentage of common shares held by outside directors.
INTLOCK	a board interlock dummy variable that equals one if two firms in the sample share a common director in that year and zero otherwise.
NOMIN	A dummy variable that equals one if a board nominating committee is present and zero otherwise.
INSTI	The proportion of common equity held by institutional shareholders.
LNASSET	Natural logarithm of book value of total assets.
ROA	Net income divided by total assets.

SALECHG Prior year sales growth.

DEBT Long term debt divided by book value of total assets.

Analysis of market valuation of corporate cash holdings

R_{it} Raw returns of the stock during the fiscal year.

R^{B}_{it} Benchmark return proxied by industry value weighted returns.

Δ $CASH_t$ Change in cash divided by market value of equity at start of the year.

$DEBT_t$ Total liabilities divided by market value of equity at start of the year.

$\Delta EARN_t$ Change in net income after tax divided by market value of equity at start of the year.

$\Delta NETASSET_t$ Change in net assets divided by market value of equity at start of the year.

ΔRD_t Change in research and development expenditures divided by market value of equity at start of the year.

$\Delta INTEREST_t$ Change in interest divided by market value of equity at start of the year.

ΔDIV_t Change in common dividends divided by market value of equity at start of the year.

$NETFIN_t$ New equity issues and new debt issues divided by market value of equity at start of the year.

CONSTRAIN A dummy variable that equals one if the firm's total payout ratio (dividends and stock repurchases divided by assets) is below the sample median and zero otherwise.

Analysis of market valuation of corporate cash holdings

Δ $CAPEX_t$ Change in capital expenditures incurred during the year divided by market value of equity at start of the year.

Analysis of joint determination of firm valuation, corporate ownership and busy boards

BETA The beta from a regression of firm's monthly stock return on its local market Morgan Stanley Capital International index in the prior 36-months period.

SIGMA Standard deviation of firm's stock return in the prior 36-months period.

TANGIBLE Net property, plant and equipment divided by total assets.

FIRMAGE Age of the firm since incorporation date.

INDRET Industry adjusted stock return in the last fiscal year.

□ □ □ □ □ □ Has BRICS Countries Decoupled from the Effect of Contagion during the 2008 Financial Crisis? Comparison of VECM Model and DCC GARCH Model

Ka-lok Kan
Department of Economic and Finance,
Brunel Univesrity
United Kingdom
ecpgkkk@brunel.ac.uk

In the light of the recent financial crisis, this paper investigates the contagion effect of the 2008 financial crisis shedding light on the decoupling recoupling theory. This paper investigates 5 BRICS countries (Brazil, Russia, India, China and South Africa) and the contagion effect from the US and UK indices. This paper compares DCC GARCH model and VECM model to conduct the investigation. This paper has found that with the exception of China, BRICS countries generally have been effected by the contagion effect.

1. Introduction

The current financial crisis has done considerable global damage in the period between 2008 and 2010, and therefore it is particularly interesting to understand the impact of the crisis. It originated from Anglo-Saxon economies, the US particularly, and to a lesser extent the UK. Much of the literature has done extensive research into the reasons behind the crisis but there is a lack of research into the impact of the crisis upon other countries such as the BRICS.

The BRICS (Brazil, Russia, India, China and South Africa) was a term for these countries coined by Goldman Sachs in 2002 and consists of five of the highest GDP growth countries in the world. It is also forecasted that the BRICS will become the dominant economies by 2050, representing half of the global GDP (Chittedi 2014). Currently, the BRICS are all in the G20 organisation and already representing a significant proportion of the world's population and economic activities.

The economic activities of BRICS are not only significant globally, they are also significant in their respective regions as they are the regional hubs in their own right, such as Brazil in Latin America and China in East Asia. The macro-economics and the climate for financial markets are very different from the traditional Anglo-Saxon countries, such that many scholars have thought that these countries have already decoupled from the US and UK economies (Leduc, Spiegel 2013, Liang 2010). The reason is that the economic model for the BRICS is predominately export-led, whereas the growth of the Anglo-Saxon economies has been reliant on domestic consumption for many years. The export-led economies have resulted in a significant amount of foreign reserves in the current accounts of the BRICS countries and, leading the above-average economic growth, regionally driving global economies.

Investors invest in these countries for a number of reasons. First the growth rate of the assets tends to be in the region of double figures, meaning that it can satisfy some risk-taking investment strategies. Investors investing into these assets are usually seeking a better return than mature markets. Secondly, most scholars thought that because of the decoupling effect mentioned earlier, it satisfies the primary principle of the portfolio theory that traders would diversify internationally to reduce the risk of the portfolio from the extreme sudden volatility of a shock in one particular country.

Because of this reason, it is particularly interesting to study the co-movement and the contagion of these emerging markets so that the effect of one of the most damaging financial crises can be understood. It is important to study the performance of the markets in the BRICS countries during the recent financial crisis so that the decoupling–recoupling theory can be investigated, as there is currently a lack of literature in this area. Studying this area will enable the academic world to gain an understanding of the behaviour of the financial markets, assisting the fiscal policy-making of emerging countries and also the formulation of crisis-prevention regulation. Secondly, diversification is an important area for investment and the study of contagion will enable us to understand how a crisis may transmit from one country to another. This will enable investors to gain an understanding of the underlying contagion that is hidden in regions and countries, enabling them to make informed decisions when undertaking investment activities. This will provide more insight for them to make better decisions in terms of diversification into emerging countries.

2. Literature Review

A great deal of the literature has focused on finding out the presence of the contagion effect in emerging markets in a given period of time (Morales, Andreosso-O'Callaghan 2014, Ahmad, Sehgal et al. 2013, Dimitriou, Kenourgios et al. 2013, Kotkatvuori-Ornberg, Nikkinen et al. 2013, Didier, Love et al. 2012, Junior, Franca 2012, Aloui, Aissa et al. 2011, Kenourgios, Samitas et al. 2011, Guo, Chen et al. 2011, Naous, Khemiri et al. 2010). Most of the literature lacks cohesion when analysing the presence of the contagion effect in a collection of countries. It is therefore the intention of the researcher that a focused analysis be undertaken in the form of a select few emerging countries, and the BRICS bloc has been chosen for this purpose.

2.1 Contagion channels

Some of the literature argues that the only way BRICS countries would be able to weather the next financial crisis would be by undertaking trade (Kim, Lee et al. 2011). Through trade and collection, and a large amount of foreign reserves together with fiscal reform, emerging countries would be able to isolate themselves from the external shocks that may negatively impact on the financial markets and economies. These studies explain the reason behind this as trade eventually leading to export-led growth of economies, ensuring above-average growth year on year.

However, it is trade that led the emerging countries into lowered growth from mid-2008. The falling demand of consumption led to a fall in exports. This has hit the export-led countries hard and resulted in the below average performance of macro-economic figures in 2008 and 2009. Combined with the pull of the currency contagion, channel presence in the traditional dollar-trading markets and those artificially pegged to the dollar, the financial markets experienced a decrease in market capitalisation and liquidity, the performance of which was found to be affected by the intensive bad news from the West.

This thesis will provide a comprehensive study of the contagion channels by comparing two mathematical econometric models, the VECM and the Dynamic Conditional Correlation (DCC) GARCH models. It will explain how contagion happened and the delay of its occurrence.

2.2 Decoupling–recoupling theory

Prior to the beginning of the 2008 sub-prime mortgage financial crisis, some of the literature argued that the BRICS economies had decoupled from the traditional Anglo-Saxon economies (Kizys, Pierdzioch 2013, Kim, Lee et al. 2011, Dooley, Hutchison 2009). This is because the BRICS have been employing export-led growth strategies, whereas Anglo-Saxon economies favour domestic consumption. The differences in these strategies led to a global imbalance and the trade deficit between these countries widened. Countries like China, Russia and India were hence able to collect a large amount of foreign reserves. Therefore, some of the literature was arguing that the emerging countries may be able to weather the next financial crisis prior to the 2008 crisis. This argument led into a debate over the strength of the linkage between emerging countries and the industrialised countries.

However, the 2008 financial crisis revealed to us that the BRICS economies were at best recoupled to the world economies, despite the fact that they outperformed the US and the UK in 2007 in many areas, such as outperforming by 40% in the financial markets. Since the collapse of Lehman Brothers and other financial institutions, the contagion of the bad news resulted in the co-movement of financial markets. Financial markets in emerging countries experienced a decline in liquidity and an increase in volatility following the intense bad news in the West. This has led to the consistent findings of many studies that the linkage between the economies has been greatly enchanted since the occurrence of 2008 financial crisis. Some even argued that they did not decouple in the calm period as the emerging countries could not weather the financial crisis technically.

This thesis will continue to shed light on this area and will use two mathematical models to contribute to the debate that the decoupling theory was at best weakly supported during the tranquil period.

2.3 Contagion in BRICS

Much of the literature focuses on examining contagion in a group of emerging countries and there is a lack of a focus on a group of similar economies such as the BRICS (Kotkatvuori-Ornberg, Nikkinen et al. 2013, Samarakoon 2011). Consistently, the literature has found that the correlation of financial contagion has increased since the collapse of Lehman Brothers and the later stage of the 2008 financial crisis. Some of the literature divided the contagion into two phases: the difference in the correlation level in the tranquil and the crisis period, providing an in-depth analysis that the intensive bad news since the collapse of Lehman Brothers has greatly affected the financial markets of the BRICS countries.

Few elements within the literature rejected the presence of contagion from the US to the BRICS and this thesis will provide further information and the reasons behind the delay of the contagion from mid-2008 onwards. In Section 3, the methodologies section, I will explain the testing of the contagion of the BRICS. Section 4 presents the data describing the performance of the financial markets in the BRICS during the financial crisis. Section 5 provides a discussion comparing the VECM and the DCC GARCH model. It provides explanations of the presence of contagion. Section 6 concludes the paper.

3. Methodology

3.1 Data Collection

The sample was taken from January 2007 to December 2010, during the peak of the financial crisis. Closing share prices of each of the BRICS countries were collected on Yahoo Finance. The sample was analysed using Microsoft Excel and EVIEWS software. Many studies have defined contagion as the sudden increase of co-movement of stock markets after a shock (Dimitriou, Simos 2013, Samarakoon 2011). Traditionally, the literature a number of different kinds of models to test the co-movement: the Chow test, the co-integration test, the causality test, a DCC GARCH model and a direct estimation of specific transmission mechanisms. Since most of the literature that employed the last methods was not especially tested for contagion, I have proposed to use the three most objective methods in EVIEWS so that the co-movement can be tested.

3.2 Johansen co-integration test

The co-integration test is a common tool since it was introduced by measuring the present and the changes in the co-integrating vector in a long-run sample. It is particularly good for a sample with a long period of observations explaining the linkages of the financial markets and the variables for testing.

Its advantage being with an assumption of unit root such that it is excellent in testing variables that often modelled as unit root such as interest rates, inflation, real exchange rates and unemployment rates. Hence it is very useful to test the impact of the current financial crisis in terms of the macro-economic determinates on the financial markets in the BRICS. In the Johansen framework, all the variables are near-integrated, testing the H0 $r \leq 0$ in trace test and the H0 $r=0$ in eigenvalue test.

Johansen's methodology takes its starting point in the vector autoregression (VAR) of order p given by:

$$y_t = \mu + A_1 y_{t-1} + \cdots + A_p y_{t-p} + \varepsilon_t \qquad 1$$

where y_t is an n x 1 vector of variables that are integrated of order one – commonly denoted as I(1), and ε_t is an n x 1 vector of innovations. This VAR can be re-written as:

$$y_t = \mu + \Pi y_{t-1} + \sum_{i=1}^{p-1} \Gamma_i \Delta y_{t-1} + \varepsilon_t \qquad 2$$

Where:

$$\Pi = \sum_{i=1}^{p} A_i - I \text{ and } \Gamma_i = -\sum_{j=i+1}^{p} A_j \qquad 3$$

Johansen proposed two different likelihood ratio tests of the significance of these canonical correlations and thereby the reduced rank of the Π atrix; the trace test and the maximum eigenvalue test, shown in equations 4 and 5.

$$J_{trace} = -T \sum_{i=r+1}^{n} \ln(1 - \lambda_i) \qquad 4$$

$$J_{max} = -T\ln(1 - \lambda_{r+1}) \qquad 5$$

One disadvantage of this model is that because it is particularly good at long-running relationships, it risks missing the periods of co-movement in the short-term relationships of markets for a short period of time after a crisis. But this can be addressed using a causality test that is designed to test short-run relationships.

3.3 VECM

Granger and Lee (1989) formulated the non-linearity in the adjustment mechanism or Error Correction Model (ECM). This representation was then developed by (Escribano, Pfann 1998) who considered that the linear ECM models are based on restrictive conditions as follows.

The uniqueness of the long-term equilibrium and adjustment with respect to the equilibrium is symmetrical. Yet according to (Masson 1999), during periods of crisis, financial markets may give rise to situations of multiple equilibrium, reflecting sudden changes in investor expectations with respect to the risk.

These carry out operations of re-adjustment and the reallocation of portfolios that thus move the market from a steady state to another. Also, and as has been suggested by several studies, the adjustment with respect to the equilibrium is asymmetric. The markets' reaction to the shock differs according to its positive or negative nature. (Escribano, Pfann 1998) shared the error correction term in the ECM model in two positive and negative parts such as:

$$z_{t-1}^{+} = \begin{cases} z_{t-1} \; si \; \Delta z_{t-1} > 0 \\ 0 \; \sin on \end{cases} \qquad 6$$

$$z_{t-1}^{-} = \begin{cases} z_{t-1} \; \sin \Delta z_{t-1} < 0 \\ 0 \; \sin on \end{cases} \qquad 7$$

This transformation allows for the creation of two situations of equilibrium, each characterised by a specific speed of adjustment. The first equilibrium of stability is captured by the term: z_{t-1}^{-}. Therefore, the new representation of the ECM is:

$$\Delta y_t = \sum_{i=1}^{p} \alpha_i \Delta y_{t-i} + \sum_{i=1}^{q} \beta_i \Delta x_{t-i} + \delta_1 z_{t-1}^{+} + \delta_2 z_{t-1}^{-} + \varepsilon_t \qquad 8$$

By testing the beta coefficient of the granger term $\sum_{i=1}^{q} \beta_i \Delta x_{t-1}$by Wald Test: H0: $\beta_1 = \beta_2 = \cdots = \beta_n = 0$, we will be able to know if the granger term has caused significant external induction to the indices of the BRICS.

Because there is structural break in all of the indices as illustrated on graphs in Appendix B, it is proposed to include a control variable to estimate the structural break that occurred during the last quarter of 2008, approximately when Lehman Brothers collapsed. It is proposed that a control variable of the announcement date of the recession in the UK is used representing the pre crisis period and post crisis period. The UK government announced the reality of recession in October 2008 and the control variable is set to 0 before the announcement date and equals to 1 after the announcement date.

3.3 Dynamic Conditional Correlation (DCC) GARCH model

The DCC GARCH model enables researchers to estimate the co-variance transmission mechanism between the sample countries. This type of model allows practitioners to construct a portfolio that can be forecasted using a set of co-variance based variables of asset returns. It is particularly important as the hedge ratio often changes according to the assets' co-variance and volatilities. Hence, this type of GARCH model is commonly employed by sophisticated traders and researchers.

We can specify a multivariate conditional variance as:

$$H_t = D_t R_t D_t \qquad 9$$

Where D_t is the (n x n) diagonal matrix of time-varying standard deviations from univariate GARCH models with $\sqrt{h_{ii,t}}$ on the ith diagonal, i = 1,2....,n. $R_t$is the (n x n) time-varying correlation matrix. The DCC model proposed by Engle (2002) involves a two-stage estimation of the conditional co-variance matrix H_t. In the first stage, univariate volatility models are fitted for each of the stock returns and estimates of $\sqrt{h_{ii,t}}$ are obtained. In the second stage, stock-return residuals are transformed by their estimated standard deviations from the first stage. That is: $u_{i,t} = {\varepsilon_{i,t}}/{\sqrt{h_{ii,t}}}$, where $u_{i,t}$ is then used to estimate the parameters of the conditional correlations. The evolution of the correlation in the DCC model is given by:

$$Q_t = (1 - \alpha - \beta)\bar{Q} + \alpha u_{t-1}u'_{t-1} + \beta A_{t-1} \qquad 10$$

Where $Q_t = (q_{ij,t})$ is the n x n time-varying co-variance matrix of u_t, $\bar{Q} = E[u_t u'_t]$ is the n x n unconditional variance matrix of u_t, and α and β are non-negative scalar parameters satisfying $(\alpha + \beta) < 1$. Since Q_t does not generally have ones on the diagonal, we scale it to obtain a proper correlation matrix R_t. Thus:

$$R_t = (diag(Q_t))^{\frac{-1}{2}} Q_t (diag(Q_t))^{-\frac{1}{2}} \qquad 11$$

Where $(diag(Q_t))^{-\frac{1}{2}} = diag\left(\frac{1}{\sqrt{q_{11,t}}}, \dots, \frac{1}{\sqrt{q_{nn,t}}}\right)$

Now R_t in Eq (11) is a correlation matrix with ones on the diagonal and off diagonal elements less than one in absolute value, as long as Q_t is definitely positive. A typical element of $R_t$is of the form:

$$\rho_{ij,t} = \frac{q_{ij,t}}{\sqrt{q_{ii,t}q_{jj,t}}}, i,j = 1,2,\dots,n \text{ } and \text{ } i \neq j \qquad 12$$

Expressing the correlation coefficient in a bivariate case, we have:

$$\rho_{12,t} = \frac{(1-\alpha-\beta)\bar{q}_{12}+\alpha u_{1,t-1}u_{2,t-1}+\beta q_{12,t-1}}{\sqrt{[(1-\alpha-\beta)\bar{q}_{11}+\alpha u_{1,t-1}^2+\beta q_{11,t-1}]}\sqrt{[(1-\alpha-\beta)\bar{q}_{22}+\alpha u_{2,t-1}^2+\beta q_{22,t-1}]}} \qquad 13$$

As proposed by (Engle 2002), the DCC model can be estimated using a two-stage approach to maximise the log-likelihood function. Let θ denote the parameters in D_t and ϕ the parameters in R_t, then the log-likelihood fund is:

$$I_t(\theta,\phi) = [-\frac{1}{2}\sum_{t=1}^{T}(nlog(2\pi) + log|D_t|^2 + \varepsilon_t' D_t^{-2}\varepsilon_t)]$$
$$+ [-\frac{1}{2}\sum_{t=1}^{T}(log|R_t| + u_t' R_t^{-1} u_t - u_t' u_t)]$$

14

The first part of the likelihood function in Eq. 14 is volatility, which is the sum of individual GARCH likelihoods. The log-likelihood function can be maximised in the first stage over the parameters in D_t. Given the estimated parameters in the first stage, the correlation component of the likelihood function in the second stage (the second part of Eq. 14) can be maximised to estimate correlation coefficients.

This DCC GARCH model has a number of advantages over the multivariate GARCH model. Firstly, it can potentially analyse a larger sample of matrices. Secondly, it has been tested that it is often more accurate for its estimation compared to the multivariate GARCH model and superior to other estimation models such as moving average methods.

4. Data

4.1 Descriptive statistics

Appendix A shows the descriptive statistics of the natural log value of the financial markets of the BRICS and the Anglo-Saxon financial centres. It is illustrated that Brazil has the highest mean value in the BRICS with 10.9326, while South Africa has the lowest mean value of 4.257997. South Africa in the meantime has the highest standard deviation, meaning that it has the highest risk of all five BRICS countries, with a value of 0.489503. In contrast, Brazil has the lowest standard deviation with a value of 0.197598. The number of observations was 972.

Appendix B shows the graphs illustrating the performance of the indices of all countries during 2007 to 2010.

Appendix C shows the DCC GARCH correlation graphs. It shows that in most countries, the DCC correlation was in high volatility in 2008 when Lehman Brothers collapsed. It also shows that South Africa in general has the highest correlation with the US market, while India appeared to have the lowest correlation with the US market. Apart from Russia, it appears that all five countries experienced an increase or no change of correlation since the credit crunch. South Africa experienced the highest increase of correlation with the UK market since the credit crunch.

Appendix D shows the DCC GARCH statistical model result and it shows that, apart from China, the correlation coefficients for the other four BRICS countries are mostly found to be significant. It means that there is an underlying financial linkage between the Anglo-Saxon financial markets and the BRICS.

Appendix E shows the VECM coefficient result and also the corresponding Wald Test and the announcement date dummy result. The VECM result shows that China, India and South Africa has significant result with the UK share index. Furthermore, Russia shows a slight contagion result in lag one with the US share index. This means that contagion was presence during the pre crisis period in most countries. It is also found that the dummy variable was found significant in South Africa and Brazil meaning that during post crisis period, contagion was presence from the US and UK for these countries.

5. Results

5.1 BRICS countries

Interestingly, apart from China, the other four countries in the BRICS have shown significant results in both the DCC GARCH and VECM models. This means that the null hypothesis for both models can be statistically rejected for the BRICS. The result means that the BRICS did not decouple from the Anglo-Saxon economies during the 2008 sub-prime financial crisis and, in fact, were fundamentally influenced by the developed financial markets.

The 2008 financial crisis presents the perfect environment to study the contagion because it is rare that financial crisis originates in the developed world. The nature and cause of financial crisis also fit into the theory of contagion that the financial crisis spread from the US to the rest of the world as a result of asset-backed securities being traded all over the world. The results of this research show that the underlying linkage between the US financial markets and the BRICS financial markets is particularly strong and might have become even stronger during this financial crisis. This can be seen from the DCC GARCH model: the correlation is generally high in the study period. The high level of correlation in the study period presented in the correlation graphs is no coincidence and they were the induced external shock that was caused by the financial crisis in the US. The shockwaves of the failing of the large financial institutions during 2007 and 2008, especially Lehman Brothers, were felt throughout the world and primarily resulted in the contagion of the sub-prime financial crisis.

The DCC GARCH models also noticed similar patterns between the UK and all five BRICS bloc countries. This could mean that the health of the banking industry in the UK was also a concern affecting the rest of the world, resulting in some form of contagion in the BRICS. The banking industry of the UK was also seriously damaged and a number of financial institutions were financially rescued by the government, affecting the confidence of the markets. This study has since confirmed that the linkage between the UK and the BRICS countries is also strong, particularly India and South Africa as they are part of the Commonwealth. Their business and financial linkages towards the UK are comparatively higher for historical reasons.

Although insignificant results were found in China, the DCC GARCH model shows that the collapse of the US and UK financial institutions had a negative impact on the Chinese financial markets. Data show a slight increase in correlations in both the US and UK graphs, meaning that in general there were negative impacts of the sub-prime financial markets but they were found not to be statistically significant.

Prior to undertaking the VECM model, all five countries were tested using the Johansen co-integration model and co-integrations were found in all five countries. This further corroborates the GARCH results that contagion was present during the financial crisis. Co-integration models are used to test the long-term equilibrium of data so that its presence means that the tested financial markets were all in long-run contagion during the study period. This is consistent with the literature that found evidence against the decoupling theory for the BRICS countries. This means that the BRICS bloc countries are strongly linked to the Anglo-Saxon economies and the recent financial crisis only made the underlying linkage stronger, as the DCC GARCH model has shown.

The VECM models show statistically significant results between the UK and the four BRICS countries China, Russia and India and South Africa. Compared to the DCC GARCH model, the VECM model did not show significant linkage between the BRICS and the US initially but has shown a significant result on the interest rate dummy variable meaning that the BRICS countries has shown some degree of contagion to both of the US and the UK market. The shockwaves of the collapse of major financial institutions affected global financial markets and resulted in the contagion of the financial crisis.

The resulting global recession has affected demand for imports in the developed world. This has caused a slowdown of growth in the export-led economies of the BRICS countries. This is particularly true to natural resources export countries like Russia, Brazil and South Africa where the contagion was found during the post crisis period. There was some insulation of contagion for manufactured and service export countries like China and India as these countries experienced a delay of slow down of economic growth that only occurred in the late stage of 2009. Hence the control variable that was set in 2008 did not manage to measure this. This resulted in the decreased level of investment and the outflow of liquidity in the financial markets of the BRICS countries. Therefore, the financial markets in the emerging economies faced significantly increased volatility, which resulted in slowdown and partial collapse in some regions. As a result, the capitalisation of the financial markets in the BRICS decreased and they also experienced a crisis directly caused by the sub-prime mortgage crisis in the US.

Secondly, the decreased price of commodities from mid-2008 also affected the confidence of the financial markets. This significantly affected the resource export-led countries like Russia, South Africa and Brazil. Hence the financial performance of the major enterprises that are listed in their respected financial markets decreased. Thus the performance of the index was affected, and confidence for the future was dented during 2008 and 2009 within the BRICS.

Thirdly, apart from China, the value of all four currencies depreciated against the dollar from 2008 as a result of low confidence in the midst of the recession. This somehow did not augment exportation for the BRICS; hence it caused major concern regarding the capacity to earn foreign currencies in the emerging countries. Furthermore, the depreciation of local currencies is one of the pieces of evidence of the outflow of liquidity of financial markets. This further caused the decreased value of capitalisation of the financial markets in the BRICS.

5.2 Comparison of models

This section will compare the findings for both the DCC GARCH model and the VECM model. VECM, instead of a conventional vector auto regressive model, is used when the model detects the existence of co-integration. In econometrics, it measures the internal shocks of lagged financial variables and also the causality of the external shocks. This thesis seeks to identify the external causalities that caused the contagion of the financial markets. Thus, as presented in the methodology section, the mathematical model of this VECM measures the impact of the lagged index data of the US and UK financial markets. This part of the VECM model can be compared to the granger causality model as it essentially measures the identical factors that might have caused the contagion. The VECM model is good at measuring the short-run equilibrium in the already identified long-run co-integration. The short-run equilibrium can be seen as the adjustment that might be needed for financial markets to stay in contagion. In this thesis, these identified short-run adjustments might be the decreased demand for exports, the decreased price of commodities and the depreciation of local currencies. These factors have all played a part in lowering the growth of the export-led economies of the BRICS countries, resulting in contagion from the Anglo-Saxon countries of the US and the UK. The collapse of the banking institutions in the US and the UK probably only had a limited impact on the BRICS countries as most of the literature reported that only limited exposure to the asset-backed securities was found in the banking systems within the BRICS.

In comparison, the DCC GARCH model predicts the correlations, measuring the strength of the underlying co-movement linkage between the financial markets of the US, the UK and the BRICS countries. In theory, the correlation of the financial markets can be argued to be background contagion as these are usually caused by the natural characteristics and the behaviour of the financial markets rather than significant external forces that can be measured by VAR and VECM models. It is also arguable that this underlying co-movement tends to be passive, hence the DCC GARCH model is an excellent tool to analyse and measure this underlying co-movement behaviour. Furthermore, most of the literature suggests that this co-movement can be developed through three traditional channels: financial, trade and competitive devaluation of local currency. In this thesis, these three channels will be analysed so that the results of the DCC GARCH model can be explained.

Financial linkage is the underlying co-movement behaviour due to historical and geographical reasons. Trade refers to the trading partnership and relationship that the financial markets may have, therefore affecting the performance of the organisations at the same time. The trade linkage can also be reflected through economic indicators and the relationship between the examined countries in their respective financial markets. This is particularly interesting as the economies of the export-led BRICS countries severely slowed during the recession as a result of the lowered demand for imports from developed countries. Competitive devaluation of currencies relates to the behaviour of emerging countries in which they may aggressively lower the foreign exchange rate in order to stimulate the export industry. During the study period, four of the five countries experienced the depreciation of local currencies. This has arguably had an impact on the correlation of financial markets through the reduction of liquidity mechanisms.

5.2.1 VECM

This sub-section will discuss the finding of the VECM model. As previously mentioned, VECM discovers and quantifies the external shocks by investigating the granger causality term in the equation. This thesis has identified a number of external forces that have dramatically increased the level of contagion between the US, the UK and the BRICS financial markets. These factors include the exposure of the toxic assets, the reduction of demand for imports from developed countries, the collapse of commodities prices and the depreciation of local currencies. This sub-section will discuss these findings that were generated through the VECM model.

Lehman Brothers and other financial institutions

The initial shock of the global financial crisis was the collapse of the major financial institutions in the US and the UK. This sent a shockwave through the world such that many large multinational financial institutions required governmental rescue. Many other lesser affected institutions also needed significant investment injection to either repair the balance sheet or re-capitalise. Although most of the literature suggested that the exposure of toxic assets for the banks within the BRICS was limited, the indirect effect of the trading of CDOs and other securities means that they were also under significant pressure to re-capitalise balance sheets. Asian banks, like India's, came out of the crisis in better shape compared to other geographical regions because they had implemented measures during the Asian Financial Crisis in the early 2000s and these measures limited exposure to toxic foreign investment. In China, the trading of asset-backed securities was only recently introduced and this further insulated it from the crisis. Indeed, according to The Economists, four of the top ten most capitalised banks are Chinese.

In Brazil, due to historical and inheritance reasons, banks are strongly linked to Spanish institutions and exposure to the crisis for Brazilian financial institutions was very indirectly coming from continental Europe. Countries such as Russia are also more traditionally closely linked with Europe than with the Anglo-Saxon economies. Hence, the finding of this thesis is consistent with the literature; there was only a limited exposure to toxic assets for the financial institutions located within the BRICS. Therefore, the causality of the collapse of the US and UK institutions, although found to be significant, was considered to be small in the VECM model.

Reduction of demand of import from industrialised countries

The success story of the export-led countries employed by BRICS in the early 2000s to the present has raised questions about whether the emerging countries have decoupled from the industrialised countries. Many of the smaller countries and to some extent the western countries were looking at the secret of the BRICS because the export-led economies had been delivering near double figures of growth for BRICS members. Export-led growth countries were also able to turn a budget deficit into budget surplus, particularly in Brazil and Russia. In China the sheer size of the exports accumulated a significant sum of foreign reserves.

However, the answer to this question has been provided during this financial crisis: manufactured goods have to be consumed and if developed countries cannot do so, the economies of these export-led countries will suffer. The resulting recession in the developed countries has impacted the confidence of the consumption. This affected the desire of the western countries, which directly resulted in the decline in demand for the manufactured goods and services provided by the BRICS. As a result, the service industry in India recorded an export decline of 60% to the US and a sharp decline of growth for China also was recorded.

This affected the performance of export-led companies and the confidence of the financial markets as the recession in the West slowed the economies of the BRICS substantially. In China, the government resorted to increasing domestic consumption by using a stimulus package. This created a cushion for the manufacturing sector in China, hence reducing the decline of employment opportunities and utilising the reserve capacity in the factories.

Collapse of commodities prices in mid-2008

While China and India are manufactured goods and service export economies, Russia, Brazil and South Africa are natural resources export countries. In these countries, over a quarter of the GDP is related to the export industry of natural resources and this sector is the major earner of foreign currencies. The financial markets in these countries are dominated by petroleum and multinational mining companies, which also have significant influence upon the national interests as well as respective indices.

Hence the BRICS not only suffered a major setback with the decline in demand for exported manufactured goods; Brazil, Russia and South Africa also suffered significantly during mid-2008 when the price of most of the commodities collapsed. This directly resulted in a decline in the performance of the indices, affecting the confidence of investors investing in the long term in these multinational companies. The indirect impact of lowered employment and investment opportunities spread among the export sector, resulting in a lowered growth of the national GDP and affecting the respective indices. This resulted in a prolonged period of high volatility, low growth opportunities and ultimately the contagion effect from the US and UK financial markets.

Outflow of liquidity

During the early part of the financial crisis, the financial markets in the developed world were suffering a liquidity crisis as a result of sub-prime mortgage events. Financial institutions in the US and the UK were instructed to rebuild their balance sheet by recapitalising. Hence, they were selling assets to replace the toxic assets on the balance sheets. The emerging markets became a very attractive region for recapitalising as this region represents some of the most liquid markets, like China and Brazil. The assets within the BRICS are also very attractive to investors for a number of reasons. First of all, they are also very liquid and can turn back to cash easily. This is very important for struggling banks as time was crucial to regain the confidence of investors. Secondly, and maybe most importantly, these assets are insulated from the toxic assets in the US and the UK. Due to local fiscal regulations, the exposure to toxic assets was found to be limited by most of the literature. Thirdly, the risk premium in the emerging markets has become lower compared to the US and the UK markets. This ensures that the assets in the emerging markets are very attractive for opportunistic investors. As a result, financial markets in the BRICS experienced a drain in liquidity, and hence an increase in volatility and decrease in value. Furthermore, some of the literature has found that individual and institutional investors may sell off BRICS assets to repay the margin that they might have lost when the US market collapsed in 2008. This affected the financial markets and increased the contagion effect.

5.2.2 DCC GARCH

The DCC GARCH model predicts the correlation of two financial markets over a period of time. As previously mentioned, the contagion that the DCC GARCH estimates consists of three channels and this sub-section will discuss these channels.

Underlying financial linkage

This channel measures the passive linkage between two financial markets depending on the characteristics and the behaviour of investors in the local region. The DCC GARCH model is useful to estimate this passive contagion channel as it uses the historical return and correlation to predict the time series' present correlation. It can take into account the relatively unknown and hard-to-quantify historical characteristics of local markets. These historical and present characteristics can be factors like cultural inheritance, fiscal policies, governmental regulations, the behaviour of local and foreign investors, political position within the geographical region and other hidden / passive relationships between financial markets such as treaties.

Governmental regulations is a popular topic to be discussed in literature that result in a contagion effect to a particular financial market. In emerging countries, there is often regulation restricting the outflow of investment, such that profits may be reinvested back to local regions or communities. In Asian countries like China and India, governmental regulations have been amended since the Asian Financial Crisis in the early 2000s such that there is insulation to this channel of contagion. Financial markets and fiscal are also heavily regulated in Russia to prevent an outward flow of investment. There are similar governmental policies, to a lesser extent, in Brazil such that there is a restriction of the outflow of liquidity in respective financial markets. However, in South Africa regulations are relatively weaker; hence, the contagion effect is relatively strong compared to the other four countries. The regulations are not adequate enough to prevent a withdrawal from investing countries. Thus, South Africa experienced a stronger decline of market capitalisation compared to the other four countries and a much stronger contagion effect.

Trade linkage

This channel is particularly important to the BRICS as an export-led growth strategy has been employed. All five countries are in the G20, showing the significance of the trade for global importance too. There is a positive relationship between trade and correlation of financial markets because the performance of trade will affect both markets. The healthy growth of trade for both markets will also increase the confidence and the capitalisation of financial markets. This will ensure that the financial markets will grow together, resulting in a higher correlation and contagion effect at the end.

For example, Russia has a lower correlation with the UK compared to India because of the traditional heritage and business partnership environment. India belongs to the Commonwealth and has been the beneficiary of the outsourcing exercise that the UK has been doing since the 1990s. Hence businesses in India are highly integrated with the UK economy compared to Russia. In contrast, Russia's economy depends on the exportation of natural resources to Holland, Germany and Eastern Europe and only 6% of natural gas is delivered to the UK. Similarly, the business relationship between the UK and Brazil is relatively immature compared to India and South Africa. The majority of the oil products from Brazil would be delivered to the US and China. Hence the correlations of Russia and Brazil found by the DCC GARCH model are insignificant and low when compared to India and South Africa.

Currency devaluation

In mid-2008, four of the BRICS currencies apart from the Chinese Yuan experienced a sharp depreciation against the dollar. Although this was not intentional and not enough to start the devaluation war against each other, this effectively became a competitive devaluation of local currencies to boost export. On the other hand, the Chinese government employed a strict policy of not allowing the Yuan to appreciate despite pressure from the US. This has further weakened the demand for Chinese exports and the growth of the Chinese GDP has fallen below a single percentage digit for a decade. As a result, the trade link between the Chinese and the world weakened when exports became less competitive compared to the rest of the BRICS.

Because of this, most of the literature has argued that Chinese contagion through this channel has been weakened. This is due to the fact that the Yuan became less competitive compared to the other four BRICS countries, affecting the trade channel as discussed previously. Together with the strict government policy for foreign investment and relatively limited exposure to the toxic assets, this has formed a further insulation layer for China to move with the US and UK markets. Therefore, the contagion effect experienced by the Chinese markets was small and insignificant.

6. Conclusion

Contagion has been an interesting subject to study during the recent 2008 sub-prime financial crisis as it is rare that a crisis originated from a developed country. From this paper, we have gained an understanding that the contagion effect was present and has affected most of the BRICS countries apart from China. Therefore, the decoupling theory that some of the literature maintained was not conclusive, as the economies of the emerging countries possessed underlying links to the US and the UK markets. This paper has found that, although the model of the BRICS economies is different from that of Anglo-Saxon countries, the underlying financial linkages are too strong for economies to have decoupled.

This paper has studied two models of common econometrics to analyse the contagion effect. The researcher has made a comparison between what the models measure and what they mean in the contagion study as well as the decoupling–recoupling theory. The correlation found by the DCC GARCH model is that the linkages between these countries are still very high and became even higher during the financial crisis. This is because the negative impacts of the turmoil that occurred in the western economies filtered into the BRICS bloc and resulted in a significant downturn in the financial markets. This has been confirmed in the discussion section: the trade linkage and currencies linkage are also very closely related across the studied countries. The external shock that was analysed in the VECM model enabled us to conclude that the fall in demand from industrialised countries dented the growth of the export-led economies of the BRICS. This analysis concluded that the global economies are strongly linked as the export-led economies must find countries to buy their goods and if demand for these goods falls, so does growth in the economies of the BRICS.

This paper investigates the links between the performances of Japanese Yen (JPY) and disasters through the insights of the event study framework and several econometrics methodologies. We further examine the transmission channels among several finance and macroeconomics activity variables during the post-disaster period. Empirical findings demonstrate the duration of the impact of disasters on the JPY and indicate the suitable timing for hedging JPY. In addition, a guideline for speculators and investors to construct a long-short term portfolio setting is suggested by our procedure and resulting evidences.

1. Introduction

Japan experienced the catastrophic Tohoku earthquake and its resulting tsunami in March, 2011. This disaster broke out in the northeastern part of Japan, which area makes up 7 % of the GDP of Japan. According to the report investigated by World Bank, this disaster results in the loss of Japan as high as $235 billion dollars while the Japanese government assessed that it would be close to $300 billion dollars and requires at least 5 years to rebuild. Besides, the dangerous reactors of nuclear power plant Fukushima also exist as a threat to the health of most Japanese. In other words, this disaster played a destroyable role for Japanese Economy.

In fact, Japan is a country suffering many natural disasters, including earthquakes and tsunamis. These facts, in general, easily infer a pessimistic forecast for the future economy of Japan. Furthermore, since the patterns of financial markets are strongly correlated to the economic activities, thus, most investors would like to know what the currency or stock market will act like for the following days after this disaster.

Taking New Zealand as an example, this pacific country lost the advantage of its exchange rate when it was rocked by a heavy earthquake, owing to its exportation dominated economy. Nevertheless, when we observe the reaction of Japanese Yen (JPY) to Tohoku earthquake, an interesting fact could be noted as follows: JPY dropped sharply as much as 0.4 per cent on average against the top counterparts initially, then it rebounded and rose up even more quickly, which once climbed to 76 against the US dollar, approaching to the peak where the currency ever achieved after the World War II. Hence, we look back to historical Japanese nature disasters in the past 20 more years and report the links between the performances of JPY and those disasters in Figure 1.

As a matter of fact, the literature investigating the impact of the disaster on JPY has been so far rather limited, even though financial practitioners have observed that the appreciation of JPY in the aftermath of the disaster recently. Some recent contributions analyze the impacts of risks of rare natural or economics disaster on asset prices, economics development and economic growth. Toya and Skidmore (2007) use disaster impact data over time to examine the degree to which the human and economic losses from natural disasters are reduced as economies develop.

Arnason (2011) investigates the paradox of nature disasters leading to economics growth by the case of the Touhoku earthquake and find that Japan is likely to experience growth following the earthquake. More importantly, Wang (2013) examines the impact of Japanese natural disasters on stock market by GARCH and GARCH-in-the mean models and indicates that natural disasters do not have a linear impact on Japanese stock return.

Thus, based on those evidences, we put our interest in explaining the seemingly paradox of natural disasters effects on JPY. Meanwhile, two further issues are also arisen here: (i)on average, how many days after the occurrence of the disaster does the disaster start to affect JPY significantly? (ii)what do the transmission channels display among several finance and macroeconomics variables , such as Japanese central bank (BOJ) intervention, Japanese risk free rate, Japanese stock market index and the interest rate differential between the Japan and U.S., etc. during the post-disaster period?

To address the above issues, in this paper, we employ PROBIT, LOGIT models widely used in literature and COAR-MLE estimation proposed by Wang et al. (2014 b) using the event study analysis. Perhaps the first published event study is Dolley (1933), which examines the price effects of stock splits by studying normal price changes at the specific time of the split. Afterwards, the event-study approach has been applied to a variety of firm-specific and economy-wide events in the academic accounting and finance field (e.g., Campbell et al., 1997; Mackinlay, 1997; Bernanke and Kuttner, 2005). The usefulness of such an approach comes from the two facts: (i) the effect of an event will be reflected immediately in asset prices; (ii) the event's economic impact can be measured using asset prices observed over a relatively short time period. Because the disasters considered in this paper, including earthquakes, typhoons and storms, are special shocks which impacts on asset prices would be expected to die out as time goes on, using the event study approach is able to explain the effects of such specific shocks on financial markets or economy more accurately. Briefly speaking, the event study approach could not only capture more accurate effects causing by specific shocks, which usually are easily ignored and missed when considering the general regression research or direct measures on whole samples of historical data, but also filter the effect and shock-unrelated noises arisen by whole samples. In addition, the selection of estimation window size is the key point for the event study approach. Since in general the impact of disaster on asset prices is the short run effect and lasts for around one month long, the estimation window size we consider in this paper is set by from 1 to 22.Furthermore, by adjusting the event estimation window size, we could conclude that around which day after the disaster, the disaster starts to affect the financial market and economy or how long such effect of disaster last for intuitively.

The literature focusing on the issues of finance and monetary policies using PRO BIT and LOGIT models has grown up rapidly for recent years. Nyberg (2008 a) predicts the direction of monthly excess stock returns using the binary dependent dynamic PROBIT model as wells as Nyberg (2008 b) examines various financial variables as predictors in new dynamic PROBIT models to predict the probability of a recession in the United States and Germany. Xiong (2012) considers an ordered PROBIT analysis to measure the monetary policy stance of the People's Bank of China.

One important issue that is pervasive in the time series literature is the danger of obtaining spurious correlation findings proposed by Granger and Newbold (1974) and Granger et al. (2001). A spurious correlation occurs when a pair of independent series, each of them non-stationary or strongly autoregressive, are found apparently to be related according to standard inference in an OLS regression. Wang et al. (2014a) develops a new estimator, CO-AR estimator, to solve spurious regressions by applying a two stage generalized Cochrane-Orcutt transformation based on an autoregressive approximation framework, even though the exact forms of error terms are unknown in practice. However, GARCH effect is not taken into account in this work. Without the loss of generality, based on the framework of CO-AR estimation, Wang et al. (2014 b) suggest COAR-MLE estimation for spurious regression with GARCH effect. Since many finance and economics variables displaying I(1) or near I(I) processes where the AR/MA coefficients is closer to 1 (see Ferson et al. , 2003) could result in spurious correlations , thus we employ COAR-MLE estimation to analyze the relationship between JPY and other finance and economics variables during the post-disaster period.

The main findings of this paper can be summarized as follows. First, we suggest the transmission channels among several important finance and economics variables during the post-disaster period, because these channels can guide the investors to build up a portfolio after the disasters. Furthermore, on the basis of event study analysis, empirical results show that on average, several variables begin to affect the JPY significantly at around the 10th day after the disaster whereas the BOJ intervention occurs earlier, i.e. at the second or third day after the disaster. This finding is consistent with the observable fact that the BOJ usually intervenes JPY after the disaster to rebuild the economy. Most importantly, during the post-disaster period, the performance of Japanese stock index is negatively correlated to that of JPY. The possible explanation of this phenomenon is to sell oversea assets to obtain more JPYs for the sake of rebuilding economy. Moreover, this result overturns the finding of Wang (2012), since we could discover the direct link between the disaster and exchange rate return based on our econometrics analysis.

Second, the impacts of disasters on financial markets and economy are short run effects, thus those empirical findings and behaviors of assets would be formed as the trading or heading guideline for speculators and investors, because the duration of the disaster effect implies the timings of entering and leaving financial markets and the varying coefficients representing the relationship between the JPY and several variables provide the information for portfolio selections. Third, compared to the analysis of the event study approach, we further consider the convention regression scheme on whole samples where we denote the earthquake as the dummy variable. We set it equal to 1 when an earthquake occurs, otherwise we set it equal to 0. Similar to the spirit of the event study approach, the event estimation window size of this dummy variable is adjusted from 1 to 22, i.e., from the first day on which the disaster happens until the 22th business day after the disaster. That is to say, when an earthquake occurs, we denote this variable as 1 and adjust it until 22 days after the disaster. Through this methodology, we could explain the appreciation of JPY in the aftermath of the disaster in a long run framework. More importantly, the most patterns of the relationship between JPY and those considered variables are different from those for event study approach which indicate the short run performance for the relationship among those variables. For example, the coefficient of the stock index in the relation to JPY becomes positive in most cases when we use dummy variable analysis on whole samples. That implies that in the long run, even the issue of earthquake is considered, the stronger the Japanese stock market, the stronger the Japanese Yen. In other words, our empirical findings provide the short and long term information for the correlation between JPY and those considered variables during the post-disaster period. Moreover, these results indicate the insights of hedging and portfolio selections and by which we could form a long-short portfolio setting.

The follow-up of this paper is organized as follows. Section 2 illustrates the event study approach and econometrics methodologies considered in this paper. Section 3 presents the data summary and variable selection. Empirical findings are reported in Section 4. Concluding remarks are in Section 5.

2. Models and Econometrics Methods.

2.1. *Event Study Analysis*

In this paper, natural disasters are treated as events and its unexpected occurrence is believed to cause exchange rate market to fluctuate in the aftermath. So here we introduce the event study framework, which has been widely used in economics and finance studies. Event study is used to measure the impact of events that usually take very short time on economy, assuming market rationality would absorb information of events in enough time. Applications of it includes acquisitions and mergers, announcements of macroeconomic variables and other short effect issue caused by all kinds of events. Natural disasters treated as events are easily to be quantized, and it works under the assumption that these disasters' shock on finance market is of same magnitude, namely nationally here though those disasters counted in this paper may strike Japan in different regions. Such disasters are surely unexpected, and its information should not be included in prices of market ahead of its occurrence.

After the disasters happen, what is more interesting is how long the market of exchange rate takes to absorb information of effects of disasters on economy. Therefore our event study framework should deal with two issues: what effects are responsible for fluctuations of exchange rate in the post-disaster period and the durations of these effects.

The first issue is normal as in general event study and we are looking to event window directly, ignoring special abnormal returns during the post-disaster period. However, for the second issue we denote the duration problem by a special way. To be specific, we don't fix the size of event window but vary it in a range from 1 to 21. That remarks a period which begins just on the date when the natural disaster occur but ends in different days as long as 21. So for each models we have 21 different cases concerning the window size, and a comparison between these cases is able to give us a hint on the duration process. Firstly, by implementing the event study with different event window sizes, we are able to uncover the possible time varying features of coefficients in the model, thus deducing dynamic effects of natural disasters on the exchange rate models as time goes on. Secondly, the significance inferred by p value is an indication of the duration of the disasters' effects, equivalently as how long coefficients in the models keep influences. Indeed an intuitive finding is p values of coefficients in models, with a guideline that coefficients changing from significantly to insignificantly or other way around.

2.2. *Econometrics Methods*

According to the Figure 1, we could find in most cases, the JPY appreciates following the disaster. It implies the power of buying the JPY is stronger than it of selling the JPY during the post-disaster period. To address this issue, we need to examine how likely several factors caused the change of the JPY. We first employ two commonly used binary dependent variable methodologies, PROBIT and LOGIT methods, to test for the relationship between the probability of positive JPY returns and those factors. These methods can give us hints on the conditional probabilities of specific events. In this study, we take the sign of JPY returns as binary dependent variables. We denote the positive and negative returns of JPY as 1 and 0, respectively. Therefore, the general model for the two methods can be written as,

$$y_t^* = X_t'\beta + \varepsilon_t$$

$$y_t = \begin{cases} 1, & if\ y_t^* < 0 \\ 0, & if\ y_t^* \geq 0 \end{cases}$$

Where we denote y^*_t as the return of JPY/USD, the negative part of which corresponds to the appreciation of Japanese yen, and its resultingyt as 1 .In addition, which of them we should use depends on the distribution of error term ε_t. Under this condition, our focus becomes what sign and magnitude of β can fit the likelihood of value of y_t.

Here what distribution ε satisfies decides whether we use PROBIT or LOGIT models, since the former indicates ε is of normal distribution and the latter of logistic distribution. Usually maximized likelihood estimation is employed for estimation and test for PROBIT and LOGIT models, and though coefficients of the two models for same data sample may be different, the marginal effects inferred by the estimation of coefficients should be similar.

In this case of modeling time series data, there may exist some problems in econometrics. A more accurate measurement of the post-disaster effect is by regression on returns. The data collected from financial market are well known to be highly persistent, and in this case as an example, the Box–Jenkins tests of data of exchange rate, bond and stock markets all indicate they are auto-correlated and may still have features of I(1) though differencing has already changed the nonstationary to the stationary. Based on Granger (1974), the serial correlation is therefore likely to cause the spurious regression problem under the traditional OLS, as a result of which the regression statistics can over reject null hypothesis. To cope with this kind of problem, Wang et al. (2013) propose an estimation using two stage Cochrane-Orcutt Autoregressive (CO-AR) methods, which fit data of AR(p,q) and ARIMA(p,1,q) both well. Another contribution of Wang et al. (2013) is that their estimation can also keep valid convergence rate after modifications referring to heterogeneity feature of data that is usually modeled by GARCH(m,n). Therefore they further advise to include GARCH effect in modeling financial data and estimate it by maximum likelihood estimation with their COAR method, thereby COAR-MLE. Here to avoid the wrong conclusion by spurious regression problem, we follow Wang et al. (2013) in the usage of COAR-MLE. For the linear models we are discussing, the two-stage CO-AR method is conducted like this: the first step is to estimate the standard OLS coefficients to obtain the OLS residuals $\hat{u}t = yt - xt'\beta$ And to remove the serial correlations, we fit an AR(k) process to the OLS residuals $\hat{u}_t$, where the order of k is selected by AIC. In this sense,

$$u_t = \sum_{j=1}^{k} \hat{b}_j \, u_{t-j} + \hat{e}_{tk} + o_p(1)$$

After estimating coefficients in AR(k) for OLS residuals $\hat{u}_t$, we similarly filter y_t and

x_t and get,

$$y_t^* = y_t - \sum_{j=1}^{k} \hat{b}_j \, y_{t-j} \text{ and } x_t^* = x_t - \sum_{j=1}^{k} \hat{b}_j \, x_{t-j}$$

Our next step is to estimate the new models of y_t^* and x_t^*, and as we discussed given the GARCH effect MLE should be employed to obtain the consistent estimator $\hat{\beta}_{COAR-MLE}$. Wang et al. (2013) proves that this new estimator is consistent at rate $T^{1/2}$ and asymptotically normally distributed without having to estimate the long run variance. So we can build convergent t statistic t_β as

$$t_\beta = \frac{\hat{\beta}_{COAR-MLE}}{S_{\hat{\beta}}} \xrightarrow[d]{} N(0,1)$$

Where $S_{\hat{\beta}}$ denotes standard errors for estimators. It is believed that with this new estimation, the duration process can be reflected relatively accurate.

3. Data, Key Variables, and Summary Statistics

3.1 Data Description

The frequency of data is daily and following the traditional wisdom in research of exchange rates, our models employ variables in the model form: $s_t = s_{t-1} + c'Z_t + u_t$, where$s_t$ denotes the exchange rate of U.S. dollar against Japanese yen, Z_t is the information set investors can obtain currently and u_t is the white noise. Our analysis indicates in the aftermath of natural disasters, Japanese yen would appreciate and therefore to verify this hypothesis we are more interested in situations when $s_t - s_{t-1} < 0$, which is equivalently as U.S. dollar depreciates in the value of Japanese yen. As a result, in our framework of PROBIT and LOGIT models we set the dependent variables equal to 1 if Japanese yen appreciates otherwise zero.

In financial market, mean reversion is believed to exist generally, which indicates price has the trend to come back to the moving average level though with some fluctuations. Thereby it is believed that in the FX market, how far prices are from the average level would cause influence on the price next period. An aim of this paper is to explore the market efficiency, which can be tested by whether historical prices are taken into the change of current exchange rate. So we include deviation of exchange price from the moving average level in the information set Z_t. Indeed the average level of exchange rate is usually referred to as targeted price level by which central banks decide whether to intervene in market. There is a large amount of literature discussing how to compute the moving average by choosing the window size to average. LeBaron (1999) justifies a term of 150 days as a very common choice among market traders, which is verified by Kim and Sheen (2002) again. While Ito and Yabu (2007) suppose that the long-run target can be only useful if approaching as long as five-year moving average. But Chen, Chang and Yu (2012) point that the short-term deviation is highly correlated to the three-year-term and five-year-term deviations. To circumvent the possible multicollinearity problem, here we follow Chen, Chang and Yu (2012) to set up three types of targets, in which the short-term is defined as target for the previous day's exchange rate, the medium-term target for the previous month's moving average rate, and the long-term target for the previous150-days' moving average rate. The exchange rate deviation on date t is then defined as the exchange rate difference between the previous-day rate and any potential target rate. Namely we have the following dependent variables, Short-term deviation: $\mathbf{SDEV}_t \equiv s_{t-1} - s_{t-2}$

Medium-term deviation: $\mathbf{MDEV}_t \equiv s_{t-1} - \frac{1}{21}\sum_{i=1}^{21} s_{t-1-i}$

Long-term deviation: $\mathbf{LDEV}_t \equiv s_{t-1} - \frac{1}{150}\sum_{i=1}^{150} s_{t-1-i}$

We categorize our models in three kinds by dependent variables included in the information set Z_t concerning these three types of deviations. To be specific, from the view point of investors, other dependent variables being fixed inZ_t, the models can have three types: (1) without historical information of FX price, (2) with the price information of last day's exchange rate as $\mathbf{SDEV}_t$,(3) with short, medium and long term price information together and that is to include $\mathbf{SDEV}_t$,$\mathbf{MDEV}_t$and $\mathbf{LDEV}_t$simultaneously. This methodology of categorizing is able to test investors' dependence on historical prices. In case of type (1), no historical price information is included suggesting investors in the market don't look back in the past exchange rate level; while in type (2), it is assumed that investors would account on historical price but only in short term which requires the past information would quickly die out; at last in type (3) the market considers complete information of historical prices and thinks its effect would last.

The rest of information set Z_t are the same for all models, including intervention by the central bank, Japanese risk free rate and its difference from U.S. risk free rate, Japan stock market index. The variable (INT) denoting amount of currencies central bank transacts in the market, which is triggered when the degree of deviation of exchange rate price the central bank think is too far from the target. In the short term after natural disasters, it is normal that market would develop fears about the local economy and thus follows the fluctuation in FX market. And to stabilize the market, government usually responses by selling or buying assets. On one side, Japan ranks the second in the amount as holder of U.S. treasury bonds and that enables the government to have strong power to provide liquidity to markets. On the other side, measures from the government are also indicators of serious deviation in market. It can thus be inferred behaviors of central banks are to some degree responsible for the change of exchange rate. Such intervention by the central bank is generally not often, yet they happen frequently around those natural disasters so that they should have power on the post-disaster price of exchange rate. So we put that in the information set as an independent variable. The information set also includes Japanese call money interest rates in addition to its difference with the U.S. Federal Funds rate, and we denote them by JPI and SPR respectively. The former is to measure the actions of domestic bond market while the latter compares that with overseas bond market. The two variables measure how finance investing environment changes in the special post-disaster period influence investors' attitudes to hold yen financial assets. Normally investors in Japan's market should be sensitive to rise of Japan's interest rate since it has been touched the bottom, and speculation motivation also warns them against violation of interest parity of Japan with other countries. However, such facts are more likely to hold in the long run, while for some short periods, for example in the disaster case, those natural disasters may lead investors to ignore the difference in bond markets since those related to Japan are usually relatively steady. Therefore it is interesting to check if relatively steady interest markets can calm the fear in the market of exchange rate. Another factor often related to the change of currency value is stock index representing development of domestic economy. Economic fundamentals of Japan are the final attractions of capital flow and the core dynamics to produce profits of yen assets, so if natural disasters cause big changes in the economy, disrupting the production of local industry and declining exports, such turbulence should also fluctuate the exchange rate market. Stock markets are proved to correlate highly with economy in Japan. So testing on stock index acts as a representation of tests of economy's correlation with exchange rate. Hence we use performance of Nikkei 225 stock index to measure the effect of disasters on economy and define $\mathbf{NIK=100 \times \Delta Ln(Nikkei_t)}$ as an independent variable. Indeed by JPI, SPR and NIK we are able to present capital inflow in finance and industry of Japan, and since they support the profits of yen assets, they must be prior considerations of the currency investors.

Besides, we treat dates when disasters break out as a dummy variable which also determines size of event window. These disasters contain earthquakes and typhoons, most of which produce effects obstructing the district or whole country's economy development. What's more, we count the sarin attack on the Tokyo subway, which is the most serious social accidents during the latest decades. It somehow causes the national fear of terrorist attack from the heresy, and disrupts the people's life as well as the economy. To give us a hint on duration of effects on exchange rate of natural disasters, the dummy standard is varying. Generally we set dummy valued at 1 only in the duration period which begins at the date when disasters break out. The durations can last from 1 day to 21 days and thereby provide 21 different window sizes for each model. In event study, the dummy is not in the model but it determines the event window while in our common case it is taken in. In addition to the advantage of excluding the possible weak effects of financial data, we can assess how long the information of unexpected disasters can keep in the financial markets. The intervention data are from Ministry of Finance of Japan, and we collect other financial data from DATASTREAM. We count the disasters by dates they happen, which is listed on what. The sample consists of daily observations of 5964 business days from 1991/04/01 to 2014/02/06.

3.2 Summary Statistics

We compute the returns of the raw price data of exchange rate market and equity market due to their generally accepted unit root features, by which we get new variables "Return=100 ×ΔLnSt" and "NIK=100 ×ΔLn(Nikkei$_t$)". This process gives us advantage of explaining appreciation of currency. For the price of exchange rate of U.S. dollars against Japanese yen, a negative return should match our interest that is the appreciation of yen. Similarly, we difference the logarithm of Japan's daily call money rate to smooth the domestic risk free interest rate as usually processed.

A brief description of data corresponding to variables is provided in the table 1. A note that should be noticed is that we diversify the central bank's intervention in models by setting INVS, INVB and INVT. The first variable denotes the intervention amount by selling Japanese yen while the second variable that by buying Japanese yen. In this sense, they are all positive values. Yet in the third variable, INVT, we construct it by the combination if INVS and INVB, however, where selling corresponds to negative value and INVB to positive value. Such further step is necessary since no INVB happens in the shortly aftermath of natural disasters as we search the data, thus giving us convenience to focus on INVS. While in treating the whole data sample, we should still deal with both selling and buying measures that are responsible for changes of currency values. Table 1 shows historically INVS works in more amount as far as 8072.2 billion yen, which reflects the recent stimulations led by government to the economy. Interest rate of Japan bond (RJPI) stays in a low level, and that makes the difference of it between U.S. interest rate keeps negative almost. Disasters happen in a frequency of 0.006. Considering those natural disasters are almost all national, it supports the aim of this paper that disaster issue should be cared about in investing in Japan's market.

We also need to impress here that in part of price deviations, we increase the magnitudes of SDEV denoting the short term price deviation to make it comparable to middle and long term price deviation in effects on yen's appreciation. To copy with nonstationary feature in financial time series, we firstly apply unit root test to the data to decide if further steps to transform stationary to nonstationary. Now we test the existence of unit root in the data by ADF and Phillips-Perron tests, with the latter robustly checking the former's results in case of autocorrelations of regressors in models. The results are as following.

Variable	Test	
	ADF	Phillips-Perron
return	-77.12694***	-77.15662***
SDEV	-76.52645***	-76.53559***
MDEV	-15.32467***	-15.86783***
LDEV	-5.415275***	-5.523307***
SPR	-1.049913	-3.28208
JPI	-7.376933***	-7.318696***
NIK	-79.42736***	-79.60225***

The results shows that all variables except SPR reject null hypothesis of having unit roots. To match the integration order, we need to first difference SPR, namely the spread of Japan's and U.S. interest rates.

4. Empirical Findings

We estimate the effect of Bank of Japan's intervention (INVT), the spread of Japan's call money interest rate minus US Federal fund interest rate (SPR), Japan's call money interest rate (JPI) , the growth rate of the Nikkei 225 stock index (NIK), the short term deviation from previous one day moving average (SDEV), the medium term deviation from previous one month moving average (MDEV), the long term deviation from previous half-year moving average (LDEV) on day t-1 on the change of the Japanese Yen/U.S. Dollar (JPY/USD) foreign exchange market on day t by the PROBIT, LOGIT, OLS, and COAR models for the sample from the event period chosen as the event window [0, 1], [0, 2],...,[0, 22]. During the event periods for 35 events, the volatilities of the JPY/USD foreign exchange market is not significant different from each other. We thus use OLS and COAR without considering the GARCH error terms. But for the whole sample period from 1991/04/01 to 2014/02/06, we include an additional dummy variable DISASTER to indicate the event periods in the regression and employ GARCH and COAR-GARCH to consider the possible different volatilities of the event periods and the non-event periods in the JPY/USD foreign exchange market. We report the results for event window [0, 10] only Table 2 and for all the event windows from [0,1] to [0,22] in Fig. 2.1 - Fig. 2.6 for the short term and Fig. 2.7 depicts time varying feature of DISASTER variable for the long term.[1] We estimate three models as described in previous section: The first model is Model A which is without historical information of FX price. The second is Model B with the price information of last day's exchange rate as $\mathbf{SDEV}_t$,. The last model is Model C is with short, medium and long term price information together and that is to include $\mathbf{SDEV}_t$, $\mathbf{MDEV}_t$ and $\mathbf{LDEV}_t$ simultaneously. The results are quite similar. Therefore, we just report the estimated results for Model C which includes all the historical price information.

4.1 Short run vs. long run for event window [0, 10]

In Table 2, we report the results from the short run and long run data based on the event window [0, 10]. They are significantly different based on the same econometric methods. For example, INVT is insignificant for all econometric models in the short run dataset, but it is very significant in the long run dataset. Another example is JPI. JPI are very significant for both cases, but it has positive sign for the short run dataset, while it has negative sign for the long run dataset. For S_DEV, it is significant for all econometric models for the short run data, but S_DEV becomes insignificant when the econometric models are GARCH and COAR-GARCH. Therefore, it is interesting to note that the short run reactions from INVT, JPI, NIK, and S_DEV is different those of the same variables. The results from GARCH and COAR-GARCH are

[1] Here for the long term we just show the figure of time varying coefficient for the DISASTER variable because other variables have not significant variations as event window become large. However, the figures for these variables are on request..

quite similar in the long run effects because all of the independent variables are stationary, In other words, the independent variables of GARCH model are stationary checked by the unit root test. For COAR-GARCH models, the AR(k) process to the dependent variable and the independent variables is to obtain the fitted values of the dependent variable and the independent variables stationary. Basically, they are the same econometric approach.

The estimated coefficients of NIK in Table 2 are all negative and significant at 1%, 5%, or 10% for short-run effects and long-run-effects. This findings show that an increase in the growth of stock price causes the depreciation of the JPY/USD foreign exchange rate. A possible explanation for these findings is that an increase in the stock market is generally an indicator of an expanding economy and expects a higher inflation (Ajayi and Mougoue, 1996). This may cause the outflows of capital and lead to the depreciation of the JPY/USD exchange rate.

The coefficients of DISASTER are all positive and significant at 1% for long-run effects. This result shows that, during the periods of natural disaster, the value of the yen in the JPY/USD foreign exchange rate market increases because the Japanese government and corporations might have to liquidate some of their U.S Treasuries for reconstruction from property damage.

The coefficients of INVT are all negative and only for OLS significant at 10% for the short-run effects. But for the long-run effects they become positive and significant at 5% for PROBIT and LOGIT and 1% for GARCH and COAR-GARCH. This results show that, after natural disasters happened, while the market would develop fears about the local economy and thus causes the fluctuation in FX market, the BOJ intervention has little effect on the exchange rate return. But in the long term, the BOJ intervention by buying JPY will increase the value of the yen in the JPY/USD foreign exchange rate.

The coefficients of S_DEV are all positive for all models and statistically significant for OLS and COAR in the short term and PROBIT and LOGIT in the long term. They are statistically insignificant for GARCH and COAR-GARCH in the long run. The positive coefficients are consistent to the policy of leaning against the wind and reflects the mean reversions of Japanese yen as the assets. In the long run, the findings that the coefficients of S_DEV, M_DEV, and L_DEV are all statistically insignificant for GARCH and COAR-GARCH demonstrates that the historical price information have no effects on the exchange rate return of U.S. dollar against Japanese yen.

4.2 Short run vs. long run for all event window

In Table 3 and Table 4, we report the results from the short run and long run data, respectively, based on different event window. We increase the length of event window from [0, 2] to [0, 20]. In Table 3, with the change of the length of event window, we obtain the different results. For example, the coefficients of S_DEV, L_DEV, INVT, and JPI are most likely statistically significant at a great length of event window. The coefficient of INVT is statistically significant when the event window is greater than 15. In Table 4, we include the DISASTER variable in the regression and increase its length of the event window, the coefficient of DISASTER are only statistically significant at some specific event window such as [0, 10]. Most coefficients of independent variables are stable in term of the magnitude of the coefficient and statistical significance level as an increase in the event window except NIK. From Table 4, we know the length of event window plays an important role for the DISASTER dummy variable.

5. Concluding Remarks

Japan's exchange market has been researched in this paper for its post-disaster performance because of the relatively highly frequent disasters there. In specific, we explore how much and how long natural disaster's effects can keep in the currency market. We employ event study methods here to measure the duration feature of disasters, and therefore locate the duration boundary by test if coefficients in models are significant. The models include information from bond and stock markets in addition to historical prices of exchange rate, which we introduce to exclude the possible endogenous bias in error terms. Besides, we divide our models into three types by including different historical prices of exchange rate, and this shows us how far back investors consider for their yen asset's value when disasters happen.

Our findings indicate disaster's effects die out as time goes on after it broke out, yet a post-disaster period ranging from 10 to 15 days proves significant in causing changing values of Japanese yen. Closely after the disaster, historical price information may be the main indicator for investors' portfolio decision, while other variables about bond and stock markets stand out in the long run. Generally disasters cause an increasing value of Japanese yen, and so does government's intervention, which matches our hypothesis. In the aftermath of disasters, the spread of interest rates in U.S. and Japan is insignificant, while Japan's overnight interest rate and NIKKEI stock returns affect exchange return of dollar against yen negatively and positively respectively. This may indicate investors care more about the conditions of Japan's economy than its comparison between other countries, and we suppose the positive stock return effect here is due to the integration of global financial markets.

Table 1
Description of Variables
(sample size: 5,964)

Variable	Description	Mean	Std. Dev.	Min.	Max.
S	Daily prices of U.S. dollar's exchange rate against Japanese yen.	108.7306	15.34742	75.76	147.14
INVT	Japan intervention in absolute values measured by billions of yen, including both selling and buying overseas assets.	15.6021	153.8283	0	8072.2
SPR	The difference between the Japan call money interest rate and the U.S. Federal Fund interest rate, namely JPI_t-USF_t.	-2.2963	2.3560	-7.3	2.858
RJPI	Japan's daily call money interest rate, the risk free rate employed in bond market of Japan.	0.8572	1.6545	-0.012	8.4375
NIKKEI	Daily historical Nikkei 225 index	14654.508	4352.7647	7054.98	26980.37
DISASTER	The first dates of natural disasters which hit Japan in the history in addition to the 1995's Sarin attack on the Tokyo subway. All of these disasters do harms to domestic economy, and cause national fears.	0.0059	0.0764	0	1
SDEV	short term deviation from previous one day moving average, $\mathrm{SDEV}_t \equiv s_{t-1} - s_{t-2}$.	-0.0066	0.7486	-8.4050	4.8050
MDEV	Medium term deviation from previous one month moving average,	-0.0651	2.0022	-15.8300	7.9190

	$\text{MDEV}_t \equiv s_{t-1} - \frac{1}{21}\sum_{i=1}^{21} s_{t-1-i}$				
LDEV	Long term deviation from previous half-year moving average, $\text{LDEV}_t \equiv s_{t-1} - \frac{1}{150}\sum_{i=1}^{150} s_{t-1-i}$	-0.4030	5.4634	-21.6850	15.7173

Notation: This table describes the raw data, yet for our aim, we also need daily log returns of U.S. dollar's exchange rate against Japanese yen, denoting by "Return", which is indeed $100 \times \Delta LnSt$. By the similar way, we also obtain daily log returns of stock index as $NIK=100 \times \Delta Ln(Nikkei)$. Also, to smooth off Japan's interest rate, we modify it by differencing the logarithm of RJPI and denote it as JPI to be used in our models. SDEV is too small compared to MDEV and LDEV, so we employ $100 \times SDEV$ in our model to make the comparison more clear

Table 2

Estimation results from the PROBIT, LOGIT, OLS, COAR, GARCH, COAR-GARCH models based on event window [0, 10]. The regression models are based on $EXR_t = \beta_0 + \beta_1 S\_DEV_t + \beta_2 M\_DEV_t + \beta_3 L\_DEV_t + \beta_4 INVT_t + \beta_5 SPR_{t-1} + \beta_6 JPI_{t-1} + \beta_7 NIK_{t-1} + \beta_8 DISADTER_{t-1} + \varepsilon_t$
The error terms for COAR, GARCH and COAR-GARCH are specified as $\sigma_t^2 = \alpha_0 + \alpha_1 \times \sigma_{t-1}^2 + a_2 \times \varepsilon_{t-1}^2 + e_{t.}$

The aim of this paper is to support a methodology proposal for the analysis of the impact on commercial globalization trend in relation to the internationalization of Mexicans firms. Also this paper analyzes the advantage the Mexican firms took in the liberalization agenda of the Mexican government with the multilateralism and regionalism policies. For this purpose, the statistic descriptive modeling methodology is used to relate grow of the internationalization of the Mexican firms and the impact in the foreign investment of the main multinationals in Mexico, forcing them to centering in competitive productive processes and improving their internal organization, innovation and development.

Keywords: Globalization, internationalization, multilateralism, multinationals, regionalism.

JEL Classifications: F62, F21, F13, F23, F15

1. Introduction

Mexico has experienced a steady increase in the internationalization of Mexican companies, which increased largely due to the openness trade policy adopted by the country. Following the entry of Mexico to the General Agreement on Tariffs Trade (GATT for its acronym in English) in 1986 and to adopt business trends on multilateralism and regionalism, has led to an increase in the internationalization of Mexican companies. In light of the foregoing, Mexico, from the late 90's, has experienced an increase in investment abroad of large Mexican companies that have survived the market reforms and structural adjustment policies (Vargas-Hernández, 2011). From this, it follows that the support of the Mexican government to Mexican companies as well as the impact of trade globalization, results in a sustained increase in the internationalization of Mexican companies.

This paper analyzes the impact of trade globalization in the internationalization of Mexican companies, same as, taking advantage of Mexico's trade policy openness, through multilateralism and regionalism have increased their presence in international markets.

Through descriptive statistical method of investigation, it is analyzed and developed the increased internationalization of Mexican companies and the impact of foreign investors and major multinationals in the competition, which forces Mexican companies to focus on innovation and development and to adopt more competitive production processes and improved internal organization.

2. Background of the problem

Following the entry of Mexico to the General Agreement on Tariffs Trade (GATT for its acronym in English) in 1986 and to take business trends multilateralism and regionalism, has led to an increase in the internationalization of Mexican companies, situation that has caused an increase in investment abroad of large Mexican companies that have survived the market reforms and structural adjustment policies (Vargas Hernández, 2011). From this, it follows that the support of the Mexican government to Mexican companies as well as the impact of trade globalization, results in a sustained increase in the internationalization of Mexican companies increased, and in the decisions of these to select an internationalization strategy to a specific market.

3. Definition of the problem

Currently, it is observed an increase in the internationalization of Mexican companies, derivative from trade openness policy adopted by Mexico and the globalization of trade out of which it is part. This trend can be divided into two branches: First observed multilateralism, same as is understood as trade openness of a country through the conclusion of free trade, and on the other, regionalism, which is understood as the trade openness of a country through regional integration (Arango Quintero and Cardona Montoya, 2008).
Therefore, the research questions are:

a. What is the degree of increase in the internationalization of Mexican companies, from Mexico's entry into the General Agreement on Tariffs Trade (GATT for its acronym in English) in 1986 to date, derived from the globalization of trade which is part of the country?

b. What is the degree of increase in the internationalization of Mexican companies, since the adoption of trade policy openness of the country, because of multilateralism?
c. What is the rate of increase in the internationalization of Mexican companies, since the adoption of trade policy openness of the country, because of regionalism?
d. What is the impact of multilateralism and regionalism in the selection of a destination country at the time of the internationalization of a company?

4. Justification

The importance on the world stage of globalization of markets, societies and cultures, is resulting in a direct impact on the internationalization of Mexican companies, same as, taking advantage of Mexico's trade policy openness, through multilateralism and regionalism have increased their presence in international markets. Similarly, to attract foreign investors and major multinationals to the country, it has impacted directly on free competition, which forces Mexican companies to focus on innovation and development, to adopt more competitive production processes and as an improvement in its internal organization.

5. Assumptions

a. The trade globalization has an impact on the internationalization strategies of companies.
b. Multilateralism adopted by a country has an impact on the internationalization of its companies.
c. Regionalism adopted by a country has an impact on the internationalization of its companies.
d. Multilateralism and regionalism adopted by a country have an impact on the selection of a country at the time of the internationalization of a company.

6. The trade globalization

6.1. *Conceptual framework*

The last 25 years the world economy has been characterized by numerous scientific and technological progresses, which has changed the pattern of production throughout the world, creating a growing interdependence that encompasses the total activities of an industrial economic sector, either regional or global level. This process is known as globalization and its main feature is that it has generated a significant increase in the flow of trade and investment; in such a way that globalization is seen as a struggle to participate in a greater number of markets and better capture larger volume of foreign direct investment (Gómez 2006).

An integration of the different concepts of trade globalization is poured in the following table:

Table 1: Commercial globalization.

Terms	Meanings and authors
Products at low cost.	Set of economic, technological and social factors that allowed multinational companies to sell their products almost there are no differences in various countries (Levitt, 1984).
Increased volume of FDI flows.	A fight for participating in a greater number of markets and achieve to capture higher volume flows of foreign direct investment (Gómez, 2006).
Operates without a country on a global scale.	Global company is one that has abandoned its national identity and operates as a non-country on a global scale (Ohmae, 1991).
Accelerated global integration of economies.	Worldwide accelerated integration of economies through trade, production, financial flows, technology diffusion, information networks and cultural flows (IMF, 1996).
Dynamic global market integration.	Dynamic process of increasing freedom and global integration of markets for labor, goods, services, technology and capital (De la Dehesa, 2000).

Source: Prepared.

The process of economic globalization is to operate with relatively low costs as if the whole world or the most important regions of the cities were a single entity.

An approach to the definition of globalization would be to integrate it from its characteristics. Globalization is an economic, technological, social and cultural scale process, which involves increased communication and interdependence among countries, unifying its markets, societies and cultures, through a series of social, economic and political transformations that give them global.

6.2. *Theoretical framework*

6.2.1. *Globalization of markets*

Pineda (1998) takes in his work an approach to the definition of globalization, analyzing seven approaches that try to explain globalization as theory. Among them, the presence of capitalism as a driving force of change worldwide in recent decades largely explains the emergence of the phenomenon of globalization. With countless multidisciplinary impacts as capitalism involves other than strictly economic, sociological, cultural, political, religious, technological, environmental, among others, none of which able to explain the complexity of the phenomenon of globalization.

The main beneficiaries of this process of globalization are multinational corporations that benefit from huge economies of scale, whether in production, distribution and administration to scale and product standardization, as stated by Levitt (1984). The most effective global competitors incorporate a higher quality and profitability to their cost structures, selling in all national markets the same products they sell in their home market, fully standardized products without any differentiation.

In light of the foregoing, Mexican companies not only face fierce competition in international markets but facing international competitors in the domestic market, with standardized products, with improved technology and above all more economical. Consumers initially had local preferences, but today they are seduced by the low price. Currently, it can be observed an increase in the internationalization of Mexican companies, derivative trade openness policy adopted by Mexico and the globalization of trade of which it is part, trend that can be divided into two branches, first multilateralism and on the other part the regionalism.

6.2.2. *Adoption of trade policy openness*

In the eighties, the economic and political framework was created for the United States and agencies like the World Bank and the International Monetary Fund actively promote implementation of neoliberal policies in developing countries, including Latin American (Ruiz Naples, 2004). Undoubtedly one of the most important neoliberal policies of that time was the adoption by Mexico of the General Agreement on Tariffs Trade (GATT for its acronym in English) in 1986-now World Trade Organization (WTO) - which had resulted in the adoption of trade policy openness.

Among the main commitments assumed by Mexico, was the gradual reduction of tariffs on trade as well as the adoption of trade policies of non-discrimination, among which are included national treatment and treatment of the most favored nation, generating with this the greater trade openness in Mexico. Derived from the developments described above, the Mexican government, in compliance with the economic policies of former President Carlos Salinas de Gortari (1988-1994), conducted a series of privatizations of state enterprises and later opened a new concept of growth national economic production that oriented outward to export.

In the context of trade liberalization and tariff scale deregulation, Mexico opted for free trade area with Canada and the United States, leading to the signature of the Free Trade with North America (NAFTA or NAFTA for its acronym in English) by Salinas de Gortari on December 17, 1992. Trade liberalization could be the start of a successful integration if it achieved positive effects on the dynamics of innovation and technological process. Any strategy to improve the local economy should be aware of the social dimension that contains the expanded vision of development on the limited size reflected only in quantitative terms of growth, as it could be understood the scope of NAFTA (Hernandez Soto Vázquez, 2008) .

a) Mexico and multilateralism

Arango Cardona Quintero and Montoya (2008) define multilateralism as trade openness of a country through the conclusion of trade agreements with a country, taking advantage of the liberalizing trade policies of both countries, in order to increase international trade protecting investors and creating trade policies that benefit both countries.

"In the area of international trade relations, the fundamental and distinctive feature of the strategy promoted by the United States to ensure stability and prosperity has been multilateralism," sustained Renato Ruggiero, Director General of the WTO on October 16, 1995. Ruggiero established the importance of vision and leadership of the United States, first under the GATT and now the WTO. The core of the international trading system is constituted by the principles of non-discrimination and the nation most favored (NMF). Ruggiero gave six reasons why governments have adhered to the principle of MFN and why it is "essential to resist the lure of the apparent short-term benefits of bilateralism" (Ruggiero, 1995).

As it asserts Jimenez Martinez (2007), the free trade agreements that Mexico has, is one of the most important elements in the process of internationalization. Thus, companies in the region should take full advantage of trade liberalization and to ensure their presence in other countries. The establishment of various treaties can serve as a trigger for the company's operations in foreign markets, and is a clear factor that directly affects the continued development of the internationalization process. After signing the Free Trade Agreement with North America, which includes tariff preferences for signers' countries, support for foreign investment, alternative means of dispute resolution against unfair trade practices, regulations, and intellectual property rights, among others.

Mexico began a race to sign trade agreements with other countries, with the sole aim to diversify exports and build tariff preferences with other countries. Currently, Mexico has a network of 10 FTAs with 45 countries (TLC's), according to the Ministry of Economy (2014). In these trade agreements, is now including the new TLC Mexico-Central America, which entered into effect on July 1, 2013. In the Mexico-Central America FTA are included Mexico, Costa Rica, Nicaragua, El Salvador, Guatemala and Honduras. This treaty, replaced the three existing trade agreements that Mexico had with Central America (FTA Mexico - Costa Rica 1995, Mexico-Nicaragua in 1998 and TLC's Triangle Northern Mexico in 2001), resulting with this, a total of 10 FTAs with 45 countries. It will be pending to attach to this trade agreements list the recent Free Trade Agreement Mexico-Panama, as in April 2014 was signed by the presidents of both countries.

Similarly, Mexico has 9 limited agreements, Economic Complementation Agreements and partial scope agreements, as part of the Latin American Integration Association (LAIA) and 30 Agreements for the Reciprocal Promotion and Protection of Investments (BITs).

b) Mexico and regionalism

Arango Cardona Quintero and Montoya (2008) explain regionalism, such as trade openness of a country through regional integration with two or more countries, through the holding of regional trade agreements. In fact, the authors argue that regional integration agreements, initially conceived as exceptions to the multilateral trading system, have become the guiding principles of global business dynamics. Regional agreements emerged as a scheme which recognizes exceptions recognizing that multilateralism is a system that is built between countries at different levels of development and seeks to create the conditions for a global free trade.

In recent years, it has been observed the establishment of economic blocs, through which various nations celebrate regional agreements that allow them to join forces to get the most out of its exchange trade (Jiménez Martínez, 2007). This situation has led to a significant increase in trade between regions of neighboring countries, as prime examples are the European Union, NAFTA, the Central American bloc Mercosur and the latest Pacific Partnership (Mexico, Peru, Colombia and Chile). According to the Ministry of Economy

(2014), Mexico participates in the Latin American Integration Association (LAIA). Also, México actively participates in multilateral and regional organizations and forums such as the World Trade Organization (WTO), the Asian-Pacific Economic Cooperation (APEC), the Organization for Economic Cooperation and Development (OECD), among others.

The flagship in the process of regionalization organisms is undoubtedly the Forum Asia Pacific Economic Cooperation (APEC for its acronym in English), of which Mexico is a party. The APEC moves on three pillars: trade liberalization, promotion of investment and technical cooperation. Unlike the European Union, the Asia Pacific region did not seek to form a community, but a forum for cooperation to achieve common goals. According to Martínez Lagorreta (2002), interest in creating an organization of this type born after World War II in a region where economic growth forced an economic and political interaction expeditiously. In this way, regional forums and organizations and industry forums and government groups were formed.

Another body, undoubtedly important, is the Pacific Alliance, led by Mexico has achieved regional integration between Mexico, Colombia, Peru and Chile, precisely those South American countries that do not belong to block of the Southern Common Market, having completely different trade and economic policies. Such regional bloc, the Pacific Alliance, aims to build a participatory and consensual membership, an area of deep integration to move progressively towards the free movement of goods, services, capital and people, i.e., a common market. Similarly, Pacific Alliances aims to promote higher growth, development and competitiveness of economies throughout, with a view to achieving greater well-being and overcome socioeconomic inequality. It intends becoming a platform of political articulation, economic and trade integration and projection to the world, with special emphasis on Asia-Pacific.

Cooperation and regional integration in Latin America are growing. In recent years, progress has been more on the real integration of Latin American economies that during the past three decades. A series of regional, sub regional and bilateral agreements is achieving increasing liberalization of mutual trade and economic and growing political (Van Klaveren, 1990) cooperation. One of the main advantages in signing FTAs with trading blocs, is not only to have a greater presence in other markets, but the power to reduce both tariff and non-tariff barriers in international trade, standardizing requirements among member countries of the block. This situation happens for example with the European Union, representing 28 countries, or the Southern Common Market (MERCOSUR), composed of five countries.

The integration then becomes an ideal geostrategic mechanism to achieve favorable positions in key areas by countries with greater bargaining power (Arango Cardona Quintero and Montoya, 2008). It will be under investigation, analyzing the mechanism that openness has impacted more Mexican companies, still the case or multilateralism or regionalism. Regionalism offers advantages for foreign investment and exports as they are counting on a single integrated market by several countries with similar market characteristics. This would represent a strategy of international expansion for the company or, standardization and reduction of regulations and tariff and nontariff restrictions. Among these nontariff restrictions can be mentioned the phytosanitary regulations, health, previous permits and export licenses, which would result in greater ease for businesses when exporting their products.

7. Internationalization of companies

7.1. *Conceptual framework*

In order to make an integration of the different concepts of internationalization, they are poured in the following table:

Table 2: Internationalization

Terms	Meanings and authors
Formulas and commitment levels subject to change.	Sequential process consisting of several stages that require progressive international nature of the company and a growing involvement of outside resources. Internationalization has to be seen as a complex process, which supports various institutional formulas depending on the level of commitment of the company in international markets. These formulas and levels of engagement are subject to change as the company consolidates its presence in the international arena (Duarte Lopez, 1996).
Evolutionary and long-term dynamic process that gradually affects the value chain.	Corporate growth strategy for international geographic diversification through an evolutionary and dynamic long-term process that gradually affects the different activities of the value chain. Also, the organizational company structure with a growing commitment and increasing involvement of its resources and capabilities to the international environment, and knowledge based (Larrinaga Villarreal, 2006).
Economic activity in other countries.	The development of the economic activity of the company in other countries (Good, 1996, 2006).
Adopt rules for transaction	The process of adapting exchange transaction modalities in international markets (Andersen, 1993).
Opening new markets, low production costs.	The objectives of internationalizing a business are opening new markets, lower production costs and structure of production and distribution of the company more efficient (Canals, 1994).
Resources or customers outside the borders.	Internationalize the company is managing any area of business or customers using resources beyond the borders of the country where the company is (Zaldo, 1997).
Gradual commitment to international markets.	It argues that the internationalization of a company is a gradual commitment of management to international markets (Johanson and Wiedershein, 1975, Johanson and Vahlne, 1977, 1990; Nordsrrom and Vahlne, 1993).

Source: Prepared

7.1.1. *Multinational companies*

The rapid emergence of developing economies is characterized by a wave of economic growth and the rise of national companies to become global competitors themselves. These companies are globalizing their businesses and competing with the traditional American model of modern multinational corporations (Vargas-Hernández, 2010).

Table 3: Multinational company

Terms	**Meanings and authors**
Multiplant company	The company that has one of its revenue-generating plants located outside the home country (Dunning, 1981).
Export company	The export company concentrates its production in the country and sells its goods or services in at least one foreign market (Pla and Leon, 2004).
Global company Multidomestic company Transnational company	They refer to the specific strategic approaches that can be adopted by multinational companies, and specify the basic strategies of multinationalization described by Bartlett and Ghoshal (1991).
Global company.	Multinational company with significant worldwide presence (Pla and Leon, 2004)
Multinational corporation	The multinational corporation is one that concentrates its productive activity in l home country and sells its goods or services in at least one foreign market (Jarillo and Martinez, 1991).
Global companies.	Such multinational companies have a significant presence worldwide, assimilates acceptance of global companies (Ohmae, 1991).
Business companies born international.	Business companies born international arise as a unit in the new currents that try to explain the accelerated internationalization (McDougall et al, 1994).

Source: Trujillo Davila, et al, 2006

The theory of monopolistic advantage is associated with the interpretations of the emergence of multinational firms proposed by Hymer (1976). He finds that for firms with production facilities abroad, they must have some kind of unique competitive advantage. This competitive advantage may originate in the production, technology, organization, management style or marketing, which means that these companies can compete with foreign companies in their own markets. Although national firms can be found more established and have greater knowledge of the market, they may be forced to bear the cost of developing such an advantage, and therefore, are incapacitated to compete with foreign companies.

7.1.2. *Foreign direct investment*

A concept intrinsically linked to the internationalization of companies and multinational corporations is the direct investment abroad. The legislation currently in force, on foreign investments respects, with some exceptions, the definitions of direct investment from organizations such as the International Monetary Fund (5.º Manual de Balanza de Pagos) and the OECD (Benchmark Definition).

The ways in which such investment occurs are: Investment for the creation of new companies, acquisition of part or all of the share capital of an existing company, reinvested earnings and intercompany loans and related stock companies (Fernandez-Otheo, 2005). Hymer (1976) also considers the cause of FDI the elimination of conflict between competing companies when the markets in which they operate are imperfect. Scepter (1999) states that

Table 4: Foreign Direct Investment

Terms	**Meanings and authors.**
Lasting relationship between a resident and a nonresident of an economy.	Lasting relationship between a resident in one economy (subsidiary) and a non-resident (holding company), with the intention of influencing their management, which is required for the latter owns at least 10% of the share capital of the first (OECD Benchmark Definition).
Flow of resources	Investments in a country other than the country of origin for the investor, which draws resources flow (Dunnign, 1988).
Strategy in the internationalization process	It establishes that foreign direct investment is an option of international presence, a mode strategy in the internationalization process of the firm (Duarte Lopez, 1996).
Multinational enterprise	Concept closely linked to multinational corporations as defined and determined (Dunnign, 1979, 1980, 1988).

Source: Prepared

rather than independent companies exist, or if they produce agreements between different market participants.

7.2. *Theoretical framework*

7.2.1. *Theory of internalization*

The internalization theory of multinational companies has its origin in the theory of transaction costs. The latter assumes that when markets are perfectly competitive, no need any control mechanism, since the threat of being replaced by another company, eliminates the possibility of developing opportunistic behavior and force companies to act efficiently (Whitelock, 2002). When reducing the number of suppliers, then the company is less likely to replace and, therefore, the transaction costs are increased due to the need of a rigorous bargaining and to assume and take some monitoring costs to ensure that the contract is fulfilled in conditions that had been established (Dwyer and Oh, 1988). The analysis of the transaction costs predicts that the company internationalizes markets, when asset specificity is high.

The theory of internationalization, as indicated, considers that experiential knowledge is the key to explain the process of internationalization of the company. It is particularly important because it allows linking its internal resources with market opportunities (Ericsson et al. 2000, 2001, Luo, 1999). In the field of exports the theory of internationalization is identified with knowledge concerning consumers, competitors, channels, environment, as a key element of the knowledge base of the firm (Morgan et al., 2003) is identified.

From the microeconomic approach, taking as its starting point the company, the called the International Development Stages Paradigm, proposed by various authors from Uppsala School (Johanson and Wiedershein, 1975, Johanson and Vahlne, 1977, 1990; Vahlne and Nordsrrom, 1993) who suggests that the process of internationalization of a company is a gradual engagement thereof with international markets.

As the main hypothesis, the model states that firms start their international operations when their size is still small, but expand following the stages of business growth strategy to the nearest markets (Johanson and Vahlne, 1990). According Canals (1997), it can be distinguished four main types of international companies, which in turn, reflect the same stages of internationalization. These stages are the exporting company, a multinational company, global company and transnational company.

There are many theories concerning the process of internationalizing and its determinants, each focusing on one or several partial aspects. This set of theories can be grouped into seven blocks of doctrinal trends: the classical theory, the theory of product life cycle, the Uppsala model, the paradigm of Porter, the strategic theory, the theory of internationalization and Dunning paradigm.

Table 5: Main theories on internationalization

School	Contribution	Authors
Theory of absolute advantage.	Ability to produce a good using less inputs than another producer (Smith, 1776)	Smith (1776)
Theory of comparative advantage.	Countries tend to specialize in the production and export of those goods manufactured with a relatively lower cost compared to the rest of the world. Where these countries are comparatively more efficient than others tend to export and tend to import goods those who are ineffective, and therefore goods are produced at comparatively higher than the rest of the world costs (Ricardo, 1817)	Ricardo (1817)
The Heckscher-Ohlin theory	If a country has relatively an abundant factor (labor or capital), it will have a comparative and competitive advantage in those goods that require a greater amount of that factor. Heckscher (1919), Ohlin (1933)	Heckscher (1919), Ohlin (1933)
Theory of product life cycle.	Analysis of the interdependence between the stage of product life and internationalization (Vernon, 1966)	Vernon (1966)
Uppsala model.	Study of the internationalization process of firms (Johanson and Vahlne, 1977, 1990)	Johanson y Vahlne (1977, 1990)
Porter paradigm	analysis location advantage in the home country. (Porter, 1990)	Porter (1990)
Strategic theory.	Analysis of strategic interdependence between the stage of product life and internationalization (Bartlett and Ghoshal, 2002)	Bartlett y Ghoshal (2002)
Internationalization theory.	Applying the approach of transaction costs at the mode of internationalization of the company. (Buckley and Casson,1976).	Buckley y Casson (1976)

7.2.2. *Business growth*

It cannot be analyzed the internationalization without studying the growth of businesses. According to Penrose (1959), company's growth is a cumulative process resulting from the interaction between external inducers such as market opportunities and productive services available in the company, derived from its own resources. The impact that foreign competition has in the country, has resulted in growth in Mexican companies while adapting to the needs of international markets. Chandler (1992) and Penrose highlight the existence of internal factors and external factors in the process of business expansion. External forces come from changes in markets, technology and population. A remarkable increase of Mexican companies is a result of regional integration which has been part of Mexico.

Integration can also help in the short term to the transmission of knowledge and technology transfer to domestic producers brings new products and processes generated by trading partners (Grossman and Helpman, 1990). The competition from foreign companies and the transfer of technology and innovative production processes results in an increase in the internationalization of Mexican companies. Having a technological breakthrough opportunities and long-term growth, it would be advantageous for a country to be able to compete successfully in an industry, field or product whose markets offer good prospects for development that rely on key technologies (Arjona, 1995). The internationalization strategy is a growing commitment and involvement of its resources and capabilities to international markets requiring different levels of investment, risk and control.

According to Johanson and Vahlne (1977), internationalization as an evolutionary dynamics nature´s phenomenon implies an increasing commitment of companies to human and financial resources in foreign markets. There are illustrative cases in the recent literature showing the importance that in the development of SMEs has had its participation as suppliers of large global companies with foreign capital. Issues such as geographic proximity or cognitive close relations established between local suppliers and global manufacturing companies (Asheim and Isaksen, 2003). Another view of the impacts of foreign direct investment (FDI) has to do with the role that transnational corporations can exert through direct operation on local businesses via its ownership of the latter (Blomström and Kokko, 1996).

It is for this reason that most Mexican companies with foreign capital comes mainly from trading partners with which Mexico has signed trade agreements. Torres and Jasso (2009) state that business growth is related not only to the use of its initial resources, but with the development of skills and abilities that accumulates during productive operations and daily management, facing a number of adverse forces arising from the conditions of the economic context in which they operate. The authors note that there are factors that cause expansion or contraction of business, such as the decline in demand for products or the opportunity to create new markets, changes in demographics and the development of technological innovations.

There has been in recent years a growth in companies in various sectors. Some large national companies have partnered with transnational counterparts to face international competition in domestic field, but also to expand into foreign markets, as it happens especially in cases of the cement, the brewing, chemical, glass and automotive industries (Vidal, 2000).

9. Final thoughts

Through the method of descriptive statistical research is to analyze the increasing internationalization of Mexican companies and the impact of foreign investors and major multinational derivative trade globalization, same as taking advantage of the openness trade policy in Mexico, through multilateralism and regionalism have increased their presence in international markets. Similarly, how globalization impacts the business, strategies for internationalization of Mexican companies when deciding to internationalize to a specific market.

In light of the foregoing, Mexican companies not only face fierce competition in international markets but facing international competitors in the domestic market, with standardized products, with better technology and above all, more economical; consumers initially had local preferences, today, are seduced by the low price.

lfchen@ccxi.com.cn

Excessive borrowing of local governments in China sparked concerns that the debt may threaten the financial stability of the economy and ultimately cause economic collapse. It becomes critically important to understand the credit rating of China's Local Government Financing Vehicle (LGFV) bonds and the association between the yields, credit ratings, and bond characteristics under this circumstance.

We use a complete pooled data set of 771 LGFV bond issues from 1999 to 2011 and OLS and two-stage-least-squares (2SLS) regressions to examine how credit ratings might affect LGFV bond yields and an ordered probit model to study the determinants of credit ratings. The main findings are: (1) bond characteristic variables, such as duration and guarantee, matter in determining yields though credit rating plays a major role in determining yields of LGFV bond issues; (2) bond issue size and bond type are the main determinants of LGFV bond credit ratings, while the bond issuer characteristics have little explanatory power; (3) at least in Eastern China, smaller credit rating agency tend to give better ratings after controlling for bond issuer and issue characteristics.

Keywords: yield, credit rating, Local Government Financing Vehicle (LGFV), China

JEL Classification: G20, G24, G28

1 Introduction

Much of China's recent growth has been driven by infrastructure projects financed by the central and local governments. China's tax reform in 1994 provided a framework for the "tax-separation" fiscal system. But problems remain in deepening the reforms and in improving financial relations among different levels of government. Besides the existing channels for raising funds, local governments need bond financing for economic development. However, institutional impediments prevent formal operations via this channel. Provision 28 of the Budgetary Law stipulates the following: "All Local government budgets should be planned strictly to assign expenditures by income and match the two. Without permission from the law or the State Council, no local government should issue bonds."

In 2009, to counter the effects of the Global Financial Crisis, China embarked on a massive 4 trillion RMB economic stimulus program. In addition, local governments were told to spend. In order to implement much of the infrastructure investment, local governments get around the restrictions by setting up Local Government Financing Vehicles (LGFVs) and use them as the platforms to borrow from banks or issue bonds. They invested in infrastructure and real estate projects to keep GDP ticking along. The heightened activity of LGFVs along with reduced lending standards helped fuel a massive investment bubble and credit boom in 2009 and 2010. Chinese banks grew their loans by 65% since the beginning of 2009 as credit expansion was the centre piece of China's stimulus package during the global financial crisis. Much of these loans were channeled to LGFVs as well as the property sector.

China's chief auditor warns of mounting debt on the 26th June 2010, "The scale is large, and the burden is quite heavy" when referring to the local government debts. A recent report released by the National Audit Office (NAO) shows that local governments in China had incurred about 10.7 trillion RMB ($1.65 trillion) in debt as of the end of 2010, about half of which was held by LGFVs. Provincial, municipal and county-level governments had 6,576 financing vehicles. Three provinces, 29 municipal cities and 44 counties had more than 10 LGFVs each. Of the total, debt among financing vehicles operated by local governments amounted to 4.97 trillion RMB.

Excessive borrowing of local government, however, sparked concerns that the debt may threaten the financial stability of the economy and ultimately cause economic collapse. By the end of 2010, there were 78 cities and 99 counties whose governments were on the verge of bankruptcy. This means that they had a debt ratio of more than 100 percent, debt exceeded revenue, according to the NAO report. Though the local government debt problem in China raises a lot of concerns, the bonds issued by the LGFV issuers are rated very high, some of them even hold a AAA rating. Many people doubt the credibility of China's domestic rating agencies. Bottelier (2003) finds that most listed corporate bonds in China received AAA ratings from the major domestic rating agencies and argues that the four major domestic rating agencies are not truly independent and their ratings are irrelevant in the market. Kennedy (2003) suggests that these domestic rating agencies have no apparent impact on the decisions of corporate bond buyers in China.

As far as we know, the credit rating of the local government debt has not been touched. The major reason is that the LGFV bonds emerged in the past few years and they differ from general corporate bonds in many ways. First, the board members and senior management are the local government officials rather than businessmen. Second, the main objective of LGFV platform is to support urban infrastructure projects and other public utilities services, not to pursue maximum profit. Last but not least, one of the most important sources of revenue is the financial subsidies or other types of transfer payment provided by the local government. Tu (2010) argues that the LGFV bonds in China could be considered as equivalent to the municipal government bonds, though these two are not exactly the same. Therefore, the LFGV bonds are exposed to not only the credit risk, but also the macroeconomic risk, industry risk, policy risk, and even a unique risk related to the local government fiscal position. It becomes critically important to understand the association between yields, credit ratings, and bond characteristics of China's LFGV bonds under this circumstance.

Due to the lack of data on China's LGFV bonds, no research has been undertaken to directly examine the relationship between bond yields and credit ratings for the LGFV bond issues. We believe our paper is the first to use a complete pooled data set of 771 LFGV bond issues from 1999 to 2011 to study this topic. We use both OLS and 2SLS regressions to examine how credit ratings might affect LGFV bond yields and an ordered probit model to study the determinants of credit ratings. The main findings are: (1) bond characteristic variables, such as duration and guarantee, matter in determining yields though credit rating plays a major role in determining yields of LGFV bond issues; (2) bond issue size and bond type are the main determinants of LGFV bond credit ratings, while the bond issuer characteristics have little explanatory power; (3) at least in Eastern China, smaller credit rating agency tends to give higher ratings after controlling for bond issuer and issue characteristics.

In addition to contributing to the literature on the local government debt and bond markets in China, this paper adds to the yield-rating nexus in the literature. The rest of paper is organized as follows. Section 2 reviews the related literature on credit rating. Section 3 presents the institutional background the local government debt and LGFV bonds. Section 4 describes the sample and variables. Section 5 provides empirical analysis on the association between yields and ratings and the determinants of credit ratings. Section 6 offers concluding remarks.

2 Related Literature on Credit Rating

Credit risk and credit ratings have been one of the most active areas of recent financial research, driven by advances in portfolio risk measurement and management techniques, growth in credit derivatives trading, and the adoption of the Basel II Accord. Within this broader literature, a growing body of research analyzes the credit ratings.

Altman, Avery, Eisenbeis and Sinkey (1981) review the early evolution and application of statistical techniques to bond ratings and other financial analyses. Moon and Stotsky (1993), Cantor and Packer (1997), and Pottier and Sommer (1999) find that rating scales, rating determinants, or weights attached to rating determinants differ across rating agencies after accounting for self-selection bias. Moon and Stotsky (1993) demonstrat that there is a significant difference between Moody's and S&P's in rating determinants. Their results indicate that split ratings reveal differences in both the degree of importance that is assigned to the specific determinants of the ratings and in the way that the bonds are classified. Amato and Furfine (2004)'s analysis is based on a model of ratings determination that takes into account factor that measure the business and financial risk of firms, in addition to indicators of macroeconomic conditions. Cantor (2004) summarizes six streams of the research around credit rating. These six streams include understanding rating transitions, rating determinants and stability, understanding the role of credit ratings as tools for portfolio governance, relating bond prices and spreads to credit ratings, relating changes in market prices to changes in credit ratings, and relating sovereign risk and sovereign ratings. Our paper is closely linked with two out of six streams mentioned in Cantor (2004) – rating determinants and relating bond yields to credit ratings.

In the study of credit ratings, the ordered probit model and panel framework are usually used by empirical analysis. Cheung (1996) estimates the relationship between the provincial credit ratings, as assessed by Standard & Poor's, and a number of economic variables, using the ordered probit methodology. All the variables in her estimation prove to be significant. In particular, she finds that downgrades take place at almost the same speed at different levels of the debt-to-GDP ratio, based on a pooled sample of nine provinces. Based on smaller pools of provinces with similar economic characteristics, she finds that downgrades take place at different speeds at different levels of the debt-to-GDP ratio. Becker and Milbourn (2011) use both OLS and ordered probit models to examine how increased competition affects the credit rates market. They conclude that ordered probit regression allows the effect of dependent variables to vary across different parts of the ratings scale. The ordered probit regression, therefore, uses data more efficiently. They find that the entry of a third major rating agency coincides with lower overall quality, as measured by both the levels and informational content of incumbents' ratings.

There is also a growing interest on the emerging bond markets and topics related to local government debt. Mizen and Tsoukas (2013) investigate the determinants of the firm's decision to issue corporate bonds in emerging Asian economies, using a novel database covering the period 1995 to 2004. Mendoza-Velázquez (2009) investigates the impact of rating changes to State and Municipal governments on bond returns in Mexico.

3 Institutional Background and Development

3.1 Institutional background

Up to the early 1970s, China's government finance planning was highly centralized. All revenues and expenditures of local governments were under the state budget, in accordance with the principles of the centrally planned economy. The sharing of annual revenue and expenditure was settled by bargaining between the central and local governments. There was little room for regional autonomy or for local governments to expand revenue sources.

The fiscal decentralization reforms at the beginning of the 1980s brought changes, such as a contract system for revenues, and division of expenditure responsibility between the central and local governments. However, this system retained many of the characteristics of bargaining. Although they had 5-year fiscal contracts, the central and local governments were always negotiating for their shares, which varied frequently, in aggregate fiscal revenue. If local governments increased their revenue collection, then they might get a higher share. Eventually, local governments received more incentives to develop the local economy under this overall rationing system, but it had serious consequences. The ratio of central government fiscal revenue to total fiscal revenue declined between 1984 and 1993. The contract system also lacked stability. Since the formula for revenue sharing between central and local governments was renegotiated only every 5 years, it induced many negative short-term activities, such as predatory exploitation of resources, duplication of economic structures, and distortion of government-enterprise relations. These acted against the tenets of sustainable development and market-oriented reform.

Chinese government thus introduced the tax-separation system in 1994, establishing a rudimentary framework for power division in fiscal administration. The central and local governments have separate powers to collect certain categories of taxes. The tax reform of 1994 simplified the tax code by specifying revenue assignments to 3 broad categories: taxes exclusive to the central government, shared taxes between central and provincial governments, and taxes exclusive to provincial governments. The scheme fundamentally shifted the focus of the revenue system away from negotiations to a more standardized tax regime. The result has been a dramatic improvement in revenue collection for the central government since 1994.

While the Chinese fiscal system appears centralized on the revenue side, its expenditure assignments are among the most decentralized in the world. Spending on education, health care, pensions, and unemployment insurance are assigned to governments in city, county, and township levels. Local governments are also responsible for investment in infrastructure that supports national economic and social development goals. Therefore, the central government is responsible for about 20% of public expenditures while 80% are assigned to and implemented by provincial, municipal, and local governments (see Table 1). The gap between local revenue and expenditure is expanding. By comparison, average sub-national government spending accounts for only 32% of total expenditure for developed countries and 16% for developing countries (Dabla-Norris, 2005).

In theory, decentralization should help governments customize public services more suitably to local needs. However, in practice, decentralized public service provision often yields substandard public services for the populace in underdeveloped regions. Moreover, this unusual degree of expenditure decentralization combined with a dearth of clearly defined legal responsibilities for each level of government make the Chinese fiscal system rather chaotic. Spending responsibilities tend to be "pushed" downward from higher levels while revenues are "grabbed" by the top. As a result, local governments often suffer from a mismatch between income and expenses. This mismatch has become particularly severe in recent years as local governments' share of total expenditure beyond 80% after the aggressive 4000 billion RMB fiscal stimulus launched in 2008. The local fiscal deficit reached a historical high of 4.14 trillion RMB at the end of 2011. A substantial part of local fiscal deficit was financed in the form of LGFVs.

Table 1. Fiscal Revenue and Expenditure at Local Level (100 million RMB)

	Local Fiscal Revenue	*Annual Change (%)*	*Share in State Total (%)*	*Local Fiscal Expenditure*	*Annual Change (%)*	*Share in State Total (%)*	*Surplus/ (Deficit)*
1993	3391.4	-	78.0%	3330.2	-	71.7%	61.2
1994	2311.6	-31.8%	44.3%	4038.2	21.3%	69.7%	(1726.6)
1995	2985.6	29.2%	47.8%	4828.3	19.6%	7080.0%	(1842.8)
1996	3746.9	25.5%	50.6%	5786.3	19.8%	72.9%	(2039.4)

3.2 The development of bond market and LGFV bonds

The bond market in China has undergone a major development in recent years. By the end of 2010, the balance of bonds under custody (not including Central Bank Bills) had reached 16.3 trillion RMB, a seven-fold increase compared to the end of 2000. The rapid development of the bond market has raised the proportion of direct financing in the total amount of financing in society, thereby having the effect of improving the financing structure. The proportion of direct financing in corporates' external financing rose from 7% at the end of 2004 to 25% at the end of 2010, while the proportion of bond financing in direct financing rose from 18% to 66%, presenting a continuous growth trend.

At present, the bond market in China has become mainly an over-the-counter (OTC) market for institutional investors. Such market formation corresponds to the regular pattern for the international development of a bond market. The OTC-driven interbank market constitutes over 95% of the overall bond market. In 2010, China's interbank market (not including Central Bank Bills) issued 4.69 trillion RMB of bonds and held 15.8 trillion RMB in custody; cash bond transactions reached 64.0 trillion RMB and repo transactions reached 87.6 trillion RMB; the number of institutional investors that invested or traded in the interbank bond market increased from 650 in 2000, to close to 10,235 at the end of 2010.

Within China's bond market, the corporate bond market is the submarket that has grown the most and the fastest in recent years. The variety of the market increases all the time and its scale keeps expanding. At present, China's corporate bond market has grown from bond for single project into varied structures that includes enterprise bonds, MTNs, short-term notes, corporate bonds, convertible bonds and asset-backed securities. The scale of the market has increased from 79.7 billion RMB in 1999 to 3.5 trillion RMB at the end of 2010. The promotions of short-term notes and MTNs in particular have fostered the development of China's corporate bond market. Prior to 2005, China's corporate bond market approximately grew a mere 30 billion RMB per year. Following the promotion in 2005 of short-term notes, it rapidly increased to around 200 billion RMB. After the promotion in 2008 of MTNs, the market made another great leap forward in scale, reaching 600 billion RMB in the same year, and over 1353.6 billion RMB by the end of 2010. At present, the short-term notes and the MTNs are mainly self-regulated by the National Association of Financial Market Institutional Investors (NAFMII), which uses a registration system to handle issuance. It has to be said that the marketized development model has been a main factor in promoting the rapid development of the bond market in China.

LGFVs normally issue bonds in the form of Enterprise Bonds (EBs) and MTNs. Table 2 reports the issurance information of LGFV bonds between 1999 and 2011. The first LGFV bond hit the market in 1999. Only 4 EBs were issued in 2002 with a total amount of 6 billion RMB. The number of issues increased dramatically to 210 and the total amount reached 356.5 billion RMB in 2011. The pooled data shows that 40% of LGFV bonds issued by municipal government and almost all LGFV bonds issued by county government entered the market after 2008, while the 4 trillion economic stimulus plan was introduced by the central government.

Table 2. The Issues and Size of LGFV Bonds by year (100 million RMB)

	Issues			*Size*		
Year	Total	MTN	Enterprise Bond	Total	MTN	Enterprise Bond
1999	1	0	1	8	0	8
2002	4	0	4	60	0	60
2003	8	0	8	166	0	166
2004	2	0	2	40	0	40
2005	25	0	25	308	0	308
2006	15	0	15	183	0	183

Source: Wind

Table 3 shows us the amount of the LGFV bonds and the share in the enterprise bonds from 1999 to 2011. Before 2008, the growth of LGFV bonds was relative stable. In November 2008, the central government introduced a 4 trillion economic stimulus plan. Central government invested nearly 1/3, around 1.18 trillion, and the rest came from local matching funds and private sources. LGFVs such as urban construction investment companies became one of the most important financing platforms for local government. The growth has become rather explosive since then.

The number of LGFV bonds issued in the form of enterprise bond was 210 in 2011, twice of the total volume between 2002 and 2008. The share of LGFV bonds in enterprise bonds also rose sharply from 22.5% in 2008 to the history high of 63.2% in 2011. The only LGFV bond issued in 1999 is not included in Table 3 because the issuance of LGFV was stopped from 2000 to 2001.

Table 3. The Amount of LGFV Bonds and Share in the Enterprise Bonds (100 Million RMB)

Year	LGFV bonds		Enterprise Bonds	Share
	Issuing volume	Amount	Amount	
2002	4	60	325	18.5%
2003	8	166	358	46.4%
2004	2	40	322	12.4%
2005	25	308	654	47.1%
2006	15	183	1015	18.0%
2007	25	289	1696	17.0%
2008	32	533	2367	22.5%
2009	176	2509	4247	59.1%
2010	166	2106	3621	58.2%
2011	210	2765	4375	63.2%
Total	663	8959	18980	47.2%

Source: Wind

The distribution of LFGV issues by credit ratings is presented in Table 4. It is obvious that the weight of AAA rated bonds decreased from 100% in 2007 to less than 15% in 2011. The median of ratings has been moving downward. The weights of

AA+ rated bonds, AA rated bonds, and AA- rated bonds were 35%, 47%, and 3%, in 2011, respectively. This downward trend may indicate that the credit quality of LGFV bond issues is deteriorating over time.

Table 4. Distribution by LGFV Issue Credit Ratings

	2007		*2008*		*2009*		*2010*		*2011*	
AAA	25	100%	11	33%	55	28%	26	13%	37	14%

Source: Wind

The distribution of LFGV issuers by credit ratings reported in Table 5 shows a slightly different pattern. The average rating of LGFV issuers is worse than that of LGFV issues. The main reason is that many platform companies issue bonds with a guarantee or other forms of support from the local government.

Table 5. Distribution by LGFV Issuer Credit Ratings

	2007		2008		2009		2010		2011	
AAA	9	36%	7	21%	35	18%	13	7%	31	12%

4 Sample and Variables

Data on all LGFV bond issues during 1999-2011 were collected from Wind Database. This database provides detailed information on yields, credit ratings and bond characteristics of 771 LGFV bond issues. To determine the association between bond yields, credit ratings and bond characteristics, we pick up the variables listed in Table 6. Apart from bond yield and credit rating, we also select a number of additional explanatory variables based on a survey of prior research on the determinants of bond ratings and yields (e.g., Sorensen, 1979; Boardman and McEnally, 1981; Kidwell, Marr, and Thompson, 1984; Fung and Rudd, 1986; Lamy and Thompson, 1988; and Ziebart and Reiter, 1992). These studies typically explain bond yields and ratings in terms of issuer characteristics and issue characteristics.

Some prior researches have used a number of financial ratios to capture issuer characteristics or used bond ratings to capture the overall measure of the default risk of a firm. In this study, however, we argue that LGFVs in China differ from other corporate issuers in many ways. First, the board members and senior management are the local government officials rather than businessmen. Second, the main objective of local government financing platform is to support urban infrastructure projects and other public utilities services, not to pursue maximum profit. Last but not least, one of the most important sources of revenue is the financial subsidies or other types of transfer payment provided by the local government. To deal with this issue, we use a unique set of local government fiscal variables as the issuer characteristics to capture the default risk related to the local government.

Table 6 defines the variables used in the empirical analysis. YIELD is the yield to maturity of LGFV bond issues. RATING is an ordinal variable taking on values from 1 to 7 representing A-, A, A+, AA-, AA, AA+, and AAA, respectively. High quality ratings should be informative about bond values, and therefore bond yield (Beck and Milbourn, 2011). RATING is expected to have a positive relation with YIELD.

Table 6. Variable Description

Variables	Description
LGFV yields and ratings	
YIELD	Yield to maturity of LGFV bond issues
RATING	Ordinal variable taking on values from 1 to 7 representing A-, A, A+, AA-, AA, AA+, and AAA, respectively.
Issue characteristics	
LSIZE	Log of the size of issue (in millions of RMB). Economies of scale in underwriting suggest that the LSIZE would be inversely related to bond yields and positively associated with credit ratings.
DR	Bond duration. Bonds with longer duration are expected to have a higher yield and a worse rating because its greater interest risk exposure.
TY	TY is a bond type dummy variable, 1 if the LGFV bond is issued in the form of Enterprise Bond, 0 otherwise. EBs are expected to be associated with higher yields and worse bond ratings.
Issuer characteristics	
LRG	Total local LGFV debt over local GDP. LRG is expected to be associated with higher yields and worse bond ratings.
FDGDP	Fiscal dividend per GDP. FDGDP is expected to be associated with higher yields and worse bond ratings.
GR	Guarantee is a dummy variable. It equals to 1 if the LGFV bond issuer is backed by the local government, 0 otherwise. Guarantee reduces default risk so that this should be negatively associated with yields and positively associated with bond ratings.
Other control variable	
RA	Ordinal variable taking on values from 1 to 6 representing the six largest rating agencies, from the largest to the smallest.
Other dummy variables	
Time dummy	$DYear_i$ =1 if LGFV bonds issued in year i; and 0 otherwise.
Regional dummy	$DArea_2$ =1 if LFGV bonds issued by local governments in North-Eastern China; and 0 otherwise; $DArea_3$ =1 if LFGV bonds issued by local governments in Central China; and 0 otherwise;

	$DArea_4$=1 if LFGV bonds issued by local governments in Western China; and 0 otherwise.

LSIZE is the log of the size of issue (in millions of RMB). Many studies, including Altman (1968), test the size effect on prediction of default. They argue that larger firms are less likely to default and they tend to issue larger amount of debt. We expect LSIZE to be negatively related to bond yields and positively associated with credit ratings. DR is the duration of LGFV bond issue. Bonds with longer duration are expected to have a higher yield and a worse rating because its greater interest risk exposure. TY is a bond type dummy variable. It equals to 1 if the LGFV bond is issued in the form of Enterprise Bond, 0 otherwise.

LRG is computed by dividing the total LGFV debt of a province by this province's GDP. FDGDP is the absolute value of a province's fiscal balance over GDP. These two fiscal variables should be positively related with the dependent variable (Cheung, 1996; Mizen and Tsoukas, 2013). GR is a dummy variable. It equals to 1 if the LGFV bond issue is backed by the local government, 0 otherwise. Guarantee reduces default risk so that this should be negatively associated with yields and positively associated with bond ratings. We also want to test if the credit rating quality is significantly different among rating agencies. RA is an ordinal variable taking on values from 1 to 6 representing the six largest rating agencies, from the largest to the smallest, namely, China Chengxin International Credit Rating Co Ltd., China Lianhe Credit Rating Co Ltd., Dagong Global Credit Rating Co Ltd., Shanghai Brilliance Credit Rating & Investors Service Co Ltd., Pengyuan Credit Rating Co Ltd., and Shanghai Fareast Credit Rating Co Ltd.

In order to preserve the numbers of observations and the relevant degrees of freedom, we also include the time and regional dummies for the comparison purposes. Time dummy $DYear_i$=1 if LGFV bonds issued in year i; and 0 otherwise. Regional dummy $DArea_2$=1 if LFGV bonds issued by local governments in North-Eastern

China; and 0 otherwise; $DArea_3$=1 if LFGV bonds issued by local governments in Central China; and 0 otherwise; $DArea_4$ =1 if LFGV bonds issued by local governments in Western China; and 0 otherwise.[1] Table 7 provides summary statistics for the sample of 771 LGFV bond issues and Table 8 presents the statistics of LGFV bond issues of four sub-regions.

[1] The four sub-regions are classified according to the different economic and financial development levels, namely, Eastern, North-Eastern, Central and Western. Eastern region consists of Beijing, Tianjin, Hebei, Shanghai, Jiangsu, Zhejiang, Fujian, Shandong, Guangdong, Hainan. Northeastern region includes Liaoning, Jilin, Heilongjiang. Central consists of Shanxi, Anhui, Jiangxi, Henan, Hubei, Hunan. Western includes Inner Mongolia, Guangxi, Chongqing, Sichuan, Guizhou, Yunnan, Shanxi, Gansu, Qinghai, Ningxia, Xinjiang. Our study covers all provinces except Tibet.

$DArea_2$	771	0.0687	0.253	0	1
$DArea_3$	771	0.182	0.386	0	1
$DArea_4$	771	0.184	0.388	0	1

Note: This table provides summary statistics of the test variables for a sample of 771 LGFV bond issues over the period 1999–2011. The variables are defined as follows: YIELD is the yield to maturity of LGFV bond issues; LSIZE is the natural log of size of the issue (in millions of dollars); RATING is an ordinal variable taking on values from 1 to 7 representing A-, A, A+, AA-, AA, AA+, and AAA, respectively; DR is the duration; LRG is the local LGFV debt over local GDP; FDGDP is the absolute value of a province's fiscal balance over GDP; RA is an ordinal variable taking on values from 1 to 6 representing the six largest rating agencies, from the largest to the smallest; GR equals to 1 if the LGFV bond issue is backed by the local government, 0 otherwise; TY equals to 1 if the LGFV bond is issued in the form of Enterprise Bond, 0 otherwise. $DYear_i$ and $DArea_i$ are the time and regional dummies, respectively.

Table 7 shows that the mean yield is about 6%, while the mean rating of LGFV bond issues is somewhere between AA- and AA. LGFV bond issues' duration varies from 0.09 to 13.896 years, with the mean slightly over 5 years. The local LGFV debt over local GDP ratio ranges from 4.9% to 15.1%, while the fiscal dividend over GDP ratio varies from 1.5% to 29.5%. The mean of guarantee dummy is slightly higher than 0.5, showing that nearly half of the bond issuers are backed by the local government. The bond type dummy reports a mean of 0.861, indicating that the most issuers prefer to issue the LGFV bonds in the form of Enterprise Bonds.

GR	142	0.606	0.490	0	1
TY	142	0.859	0.349	0	1

Note: This table provides summary statistics for a sample of 771 LGFV bond issues of four sub-regions. The variables are defined as follows: YIELD is the yield to maturity of LGFV bond issues; LSIZE is the natural log of size of the issue (in millions of dollars); RATING is an ordinal variable taking on values from 1 to 7 representing A-, A, A+, AA-, AA, AA+, and AAA, respectively; DR is the duration; LRG is the local LGFV debt over local GDP; FDGDP is the absolute value of a province's fiscal balance over GDP; RA is an ordinal variable taking on values from 1 to 6 representing the six largest rating agencies, from the largest to the smallest; GR equals to 1 if the LGFV bond issue is backed by the local government, 0 otherwise; TY equals to 1 if the LGFV bond is issued in the form of Enterprise Bond, 0 otherwise.

Table 8 shows that the mean yield is about 6%, while the mean yield of LGFV bond issues in the Eastern China is the lowest and mean yield in the Northeastern region is the highest. The 10 provinces in the Eastern region are the most developed areas in China. There is no doubt that this region's LGFV bond issues are associated with larger size and higher rating. This region also dominates the LGFV bond market with a total issues of 274 and total amount of 412.5 billion RMB (see Table 9).

Table 9. The issuance information of four regions

	Total Issues	Total Amount (100 mil)	MTNs	Amount of MTNs (100 mil)	EBs	Amount of EBs (100 mil)

5. Empirical Analysis

5.1 Does credit rating capture it all?

The relationships between bond yield, credit rating and bond characteristics have been the focus of many researchers (Fisher, 1959; Cohen, 1962; Horrigan, 1966; West, 1970; Kaplan and Urwitz, 1979; and Weinstein, 1981). It is commonly believed that a bond with a worse credit rating carries a higher risk of default and a correspondingly higher risk to the investor. As a result, investors require lower-rated bonds to pay a higher rate of interest to compensate them for the additional risk. Bhojraj and Sengupta (2003) argue that bond yields and ratings are essentially determined by the probability that the firm will not be able to meet its debt obligations and by the degree of protection afforded to the lenders in such an event. Therefore, the financial risk characteristics of the firm and the characteristics of the debt issuance are the factors influencing yields and ratings.

We examine the association between yields, ratings, and bond characteristics of LGFV bonds following Bhojraj and Sengupta (2003). Bond yields are regressed against ratings and control variables capturing the issuer characteristics and the specific features of the LGFV bond issues to examine the explanatory power of these variables.

$$\begin{aligned} YIELD_i &= \beta_0 + \beta_1 RATING_i + \beta_2 LSIZE_i + \beta_3 DR_i + \beta_4 LRG_i + \beta_5 FDGDP_i \\ &+ \beta_6 RA_i + \beta_7 GR_i + \beta_8 TY_I + \sum_{i=1}^{n} \beta^{'} DArea_i + \sum_{i=1}^{n} \beta^{''} DYear_i + \varepsilon_i \end{aligned} \tag{1}$$

In order to mitigate the biases caused by endogeneity of the predictor variables, we run a 2SLS regression by applying instrumental variables consisting of appropriately lagged levels of the variables. The OLS and 2SLS results obtained from the regression of the bond yields on ratings and control variables are presented in Table 10. The reported t-statistics are based White's (1980) heteroscedasticity-corrected covariance matrix. The regression results are based on bond characteristics variables in addition to bond ratings. The objective here is to examine if LGFV bond characteristics variables help to explain bond yields beyond what is captured by the ratings.

Note: This table gives the OLS and 2SLS estimates of equation (1). The dependent variable for YIELD is the yield to maturity of LGFV bond issues. The independent variables are defined as follows: LSIZE is the natural log of size of the issue (in millions of dollars); RATING is an ordinal variable taking on values from 1 to 7 representing A-, A, A+, AA-, AA, AA+, and AAA, respectively; DR is the duration; LRG is the local LGFV debt over local GDP; FDGDP is the absolute value of a province's fiscal balance over GDP; RA is an ordinal variable taking on values from 1 to 6 representing the six largest rating agencies, from the largest to the smallest; GR equals to 1 if the LGFV bond issue is backed by the local government, 0 otherwise; TY equals to 1 if the LGFV bond is issued in the form of Enterprise Bond, 0 otherwise. $DYear_t$ and $DArea_i$ are the time and regional dummies, respectively.

The *t*-ratios are computed using White heteroskedasticity corrected standard errors (White, 1980). The significance levels of 1%, 5% and 10% are noted by ***, ** and *.

We find that credit ratings do indeed play a very major role in determining yields of LGFV bond issues in both OLS and 2SLS regressions. This result is in line with Crabbe and Post (1993), Gande et al. (1997), and John et al. (2003). The coefficients of RATING have negative sign and significant at 1% level, indicating that the better the credit rating, the lower the yields (and the better the prices). An interesting finding, however, is that other variables matter in determining yields, even after controlling for credit rating. Table 10 shows us that out of the three variables representing issue characteristics, the coefficients of DR are positive and significant at 1% level in both OLS and 2SLS regressions, while the coefficients of LSIZE and TY are significant in OLS but insignificant in 2SLS results. It supports our hypothesis that the LGFV bonds with longer duration have a higher yield because they have greater interest risk exposure. GR is the only issuer characteristic variable that has proper sign and significant at 1% level in both regressions. This result shows that the local government guarantee is an important variable in affecting the LGFV bond's yield. The average yield of LGFV bonds with local government guarantee is significantly lower than the yield of those without such kind of support from the local government.

In that occasion, we argue that credit rating alone is not a sufficient statistic for determining the LGFV bond yield. This is an interesting but puzzling result. There is little in the prior theoretical or empirical literature to guide us on this finding. One possible explanation that we present is that there are imperfections in the rating process. These imperfections impart biases in ratings whose magnitudes depend on bond issue characteristics like the duration or issuer characteristics like the guarantee.

An alternative explanation is that the credit ratings offered by Chinese credit rating agencies do not have sufficient information content. Bottelier (2003) finds that most listed corporate bonds in China received AAA ratings from the major domestic rating agencies and argues that the four major domestic rating agencies are not truly independent and their ratings are irrelevant in the market. Kennedy (2003) suggests that these domestic rating agencies have no apparent impact on the decisions of corporate bond buyers in China. However, Poon and Chan (2008) examine the asymmetric certification effect of initial rating announcements and the signaling effect of rating downgrade announcements in China using a pooled time-series cross-sectional issuer rating data from 2002 to 2006. Their empirical evidence supports the hypothesis of an asymmetric certification effect.

To better understand this interesting but puzzling result, we examine the determinants of LGFV bond issue credit ratings using an ordered probit model in the next section.

5.2 The determinants of credit rating

We follow Altman and Rijken (2004) and Amato and Furfine (2004) to establish an ordered probit model[2] to predict LGFV bonds credit rating conditional on financial, debt-related, and local government related characteristics. There are five explanatory variables and three dummy variables in our model. Explanatory variables include size (*LSIZE*), duration (DR), leverage (LRG), fiscal balance to GDP ratio ($FDGDP$), rating agency (RA), guarantee (GR) and bond type (TY). The empirical specification obtained for 771 bonds pooled together is:

$$
\begin{aligned}
RATING_i &= \beta_0 + \beta_1 LSIZE_i + \beta_2 DR_i + \beta_3 LRG_i + \beta_4 FDGDP_i \\
&+ \beta_5 RA_i + \beta_6 GR_i + \beta_7 TY_i + \sum_{i=1}^{n} \beta' DArea_i + \sum_{i=1}^{n} \beta^{*} DYear_i + \varepsilon_i
\end{aligned}
\tag{2}
$$

Where i is an index for the bond issues.

Table 11 reports maximum likelihood estimation results of an ordered probit model using the entire sample that pools four sub-regions together. To allow for heterogeneity across observations, we estimate the ordered probit model with the robust standard errors option. Consistent with our hypothesis, the size of bond issue

[2] The ordered probit model for credit rating is presented in the Appendix.

has a positive impact on the rating determination. The sign of the coefficient of LSIZE is positive and is significant at 1% level. The coefficient of TY is also significant and with negative sign which is consistent with our hypothesis.

Table 11. The result of ordered probit regression on ratings (whole sample with time and regional dummies)

Log Like.	-774.2689	

Note: This table gives the ordered probit estimates of equation (2) for the whole sample with time and regional dummies. The dependent variable for RATING is an ordinal variable taking on values from 1 to 7 representing A-, A, A+, AA-, AA, AA+, and AAA, respectively. The independent variables are defined as follows: LSIZE is the natural log of size of the issue (in millions of dollars); DR is the duration; LRG is the local LGFV debt over local GDP; FDGDP is the absolute value of a province's fiscal balance over GDP; RA is an ordinal variable taking on values from 1 to 6 representing the six largest rating agencies, from the largest to the smallest; GR equals to 1 if the LGFV bond issue is backed by the local government, 0 otherwise; TY equals to 1 if the LGFV bond is issued in the form of Enterprise Bond, 0 otherwise. The significance levels of 1%, 5% and 10% are noted by ***, ** and *.

Table 12 presents the ordered probit regression results for four sub-regions in China. The coefficients of LSIZE are positive and significant for Eastern, Central and Western regions, which support our expectation that larger issues will be rated higher. The coefficients of TY are significant at 1% level in two regions, Eastern and Western China, and 5% in one region, Central China. It shows that the LGFV bonds issued in the form of enterprise bonds are rated lower. The coefficients of DR are negative and significant in only two sub-regions, Eastern and Western China. Two fiscal variables, LRG and FDGDP, do not have favorable impact on the determination of credit ratings. An interest finding is that the coefficient of RA is negatively significant in Eastern China alone. It indicates that smaller credit rating agency tend to give higher ratings after controlling for bond issuer and issue characteristics, at least in Eastern China. This finding supports Lee (2006)'s argument in some extent. Lee (2006) claims that major Chinese credit-rating agencies have put too much emphasis on winning business by giving top ratings to most issuers, whether top ratings were deserved or not.

The significance levels of 1%, 5% and 10% are noted by ***, ** and *.

6 Conclusion

Excessive borrowing of local governments in China sparked concerns that the debt may threaten the financial stability of the economy and ultimately cause economic collapse. It becomes critically important to understand the credit rating of China's LFGV bonds and the association between the credit rating, yield and bond characteristics under this circumstance.

We use a complete pooled data set of 771 LFGV bond issues from 1999 to 2011 and OLS and 2SLS regressions to examine how credit ratings might affect LGFV bond yields and an ordered probit model to study the determinants of credit ratings.

The OLS and 2SLS regression results show that other variables, such as bond issue size, duration, and guarantee, matter in determining yields though credit rating plays a major role in determining yields of LGFV bond issues. This is an interesting but puzzling result. In this occasion, we argue that credit rating is not a sufficient indicator on which the LGFV bond investors can rely. The two possible explanations are rating process imperfections and insufficient informational content of the rating offered by Chinese credit rating agencies.

We then employ an ordered probit model to examine the determinants of LGFV bond issues' credit ratings. The coefficients of bond issue size and bond type are significant and with proper sign. This finding supports our expectation that larger issues are rated higher and the LGFV bonds issued in the form of enterprise bonds are rated lower. Two bond issuer variables, LRG and FDGDP, do not have favorable impact on the determination of credit ratings. An interest finding is that the coefficient of RA is negatively significant in Eastern China alone. It indicates that smaller credit rating agency tend to give higher ratings after controlling for bond issuer and issue characteristics, at least in Eastern China. The implication is that, in a less developed bond market, smaller rating agencies probably give credit ratings with less informational content.

Appendix: The ordered probit model for credit rating

Credit ratings are often viewed as important assessments of firms' underlying credit risk as certified by rating agencies such as Moody's and Standard & Poor's. Without such certification, firms who want to borrow from the public debt and loan markets may not be able to do so, and investors would be reluctant to lend money to the firm (Sufi, 2009). Credit ratings may also contain information on firms' credit quality beyond other publicly available information. For instance, firms may be

reluctant to release information to the market that would compromise their strategic programs, in particular with regard to competitors. Credit ratings in comparison allow them to incorporate inside information without disclosing specific details to the public at large. Credit ratings can be viewed as resulting from a continuous, unobserved creditworthiness index. Each credit rating corresponds to a specific range of the creditworthiness index, with higher ratings corresponding to a higher range of creditworthiness values. Since the credit rating representation of creditworthiness is a qualitative ordinal variable, the estimation of a model for such a dependent variable necessitates the use of a special technique.

Consider the simple case of a qualitative unordered dichotomous dependent variable, i.e., a variable that can take only two values (such as yes or no, on or off). Assume that this variable, represented as a 0-1 binary variable, is modeled as a linear function of a set of explanatory variables and of an error term. The predicted values from the estimation of this model should fall mainly within the 0-1 interval, suggesting that they could be interpreted as probabilities that the dependent variable takes the value 0 (or 1), given the values of the explanatory variables. However, such estimated probabilities can fall outside the 0-1 range. Various distribution functions are available to constrain the estimated probabilities to lie in the range (0,1), the most frequently used being the cumulative standard normal probability function and the logistic function. The probit model makes use of the former, while the logit model makes use of the latter. If the qualitative dependent variable can be classified into more than two categories (i.e., if it is a polychotomous variable), estimation can be undertaken by means of the multinomial probit or the multinomial logit models, which are generalizations of the binary probit and logit models. However, the credit rating representation of creditworthiness is not only a polychotomous qualitative variable; it is also an ordinal variable, i.e., a variable with an inherent order (unlike a polychotomous variable representing, say, choices of colors or travel destinations). An ordinal polychotomous dependent variable would usually be coded as 0, 1, 2, 3, and so on. This representation reflects only a ranking; it is not known to what extent going from 0 to 1 is different from (or equivalent to) going from 2 to 3. For such an ordinal dependent variable, using multinomial probit or logit would not be efficient, because these models would misspecify the data-generating process in assuming that there is no order in the different categories that the dependent variable can take.

The ordered multinomial probit (OMP) is used for estimation in the context of an ordinal polychotomous dependent variable. While taking into account the existence of a ranking, the OMP also assumes that the size of the difference between any two adjacent ratings is not known but does not matter to the carrying out of the analysis, unlike, for example, the usual regression techniques, where the size of the difference between adjacent elements is known and matters to the carrying out of the analysis.

Assume that the unobserved continuous measure, creditworthiness, is a linear function of a set of explanatory variables x, with parameter vector β, and an error term ε:

$$\tilde{y} = \beta' x + \varepsilon \tag{3}$$

As usual, $\tilde{y}$ is unobserved. What is observed are the credit ratings assigned to the bonds, which range from AAA to A-.

$$y = AAA \quad if\, \tilde{y} \le \mu_1 \tag{4}$$

$$y = AA+ \quad if\, \mu_1 < \tilde{y} \le \mu_2$$

$$\ldots\ldots$$

$$y = A+ \quad if\, \mu_5 \le \tilde{y}$$

This is a form of censoring. The μ s are unknown partition boundaries (or cut points) that define the ranges of the creditworthiness index (i.e., AAA, AA+, AA, AA-, A+, A, A-); these parameters must be estimated in conjunction with the vector. Estimation proceeds by maximum likelihood.

It is assumed that ε is normally distributed across observations, and the mean and variance of are normalized to zero and one. With the normal distribution, the following probabilities result (for simplicity, AAA, AA+, AA, AA-, A+, A and A- are denoted as 7, 6, 5, 4, 3, 2 and 1respectively), where is the cumulative function of a normal distribution:

$$prob(y = AAA) = \phi(\mu_1 - \beta' x) \tag{5}$$

$$prob(y = AA+) = \phi(\mu_2 - \beta' x) - \phi(u_1 - \beta' x)$$

$$\cdots\cdots$$

$$prob(y = A+) = 1 - \phi(\mu_5 - \beta' x)$$

A likelihood function can be formed as follows:

$$L(y/x) = \sum_{k=1}^{n} \left\{ Y_{1k} \times \ln \phi(\mu_1 - x_k{}' \beta) + \sum_{i=2}^{5} Y_{ik} \times \ln \left[\phi(\mu_i - x_k{}' \beta) - \phi(\mu_{i-1} - x_k{}' \beta) \right] + Y_{5k} \times \ln \phi(\mu_4 - x_k{}' \beta) \right\} \tag{6}$$

where Y_{ik} is an indicator variable that takes on the value one if the realization of the k th observation Y_k is the i th rating, and zero otherwise. Once the likelihood function is formed, the estimation of the unknown parameter μ's and β's can be undertaken. The estimated cutoff points, μ's, along with the estimated β's, maximize the log-likelihood function stated above.

Capital Investment in Logistics Technology: Lessons Learned from Song Than ICD Co. Ltd

Tung Nhu Nguyen
International University
Vietnam National University Ho Chi Minh City
Vietnam
nntung@hcmiu.edu.vn

Capital investment made by logistics companies in technology aims to enable their customers achieve competitive advantage through cost leadership and value-added services. The paper reviews different perspectives on appraising an investment in a new technology. A case study of Song Than ICD Co., Ltd., a third-party logistics (3PL) company shows that a strategic investment in warehouse management system (WMS) is a right decision in order to achieve investment success. The study findings provide valuable lessons learned in relation to decisions on investment on a state-of-art logistics technology in the context of regional and global integration being undergone by Vietnam's logistics companies.

Keywords: warehouse management system, logistics, technology

Introduction

Logistics market

Full-service logistics functions provided by a third-party logistics (3PL) company should include warehousing, transportation and distribution. Logistics market in the Asia Pacific region has been growing in recent years when companies are outsourcing logistics services but the customers are expecting better, faster and cheaper logistics services. Table 1 shows the relevant economic data on the logistics industry in the world. Especially, the 3PL revenue in the Asia Pacific accounts for the biggest cut of the total global 3PL revenue (31%).

Table 1 - Global 3PL market size estimates (in billions of US dollars)

Region	2011 GDP	Logistics (as % of GDP)	2011 logistics cost	3PL (as % of logistics cost)	2011 3PL revenue	% of total 3PL revenue
North America	$18,004	8.9%	$1,598	10.0%	$160	26.0%
Europe	$17,690	8.9%	$1,567	10.2%	$160	26.0%
Asia Pacific	$19,208	12.8%	$2,458	7.8%	$191	31.0%
South America	$4,178	12.3%	$ 514	7.7%	$40	6.4%
Remaining	$11,081	11.3%	$1,762	3.7%	$65	10.6%
Total	$ 70,161	11.3%	$ 7,899	7.8%	$616	100.0%

Source: (Armstrong&Associates 2013)

Nevertheless, the logistics industry is facing a number of complaints from customers. Table 2 summarized the findings on what logistics customers want and it is found that information technology (IT) capabilities received the second worst evaluation score on continuing problem (35%). Noticeably, the IT capabilities in the Asia Pacific region is the lowest in comparison with other regions.

Problems facing Vietnam's logistics industry

The logistics industry in Vietnam is still on the nascent stage. Logistics costs in Vietnam are estimated to be between 15 and 20 percent (Frost and Sullivan Report). The demand for logistics services provided by third-party logistics (3PL) companies is on the rise but Vietnam's logistics companies are reported to be struggling to be third-party logistics (3PL) companies as they lack capabilities to provide full-range logistics services to customers. Vietnam's logistics industry is very highly fragmented. A large number of domestic companies provide only discrete distribution services, mainly as shipping, trucking and customs clearance. Very few domestic companies are truly 3PL company. Foreign logistics companies, with their capability to provide integrated full-service logistics have been dominating logistics market in Vietnam.

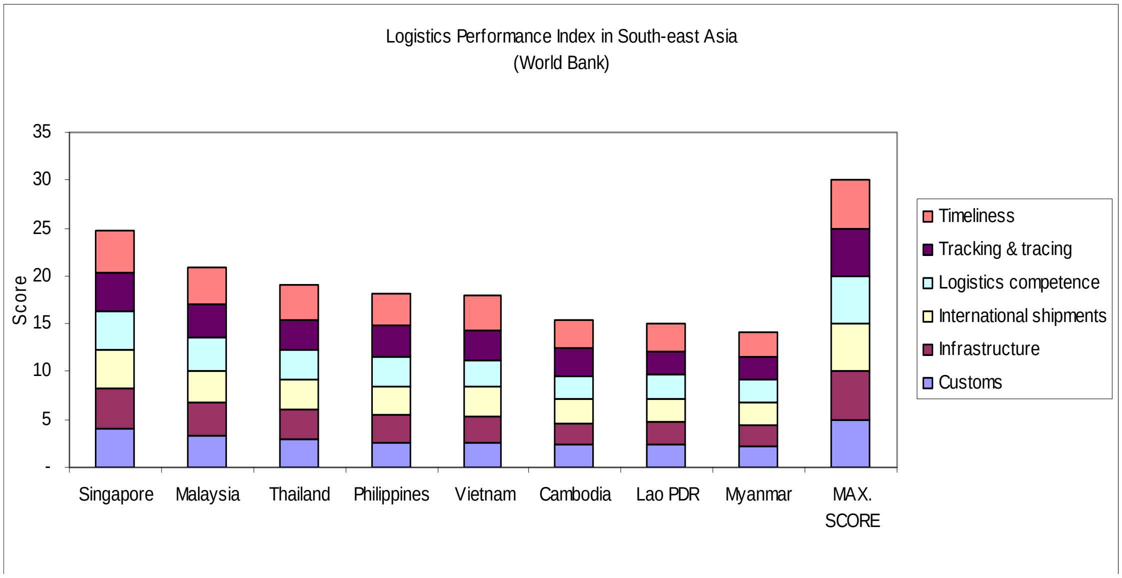
Table 2 - Continuing problems with 3PL providers as reported by customers

	All regions	**North America**	**Europe**	**Asia Pacific**	**Latin America**
Service level commitment not realized	46%	43%	46%	46%	50%
Lack of continuous, ongoing improvements and achievements in offerings	40	37	41	41	43
Cost reductions have not been realized	35	37	37	34	32
Information technology capabilities not sufficient	35	38	31	38	33
Lack of project management skills	33	31	35	36	31
Unsatisfactory transition during implementation stage	30	34	28	33	21
Ineffective key performance indicators (KPIs)	30	28	27	31	39
Too many human conditions related problems	29	30	24	32	34
Lack of consultative/knowledge-based skills	26	22	23	34	27
Lack of business process integration across regions and supply chain services	20	21	16	28	12
Lack of global capabilities	19	16	19	20	21
Inability to form meaningful and trusting relationships	13	15	13	13	12
Poor post-merger integration of acquired companies	13	12	13	21	3
No problems	13	17	16	6	15

Source: (Langley 2007)

Table 3 shows that Vietanm is placed number five out of eight Asean countries in logistics performance index (LPI) scores. Among the evaluation criteria, timeliness, tracking and tracing problems can be handled by improving information quality. Investments in information communication technology (ICT) specialized in logistics operations can help improve the LPI indicator results. There are a number of trends that put downward pressure on investment in ICT for domestic logistics companies. First, regional and global integration, especially with 2015 Asean Economic Community (AEC) realization and looming Trans-pacific Partnership (TPP), more strong global 3PL companies enter Vietnam's logistics market, making competition more intense in this field. Also, companies tend to operate globally, demanding a higher level of logistics management, which can be met by a higher level of ICT. Second, rapid technology change creates opportunities for logistics to apply advanced ICT to improve their customer service. Third, e-logistics services are on the trend. E-logistics is defined to be "the mechanism of automating logistics processes and providing an integrated, end-to-end fulfillment and supply chain management services to the players of logistics processes. Those logistics processes that are automated by e-logistics provide supply chain visibility and can be part of existing e-Commerce or Workflow systems in an enterprise"

Table 3 – Logistics Performance Index in Southeast Asia



(Watson Research Center, 2007). If a domestic company is behind in adopting e-logistics, it will left behind in competition for logistics markets.

Warehouse Management System

One of the software and solutions for running 3PL services is Warehouse Management System (WMS). The WMS acts as the hub of a company's supply chain solution, integrating accounting/order and shipping software systems, electronic data interchange (EDI) systems, radio frequency and barcode hardware, and warehouse automation equipment. This inventory-control system would link customers, distributors, drivers, warehouses and retailers. The system would help reduce the time of ordering and order fulfilling, better control inventory, reduce inventory shrinkage and pilferage and faster recognize changes in demand at the customer level. The costs may range from 10 to 16 million US$ to include about 15 million USD for the system. For example, WMS investment in WMS by DHL Vietnam cost about 15 million US$. Vinafco, a domestic logistics company spent 16 million US$ for this system in 2013. Normally, some time after installation of the system, another phase of investment with several additional million US$ is needed for ancillary equipment.

The benefits of WMS

WMS is a must for effective and efficient operation of a distribution center. It covers all functions involved in physically distributing and handling goods at a distribution center (DC). These functions include inventory management operations (maintaining items, groups, orders) and order flow (retrieving orders, storing orders, tracking and tracing). Together, distribution and warehouse management system (WMS) aim to improve customer service. The benefits to customers are real-time enterprising in material management, improved operations in terms of accuracy, reduced paperwork, integration to automated warehouses. WMS providers claim its benefits as inventory control, stocking, cross-docking, quality control, returns management, task management, yard management, locating and picking (Fig. 1).

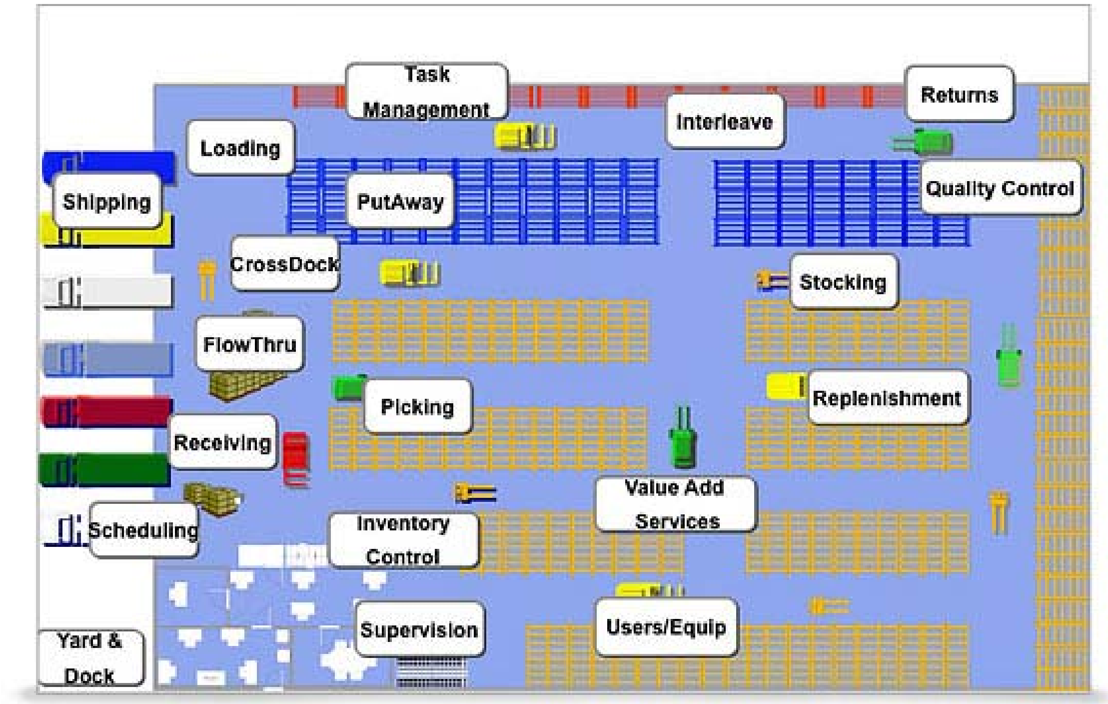


Figure 1 – Claimed benefits of warehouse management system (source: Oracle Corporation)

Some key providers of WMS are Marc Global Services, PeopleSoft, SSA Global, Microsoft Business Solution, Oracle Corporation, JD Edwards, Pulse Logistics System.

A company with advanced technology would be a first mover, occupying markets ahead of competitors hence increase revenues. A typical example is UPS or FedEx, who entered Vietnam's market in 2000s and occupied a large portion of Vietnam's logistics markets because their service quality is much more compelling than that of domestic ones. For example, they deliver packages fast and very accurately, thanks to their modern information technology application. Warehouse management system helps customer businesses boost productivity, reduce inventory-carrying costs, shorten order fulfillment times, and deliver a rapid return on investment (ROI).

Study Objective

The purpose of this study is to investigate why Song Than ICD Co. Ltd., a state-owned logistics company invested in warehouse management system and examine its performance outcomes as a results of the system installation. The proposition is that a company with investments in an advanced information system can be justified by its business strategy, operational, tangible, intangible benefits. The study results would identify critical lessons learned from the company in making decisions on technology investments.

Methodology

Qualitative approach is applied for this study. The purpose is to determine critical success factors to the phenomena of an investment in an advanced warehouse management system to serve the business model of distribution center. The study process began from personal contact with executives of Song Than ICD Co. Ltd., firstly via email and then an in-depth interview. Semi-structured interview has been conducted in July 2014. For the quality and validity of interviewed, the interviewee was business and planning manager of Song Than ICD, Co. Ltd. The advantages of the important people in the organization is that the researcher can gather valuable and correct information such as company policies, history and plans. In addition, the researcher collected relevant information from different sources such as company records, websites and related reports.

Relevant Literature

Justifications for logistics technology

A great deal of literature wrote about the relationship between information technology and business performance. (Porter 1998) postulated that information technology is one of the sources for sustained competitive advantage and profit. However, in order for the IT to contribute to business performance, some conditions are that the resources, including IT resources should be are firm specific, valuable, rare, imperfectly imitable, and not strategically substitutable by other resources (Barney 1991) There have been many efforts to link financial ratio with IT capability. Some noticeable revelations are that the average profit ratios of firms that have superior IT capability are higher than the average profit ratios of all other firms in the industry (Santhanam and Hartono 2003) and the financial performance of IT leader firms is significantly better than those of the matched firms on several measures of financial performance Bharadwaj (Bharadwaj 2000).

A classical approach used to appraise a capital investment is from the neoclassical theory (Jorgenson 1963) and the Q theory (Tobin, 1969) as follows.(Tobin 1969), as follows.

$$\Delta_j = \int_{t=0}^{\infty} e^{-rt} E\left\{\left[\mathrm{MR}_t\left(\frac{1}{\varepsilon_t}+1\right)\right] - g_I - q\right\} \mathrm{d}t,$$

in which $g(I_t) = dG(I_t)/dK_t$ *and* $G(I_t)$ is the adjustment cost of investment as defined by Tobin (1969). The equation above poses that the factors influential to the investment decisions are: marginal adjustment cost $g(I_t)$, which is internal to the firm; (ii) marginal revenue MR)and demand elasticity *(є)*, which represent the characteristics as well as changes in demand in response to the firm’s adoption of technology; (iii) the cost of investment, including funds ® and equipment (*q*); and (iv) firm’s business expectation indicated by the operator E[…]. According to the neoclassical investment theory, investment objective is to maximize its net worth or profit and the investment decision is determined by the costs of equipment and labor.

Nevertheless, business performance should not only be measured by financial returns but also other performance outcomes. Kaplan and Norton (1992) added financial model with customer service, internal business measures and learning measures through the balanced scorecard framework for an IT-company (Kaplan and Norton 2005). A general framework of factors justifying an investment in a IT project covers strategy fit, tactic and operational considerations, tangibles and intangibles (Gunasekaran, D. et al. 2001). Tangibles can be measured by return on investment (ROI), lead time, inventory cost reduction while intangible benefits include better competitiveness, improved customer service and even risk of not investing in a technology (ibid). In his survey, Kirkpatrick found that only 30% of the Chief Information Officers said that monetary metrics are sufficient to justify substantial benefits from an IT investment, implying that intangibles are very important (Kirkpatrick). In terms of strategic fit, technology investment should be aligned with the company's long-term growth strategy. Although a ROI is not ascertained for an investment, a strategy reason can dominate an investment decision. At the tactical and operational level, integration with existing system, satisfied evaluation indicators are among the items required for consideration prior to an investment (ibid). Besides, mandates from big customers force a logistics service provider to install an management information system if the provider wants to maintain service contracts with them. For example, large retailers such as Wal-Mart and Target issued mandates to logistics service providers to install advanced information systems for better inventory control, meaning that the providers have no choice but invest in the systems (Vijayaraman and Osyk 2006). Firm characteristics such as firm size, diversification, sector, structure also affect IT investment (Yap 1990).

Technology Transfer in Vietnam

Most of technology investments in Vietnam have been implemented through technology transfer contracts between a foreign company as a transferring partner and a Vietnamese company as a recipient. However, due to the reasons given as above, the number of such contracts is not numerous. Vietnamese companies not only lack capital for investment, information for seeking and acquisition, but also are limited in appraising an investment in technology. Some large corporations have spent a lot of money buying equipment which are underutilized or wasted. The most recent study on 8,010 Vietnamese firms in many industries was conducted to assess their technology and competitiveness (2014). The results found that only about 8% had some form of R&D expenditure. More than a half of this expenditure was used to develop technology new to the market the firm operates in. The firms preferred adaptation of existing technologies for use within the firm. This finding is consistent with the results of a previous study that "investments in existing technologies providing a better return for firms compared to the costly innovative R&D" (Basant and Fikkert 1996). The critical reasons for technology adaption included that the firms wanted to improve quality for improved competitiveness, increased productivity, enriched product variety, capacity expansion, outdated technology replacement (Newman, Rand et al. 2014). This reflects the fact that Vietnamese firms are conscious of importance of technology investments in operations and competitiveness. The biggest obstacle for the surveyed firms to adapt a technology is the lack of access to financial capital or credit, similarly to other emerging economies (Basant & Fikkert, 1996).

Findings

Vietnam logistics industry overview

Among about 1,200 logistics companies operating in Vietnam market, about 18% are state-owned, 70% privately owned and 10% non-registered and about 2% foreign logistics companies (Sullivan 2007). Multinational and joint venture companies (foreign-invested) target global customers in Vietnam by offering logistic packages (such as 3PL package – Third Party Logistics). State owned companies/corporations dominate local market on freight transportation and delivery. Joint Stock and private companies targets customers who are in private sector in Vietnam and are competing with players in the first group to offer 3PL package to multinational customers in Vietnam. The demand for warehousing, transportation and freight forwarding services has steadily increased for recent years due to the high volumes of materials and finished goods. Table 3 shows the increase trend of container volumes.

In addition, revenues from logistics services in Vietnam's market is steadily increasing, at a rate of around 25% per year (Vietnam's General Statistics Office).

The Case of Song Than ICD Co. Ltd

Company Profile

Vision: "to be one of the five (5) top professional logistics service providers among Vietnam's domestic logistics companies (excluding foreign logistics companies) in 5 years; to be one of the top ten logistics services providers in Vietnam market" (Source: Company Document).

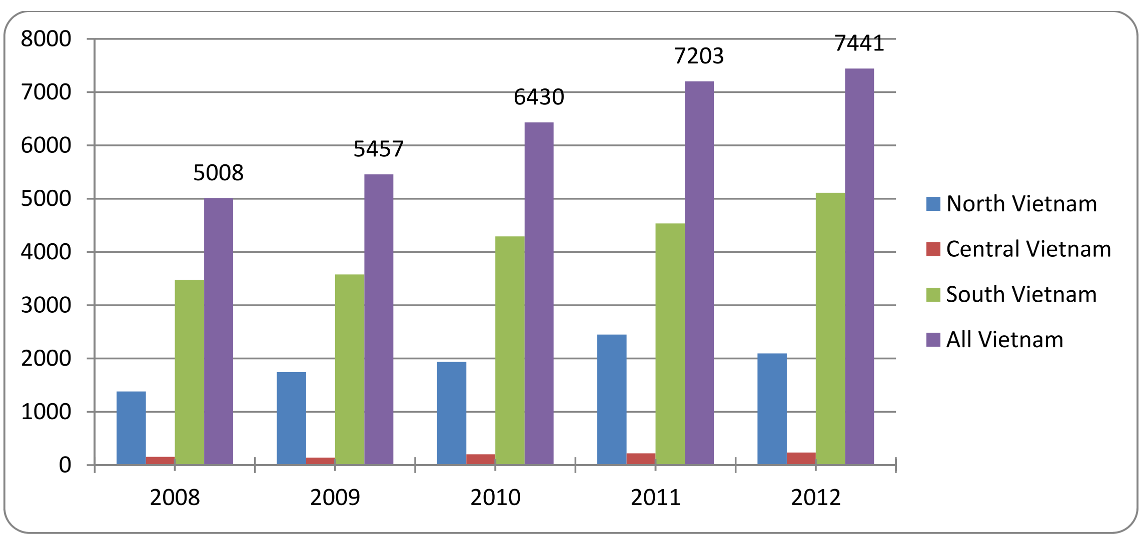

Figure 2 – Vietnam Container Throughput in million TEUs (Source: Vietnam Seaports Association)

History of the company

The company is based in Binh Duong Province. Established December 2000, the company was subsidiary to Tan Cang New Port Corporation, headquartered in Ho Chi Minh City. Originally, the company provided a limited number of logistics services such as warehouse lease, transportation, customs brokerage, container loading and unloading. With these basic services, at that time Song Than ICD was regarded as two-party logistic company. Later, the company had taken dramatic transformation steps. It expanded logistics services as a true three-party logistics (3PL) provider, running a distribution center for a multinational corporation Kimberly Clark. It had capability to integrate many logistics and supply chain processes such as production, distribution and retailing. Now its business activities include container yard and warehousing service, terminal service, customs clearance, bonded warehouses, cold warehouses, container handling, storage and haulage, commodity classification and packing, container sanitation and repairing, domestic commodity distribution, shipping agent. Its logistics capabilities include container yard of 95,000 m^2, warehouse of 164,500 m^2 (domestic warehouse: 123.458 m^2, CFS warehouse: 17.614m^2, bonded warehouse: 23.428m^2), 4 depots (Depot 1: 49.500m^2, Depot 2: 23.500 m^2, Depot 3: 10.000 m^2, Depot 4: 12.000m^2). The company invested in hardware and software for logistics activities. The purchased advanced equipment includes rail mounted gantry crane (3), reach-stacker (02), empty reach-stacker (01), forklift (06), prime mover (12). The software includes Warehouse Management System.

Business Performance

The annual revenue growth has been 15% on average over the last 14 years. In 2012, its total revenue was VND 186,685 billion (or 8.6 million $US), equivalent to 109.27% of the planned one; total profit was VND 32,250 billion (or 1.5 million $US), equivalent to 104.85% of those planned. With its business achievements, in Mar 6, 2015 Song Than ICD Co. Ltd, a subsidiary company to Saigon New Port Corporation, was honored with the "2nd-rank Labor Medal" presented by the President of Vietnam. In 2015, the company has total assets of 280 billion VNDs or about 13 million $US.

Strategy Change and Technology

The remarkable strategy change made by the company was that the company decided to shift from a single-function business model of freight forwarding to a multi-function model of distribution center, including all logistics services such as warehousing, distribution and shipment. Song Than ICD Co. constructed its vision to be a top domestic 3PL. This shift came from its investigation and analysis of opportunities from external environmental factors as well as internal strengths. To run a distribution center effectively, an advanced warehouse management system (WMS) was purchased. With its advantages from strong logistics infrastructure such as ports, warehouses, advanced management software, it is the first domestic logistics company that won an international 3PL service contract with a big US multinational corporation, Kimberly Clark.

"Originally, its function was to exploit (the use) of the port (Tan Cang Port). In recent years, (we) recognized intense competition trend. The potential for logistics is very big but logistics logistics companies are occupying the market. Therefore, Tan Cang Corporation identified the second pillar, in addition to the pillar of port exploitation, is logistics services. The company was established in 2000 from an enterprise under Tan Cang Corporation. Since 2007 the company has been financially independent. Its functions include warehousing, container transportation, customs brokerage service. In 2009, Song Than ICD won a logistics service contract for Kimberly Clark, a U.S. corporation. In this bid, Song Than ICD was the only domestic participating company, together with other seven foreign logistics companies. The contract services include provision f service solutions for a distribution center for Kimberly Clark. These services are really third-party logistics ones. This opened a new direction, i.e. third-party logistics services." (Tran Tri Dung, Business and Planning Manager, Song Than ICD).

Lessons learned

What drove Song Than ICD adopt the model of distribution center and the acquisition of warehouse management system (WMS) to run the center should be examined for lessons that would be learned from Vietnamese logistics enterprises prior to following it.

Technology investment as an organizational strategy, not departmental interests

Their top-level managers studied opportunities from external environment and strengths from inside to prepare this strategy. Externally, facilitating environmental factors include its easy access to logistics infrastructure (ports, etc), growing demand for 3PL services. Internally, centralized organizational structure, as a military-originated organization, created a unity of command culture, top-down approach to implement any strategic decision. Once senior management issues a strategic decision, all lower-level personnel must abide by it. This organizational structure is ideal in managing expensive investments. The decision on buying a management information system should be due to necessity for competition and long-term plan, not short-term benefits based on a specific discipline. If the appraisal of technology investment is made by lower-level managers, different perspectives can cause lack of consensus. Financial department manager will prefer profit ratios, e.g. payback period, return-on-investment (ROI), internal rate of return (IRR). The financial people may be concerned that new huge investment in technology may dilute return on investment if the current ROI has been high from current operations. Chief information officer (CIO) or the head of IT Solutions Company, another sister company of Saigon Newport Corporation, may belittle profit considerations. Rather he will highly appreciate non-profit criteria such as system integration, data migration. Managers in charge of customer relationship may consider intangible benefits such as improve customer relationship, risk of not investing in technology. Senior manager at Song Than ICD used top-down approach to make strategic decision in this case.

Intangible vs. tangible benefits

Investors should not focus too much on tangible benefits such as profit indictors. Intangibles such as improved staff skills, customer service, process effectiveness should be considered for investment decision. These suggested measures are consistent with the balanced scorecard of a company (Kaplan and Norton, 2005). Managers at Song Than ICD recognized that the new WMS improved computer skills for its staff.

> *"In terms of project efficiency, initially there was difficulty due to personnel quality. But after one year, staff's capability improved. They changed their working attitude and styles. Previously, warehouse staff used to be responsible for opening and closing the gate for warehouses only, but now they should know to process orders accurately". (Tran Tri Dung, Business and Planning Manager, Song Than ICD).*

Strong support from top management for investment implementation

The investment success depends on management support, commitment, policies, organizational culture for innovation, strategic points. Two organizational elements that inspire technology adoption at Song Than ICD are obviously seen to be strong commitment from management and strategic goal to be top 3PL company.

> *"We as military side are disciplinary. When a plan is started, there is project management board, steering board and experts' team. When the project is right, it must be implemented. Nobody may obstruct it. It is our advantage to be well-organized and highly disciplined" (Tran Tri Dung, Business and Planning Manager, Song Than ICD).*

Besides, a sister company Tan Cang IT Solutions Co., assisted in appraising the investment proposal and monitoring the investment process. With its expertise and experience in evaluation IT projects, Song Than ICD feels less concerned on technological issues but focus more on its logistics operations.

Future Studies

As follow-up to these findings, future studies should include quantitative research that covers a robust sample of logistics companies in Vietnam. Hypotheses should be tested on the impact of the factors such as strategy, tangible and intangibles on the decisions on technology investments and how the business performance is predicted by technology investments. Furthermore, the issues on risks should be explored. The investment as above was based on the assumption that 3PL logistics customers, such as Kimberly Clark, are increasing its outputs in line with economic growth in Vietnam hence maintain supply relations in a long term, e.g. more than 5 years. Nevertheless, there are some risks. The fact is now that the contract between the company with Kimberly Clark is 5 years. The possible risk to the success of this investment is that changes in the customer's business performance can influence the continued service contract with the company. These changes may be classified in three scenarios: 1) after some years of using the company services, the customer may begin to use services from other 3PL services providers; 2) the business performance of the customer in Vietnam is not going well. For example, Kimberly Clark will lose some market because of more and more competitors to Kimberly Clark in producing the same products in Vietnam's market and worse, its competitors save a lot of logistics costs. This may require Kimberly Clark to reevaluate its contract with Song Than ICD logistics. Another proposed research topic is to investigate which factors make a company self-develop an inhouse management system rather than purchase expensive management software developed by big IT solutions corporations. A comparative study of buying and making cases would draw useful conclusions for companies to make a suitable choice.

We examine the effect of corporate diversification on firm performance, for firms listed on Vietnamese stock exchanges, using 2744 firm year observations over the period from 2007 to 2012. We find that corporate diversification has negative impact on firm performance. Our results are robust to various econometric estimation techniques including fixed effect, instrumental fixed effect, Heckman Selection model and System Generalized Method of Moments. In the Vietnamese context, lack of efficient corporate governance system may encourage firms to take corporate diversification strategy, which impairs firm performance.

Keywords: Corporate Diversification, Firm performance, Heckman selection model, System GMM

1. Introduction

In the past, Vietnam was a centrally planned economy; however in 1986 there was an important economic reform (named as Doi Moi) wherein a market economy was adopted. Following the economic reforms, the privatization process of state owned enterprises, also called "equitization" in Vietnam, was proposed in 1991 and was launched in 1992. The Vietnamese government encouraged firms to diversify[1] their businesses in late of 1990s[2]. Thus many firms began operating in multi segments, particularly state-owned enterprises. These firms then were privatized and listed on stock market.

There are many studies on relationship between corporate diversification and firm performance in developed markets and developing markets[3]. The research on impact of corporate diversification on firm performance is still unexplored in Vietnamese context. This paper fills in the gap in existing literature by investigating the impact of corporate diversification on firm performance for Vietnamese listed firms over the period from 2002 to 2012. We employ fixed effect, Heckman selection and system generalized method of moments econometric estimation to investigate the relationship between corporate diversification and firm performance. We find that in Vietnamese context, corporate diversification has negative impact on firm performance.

This paper is structured as below: Section 2 discusses various theories, benefits and costs related to corporate diversification. Section 4 discusses literature review and develops hypotheses. Section 5 discusses methodology. Section 6 discusses data and variables. Section 7 illustrates classification of diversified firms. Section 8 discusses summary statistics and correlation matrix. Section 9 discussed empirical results and finally, section 10 concludes.

2. Corporate diversification: Theoretical perspective, Benefits and Costs

When a firm expands, it tends to diversify its operations because of the existence of surplus resources in current businesses. Corporate diversification is often considered as a strategy for

---

[1] Corporate diversification is an expansion strategy adopted by many enterprises around the globe (Lin and Su, 2008).

[2] The Law On Domestic Investment Promotion signed by Chairman of National Assembly on 20/05/1998 (http://www.moj.gov.vn/vbpq/en/Lists/Vn%20bn%20php%20lut/View_Detail.aspx?ItemID=1543)

[3] Lang and Stulz (1994), Berger and Ofek (1995), Claessens et al. (1999), Chen and Ho (2000), Khanna and Palepu (2000), Schoar (2002), Lu and Beamish (2004), Villalonga (2004a), Mishra and Akbar (2007), Boubaker et al. (2008), Li and Rwegasira (2008), Bae et al. (2011), La Rocca and Staglianò (2012), George and Kabir (2012), Lien and Li (2013), Choe et al. (2014)

firms in order to expand their operations and reach the goal of profit maximization. Further, corporate diversification refers to an expansion of a firm into "related and unrelated" investments (Kim et al., 2009)[4]. It is suggested that firms tend to diversify because of changes in economic or industry conditions (Campa and Kedia, 2002). There are three main theories (agency theory, resource-based view and internal capital market) that examine corporate diversification. These theories are discussed in the following subsections.

2.1 Agency theory

Agency theory is developed by Jensen and Meckling (1976). The theory reflects the relations, goals and conflicts arising in corporations between agents (the managers) and owners (the entrepreneurs). Aggarwal and Samwick (2003) state that there are two main agency arguments which can be used to explain why managers tend to diversify their firms' businesses. The first agency explanation is risk reduction. Senior managers in corporations typically have their own equity in their own firms. Therefore, they tend to face idiosyncratic risk when firms do not diversify. As a result, managers have more incentive to diversify their firms' business. They argue further that the higher equity ownership the managers have; the higher idiosyncratic risk they face and therefore they try to diversify their firms in order to lower that risk. The second explanation of diversification activities is private benefits of managers. Although new investments may not be valuable, managers may obtain a better reputation when they manage a more diversified firm. Thus, managers become more valuable to firms and they can demand more compensation.

A recent explanation that arises to justify the diversification propensity is the nature of corporate governance system of firms. Corporate governance can refer to the ways that the board of directors and managers control a company, and make decisions, especially decisions that have an important effect on shareholders. It is revealed that firms with weak corporate governance may motivate managers to diversify the firms because they can exploit the inadequate corporate governance in order to obtain benefit from corporate diversification. Jiraporn et al. (2006) states

[4] Related diversification refers to the diversification strategy employed to set up new products or new businesses that are related to current business of firms. Unrelated diversification is a diversification activity that introduces new products or new areas that are not related to firms' existing business.

that managers can take advantage of the weak shareholder rights, associated with restrictive corporate governance mechanisms, and diversify the firm unwisely.

2.2 Resource-based view theory

The resource-based view is discussed by Wernerfelt (1984). He argues that firms can become bigger with a strategy of conducting a balance between exploiting existing resources of the firms and also developing the new ones. Furthermore, Chatterjee and Wernerfelt (1991) explain that most resources of firms are not simply used for one product, and therefore it is an incentive for firms to diversify.

From the resource-based perspective, it is observed that diversification would occur in firms if the firms' resources and capabilities are in surplus and these resources can be transferred across industries (Mishra and Akbar, 2007). Thus, if firms can exploit their unused resources, they are willing to expand. Based on the idea of resource-based view, Matsusaka (2001) suggests a theoretical model of diversification strategy of firms. He contends that diversified firms tend to have lower performance compared to undiversified firms because these firms do not appropriately match their organizational capabilities to the new businesses. However, if the firms that have organizational capabilities[5] find businesses matching their capabilities, they would diversify their businesses. Hence, this is the reason that firms try to find new products or enter new industry.

2.3 Internal capital market theory

This theory suggests that if a firm has the ability to allocate capital generating from its business unit to another business unit, the firm can operate efficiently. This action can be explained by informational advantages of the firm in raising capital compared with the external capital market. It means that the firm can avoid the cost of capital financing from outside. Indeed, Matsusaka and Nanda (2002) argue that cost of external financing is greater than the cost of internal funds. They also state that internal capital allocation may provide the firm the benefit of selecting internal capital instead of raising funds from external capital market. This feature cannot be found in a stand-alone firm. Moreover, in an environment of agency problems and asymmetric information, the internal capital market is beneficial because it eliminates costs of capital from the external market. Lins and Servaes (2002) study corporate diversification in emerging

[5] Senior managers' capabilities are also considered as organizational capabilities.

markets. They contend that internal capital market can be an attractive motivation for corporate diversification because of imperfections in external capital market in emerging economies.

2.4 Benefits and costs of corporate diversification

Berger and Ofek (1995) propose that corporate diversification has "value-enhancing and value-reducing effects". They state that corporate diversification helps firms operate different businesses with larger debt capacity and lower taxes i.e. increasing tax shields, and tax savings by offsetting losses in several divisions against profit in other divisions. Firms in emerging markets may gain benefits from corporate diversification due to high reputation, easy access to foreign capital and advanced technology (Khanna and Palepu, 2000). Diversification of product and geography may encourage firms take advantages of multiple markets (David et al., 2010).

Diversified firms can easily transfer capital from one segment to another segment while stand-alone firms have difficulty in doing so (Matsusaka and Nanda, 2002). They also propose the coinsurance effect of diversification. The coinsurance effect occurs when firms with diversification can reduce the variation of cash flow and then lower the likelihood of insolvency compared with focused firms. Coinsurance thus can make diversification more attractive by allowing diversified firms to have access to loan with lower cost than non-diversified firms. Hann et al. (2013) add that the coinsurance effect in diversified firms may decrease systematic risk and therefore lower their cost of capital. Wan et al. (2011) state that from the perspective of resource-based view theory, high firm performance can be contributed by related diversification activities. They argue that firms can benefit from diversification by maximization of resource transfer among business divisions in firms.

Berger and Ofek (1995) argue that potential costs of diversification include the investment in bad projects which lead to poor divisions and thus exhaust resources from better performing divisions. Sharing the same view of the investment activities of firms, Lamont and Polk (2002) state that diversified firms may invest inefficiently, as they spend too little on their good business units while they spend too much on their bad business units. From the perspective of internal capital market, diversification destroys value of firms because diversified firms allocate capital inefficiently across their different units. Stowe and Xing (2006) reveal that diversified firms may have fewer growth opportunities than non-diversified firms. This can be explained by the restricted ability of expansion in the future.

3 Vietnam's Stock Market and Classification of diversified firms by industry

3.1 Vietnam's Stock Market

The Vietnamese stock exchange was established in 2000[6]. There are currently two stock exchanges in Vietnam i.e. Ho Chi Minh Stock Exchange (HSX) and Hanoi Stock Exchange (HNX)[7] (Viet Capital Securities, 2011). In 2000, there were only 5 firms listed on the Ho Chi Minh Stock Exchange and in 2006, the number of listed firms rose to 106. The number of listed firms in Hanoi Stock Exchange increased, from 9 in 2005 to 364 in 2010. In 2013, the number of listed enterprises were 301 in Ho Chi Minh Stock Exchange and 377 in Hanoi Stock Exchange[8]. The market capitalization value has also increased significantly, along with the increase in number of listed firms. The value of market capitalization increased significantly, from only 0.154 U.S billion dollars in 2003 to 20.385 U.S billion dollars in 2010, and reached 32.933 U.S billion dollars in 2012. Moreover, while the market capitalization of listed firms as percentage of GDP was only 0.36 percent in 2003; this figure increased to 21.14 percent in 2012[9]. This implies that the stock market in Vietnam plays an important role in the development of Vietnam's economy.

[Table 1]

Table 1 illustrates number of diversified firms and their market capitalization by industry in 2012. Column (1) illustrates number of listed firms by industry in both Ho Chi Minh stock exchange and Hanoi stock exchange in 2012. Column (2) shows market capitalization value of listed firms by industry in 2012. Column (3) illustrates number of diversified firms in industry. Construction industry has a highest number of diversified firms (63), followed by Real Estate (37), Wholesales Trade (18) and others. Column (4) illustrates market capitalization of diversified firms in industry. Real Estate has a highest market capitalization (86000 billion

---

[6] The appearance of Vietnam stock market is originated from Decree No. 48/1998/ND-CP of July 11, 1998 On Securities And Securities Market (http://moj.gov.vn/vbpq/en/Lists/Vn%20bn%20php%20lut/View_Detail.aspx?ItemID=1502).

[7] HSX was formerly Ho Chi Minh City Securities Trading Center (HOSTC) established in 2000, and HOSTC was transferred to HSX in 2007. HNX was formerly Hanoi Securities Trading Center (HASTC) established in 2005, and HASTC was transferred to HNX in 2009.

Vietnam dongs), followed by Construction (18000 billion Vietnam dongs), and Support Activities for Mining and Wholesale Trade (12000 billion Vietnam dongs). In 2012, there are 233 diversified firms which account for 37.3 percent and their total market capitalization accounts for 32.7 percent.

4 Literature review

There are many research papers that provide empirical evidence of the link between corporate diversification and firm performance. While most of the research is on the U.S. market, there are some studies about emerging markets. While examining the effect of corporate diversification on firm performance, it is found that the relationship between corporate diversification and firm performance is mixed.

Lang and Stulz (1994) use the U.S. data from the late 1970s and the 1980s to analyse corporate diversification and find that diversified firms have lower market value than single segment firms. Specifically, their study demonstrates that highly diversified firms have a mean and median Tobin's Q below the average figure of the sample. Besides, Berger and Ofek (1995) posit that the loss of value is around 13% to 15% with a sample of U.S. firms over the period from 1986 to 1991. Their results suggest that unrelated diversification creates a larger decrease in firm value than related diversification.

A study of East Asian firms by Claessens et al. (1999) find that corporate diversification is associated with a five percent discount of firm value. However, the study also cites that losses are less prominent in the case of diversified firms in poor economies. Moreover, they observe that group-affiliated firms (firms that are related through common ownership – for example, a parent company) are more likely to diversify compared with independent firms, especially in less developed economies. Likewise, Chen and Ho (2000) conduct a study on corporate diversification in Singapore and show that diversification has a negative impact on firm value, which implies that corporate diversification leads to a diversification discount. Their study also shows that large firms tend to diversify more.

Stowe and Xing (2006) study the growth opportunities of diversified firms and find that on average, diversified firms have fewer growth opportunities than do single-segment firms. They find that excess value of firms becomes significantly lower after diversification. Using annual data from twenty five non-banking firms listed on the Tunis stock exchange, Boubaker et al.

(2008) find strong evidence of a discount value on diversified firms i.e. corporate diversification decreases firm value. Singh et al. (2007) analyse the relationship between corporate diversification and performance for 889 Indian firms and find that diversified firms perform significantly worse than focused firms. Furthermore, they also find that there is a significant negative relation between the degree of diversification and firm performance. They conclude that this is due to the cost inefficiencies of diversified firms.

Bae et al. (2011) investigate the relationship between corporate diversification and firm value in Korea and find that while unrelated corporate diversification decreases firm value, related corporate diversification has no effect on firm value. Besides, they also state that this negative effect is exacerbated if firm is affiliated to a large business group. By using a sample of 607 listed companies on the Bombay stock exchange in 1999 – 2000, George and Kabir (2012) also indicate a negative effect of corporate diversification on firm performance in India.

Villalonga (2004a) examines the effect of diversification and states that diversified firms are traded at a premium compared to undiversified firms within the same industries. Villalonga (2004b) use three treatment effects estimators (Dehejia and Wahba, 2002; Dehejia and Wahba, 1999; Abadie and Imbens, 2002; Heckman, 1979) with 1978-1997 Compustat database to investigate the corporate diversification effect and posits that diversification does not destroy value. Similarly, Çolak (2010) use data of 6233 companies from Compustat between 1989 and 1998 and finds that corporate diversification does not increase or decrease firm value. He argues that corporate diversification itself does not affect firm value. The firm value may be affected by other factors such as lack of innovation or economic conditions.

In researching the relation between diversification and firm performance in India, Mishra and Akbar (2007) (through the perspective of resource-based view) suggest that group affiliation (diversification) is beneficial. Moreover, Lin and Su (2008) point out that diversified firms have higher Tobin's Q than focused firms. They also state that non-government controlled multi-division firms have better performance than government controlled diversified firms. La Rocca and Staglianò (2012) find that unrelated corporate diversification has positive effect on firm performance in Italian firms over the period from 1980 to 2007. This positive effect is explained by the fact that Italian firms diversify to lessen information asymmetry and achieve benefits from internal capital market.

Based on coinsurance arguments, for US firms over the period from 1998 to 2006, Hann et al. (2013) state that diversified firms can lower cost of capital (thus can improve firm value). By using a sample of Australian listed firms over the period from 2004 to 2008, Choe et al. (2014) find that diversified firms enhance firm value compared to that of undiversified firms and this positive effect is accelerated when firms' managers receive incentives such as stock or stock options. In studying the impact of corporate diversification on firm performance in recession period, Volkov and Smith (2014) find a significant increase in firm value of diversified firms, but this positive effect is temporary.

There are papers which indicate a nonlinear relationship between corporate diversification and firm performance. Khanna and Palepu (2000) conduct a study on 1309 Indian listed firms and show a nonlinear relationship between corporate diversification and firm performance. Corporate diversification initially decreases firm performance, and then improves firm performance when it reaches a certain level. In the case of Japanese companies, Lu and Beamish (2004) reveal a horizontal S shaped link between geographic diversification and firm performance. Li and Rwegasira (2008) report a U shaped relationship between corporate diversification and firm performance when investigating 300 listed firms in China over the period from 2003 to 2004. For Taiwanese firms, Lien and Li (2013) contend that corporate diversification has a concave effect on firm performance.

Jiraporn et al. (2006) find evidence that firms with weak shareholder rights tend to be industrially diversified. Firms' managers try to exploit the weakness of shareholder rights by unwise diversification activities. Indeed, the imperfection of market together with ineffective law in emerging countries make the agency problem associated with corporate diversification more severe (Lins and Servaes, 2002). The weak and inefficient environment can encourage firms' managers diversify businesses for their power, benefits, or ensuring their current job. Thus, diversification could lead to a discount value and firms with weak shareholder rights may experience a large diversification discount.

Vietnam began to transform from a centrally planned economy to market based economy in the mid of 1980s, and legislative reform was engaged in 2006[10] (Lobet, 2008). However, Vietnam

[10] Before 2006, there are a law for domestic companies (Law on Enterprises 2000), a law for state-owned enterprises (Law on State Owned Enterprises 2003), a law for foreign-owned companies (Law on Foreign Investment 2000), and a law for

has weak and inefficient system of economic law (Lobet, 2008; The Heritage Foundation, 2015), and low investor protection (Export Entreprises SA, 2014). Stock market in Vietnam is also characterized by low information disclosure (Nguyen et al., 2014), that creates an environment for firms' managers to exploit shareholders. Hence, it can be argued that listed firms in Vietnam do not have strong shareholder protection, and therefore the firms' managers tend to undertake discount value diversification strategy. We test the following hypothesis:

Corporate diversification has negative impact on firm performance of listed firms in Vietnam.

5 Research methodology

The following empirical model will be used to test the hypothesis:

$$FP_{it} = \alpha + \beta_1 DIV_{it} + \beta_2 X_{it} + \varepsilon_{it} \tag{1}$$

where FP_{it} is firm performance of firm i at time t, DIV_{it} is corporate diversification level of firm i at time t, X_{it}s are control variables of firm i at time t, and ε_{it} is error term.

5.1 Fixed effect estimation

There may be problem related to endogeneity, which leads to potential bias in estimations (Greenbaum, 2007). In the empirical model (1), corporate diversification may be endogenous (Campa and Kedia, 2002; Choe et al., 2014; Dastidar, 2009; Hann et al., 2013; Bae et al., 2011; Lin and Su, 2008; Villalonga, 2004b). Therefore, it is necessary to control for endogeneity of corporate diversification variable in the empirical model. The paper firstly uses fixed effect approach to deal with endogeneity caused by unobserved variables as in previous studies (Campa and Kedia, 2002; Shyu and Chen, 2009; David et al., 2010; Jiraporn et al., 2008; Choe et al., 2014). The fixed effect method uses within transformation to eliminate individual time invariant effect and then obtain the estimators through OLS estimation (Wooldridge, 2011).

5.2 Instrumental variable fixed effect estimation

The fixed effect method, however, cannot control for endogeneity when explanatory variables are correlated with error terms. Therefore, instrumental variable (IV) estimation with fixed effect method is used. Instrumental variables need to be correlated to endogenous variable (corporate diversification) and uncorrelated to dependent variable (firm performance). David et al. (2010)

---

agricultural companies (Law on Cooperatives 2003). New Law on Enterprise 2005 unified 4 laws above and was implemented in 2006.

argue that industry level variables can serve as valid instruments. The industry level instrument variables are the following: fraction of diversified firms within industry, fraction of sales of diversified firms within industry (Campa and Kedia, 2002), capital expenditure over sales within industry (He, 2009), and industry median of corporate diversification measures. For testing the validity of these instruments, Hansen J test is used in the case of heteroskedasticity (Baum, 2006; Baum et al., 2003).

5.3 Heckman self-selection model

When examining effect of corporate diversification on firm performance, corporate diversification decision may be endogenous (Dastidar, 2009) because firms are likely to diversify if they obtain benefits from diversification (He, 2012) and factors impacting corporate diversification propensity may also affect firm performance (Campa and Kedia, 2002; Choe et al., 2014). Besides, corporate diversification decision of firms may be based on firm characteristics (such as profitability, firm size, and growth opportunities) that are not a random sample but selected by firms themselves (Dastidar, 2009). Therefore, a Heckman self-selection model (Heckman, 1979) should be employed to examine effect of corporate diversification on firm performance (Dastidar, 2009; Campa and Kedia, 2002; Lin and Su, 2008; Jiraporn et al., 2008).

Based on Heckman selection approach, firm performance model is as follow:

$$y_{it} = \alpha + \beta_1 D_{it} + \beta_2 x_{it} + \varepsilon_{it} \tag{2}$$

where y_{it} is dependent variable (firm performance), D_{it} is a binary independent variable ($D_{it} = 1$ if diversified otherwise $D_{it} = 0$ if undiversified), x_{it} is a set of control variables that affect firm performance, and ε_{it} is error term.

Corporate diversification decision (selection equation) is as below:

$$D_{it}^* = \delta z_{it} + u_{it}, \tag{3}$$

$D_{it} = 1$ if $D_{it}^* > 0$ and $D_{it} = 0$ otherwise. z_{it} is a set of factors that affect diversification decision of firm, u_{it} is error term.

Then, by substituting D_{it} in equation (2); firm performance model is as follow:

$$y_{it} = \alpha + \beta_1(\delta z_{it} + u_{it}) + \beta_2 x_{it} + \varepsilon_{it} \quad (4)$$

when $D_{it}^* > 0, D_{it} = 1$

$$y_{it} = \alpha + \beta_2 x_{it} + \varepsilon_{it} \quad (5)$$

when $D_{it}^* \leq 0, D_{it} = 0$

In order to estimate regression coefficients of equation (4) and (5), Heckman's two – step procedure or maximum likelihood estimation is used (Guo, 2015). The first step of Heckman procedure is to estimate the probability of taking corporate diversification by probit or logit model, and obtain estimates of selection correction – called lambda or inverse mills ratio[11]. The second step is to include the lambda estimates from the first step in the regression model of firm performance. The two – step approach is simpler but the maximum likelihood is more efficient (Guo, 2015). The paper examines both estimation approaches.

5.4 System GMM estimation

Firm performance may be dynamic in nature (Mishra, 2014) and the econometric treatment of dynamic nature of firm performance includes lagged values of firm performance among the explanatory variables.

$$y_{it} = \delta y_{i,t-1} + x_{it}^{'}\beta + u_{it} \qquad i = 1,........,N \qquad t = 2,............T \quad (6)$$

where δ is a scalar, $x_{it}^{'}$ is a $1 \times K$ vector of explanatory variables and β is a $K \times 1$ vector of parameters to be estimated. The error term u_{it} is composed of an unobserved effect and time-invariant effect μ_i and random disturbance term ν_{it}.

$$u_{it} = \mu_i + \nu_{it} \quad (7)$$

where $\mu_i \sim IID(0, \sigma_\mu^2)$ and $\nu_{it} \sim IID(0, \sigma_\nu^2)$ independent of each other and among themselves. The dynamic panel data regressions described in above equations (6) and (7) are characterized by

[11] See Greene (2012, p. 876) for a discussion on inverse mills ratio.

two sources of persistence over time i.e. autocorrelation due to the presence of a lagged dependent variable among the regressors and individual effects characterizing the heterogeneity among the individuals. Since y_{it} is a function of μ_i, this implies that $y_{i,t-1}$ is also a function of μ_i. Therefore, $y_{i,t-1}$ is correlated with the error term through the presence of μ_i. The OLS estimator for equation (6) is biased and inconsistent even if the v_{it} are not serially correlated. The fixed effect estimator of (7), which eliminates the individual effects μ_i, produces biased and inconsistent estimates (Nickell, 1981; Kiviet, 1995). Anderson and Hsiao (1982) suggested first differencing the model to get rid of the μ_i and then using $\Delta y_{i,t-2} = (y_{i,t-2} - y_{i,t-3})$ as an instrument for $\Delta y_{i,t-1} = (y_{i,t-1} - y_{i,t-2})$. These instruments will not be correlated with $\Delta v_{it} = v_{i,t} - v_{i,t-1}$, so far as the v_{it} themselves are not serially correlated. This instrumental variable (IV) estimation method leads to consistent but not necessarily efficient estimates of the parameters in the model because it does not make use of all available moment conditions (Ahn and Schmidt, 1995) and it does not take into account the differenced structure on residual disturbances (Δv_{it}). Arellano (1989) states that for simple dynamic error components models, the estimator that uses differences $\Delta y_{i,t-2}$ rather than levels $y_{i,t-2}$ for instruments has a singularity point and very large variances over a significant range of parameter values. On the other hand, the estimator that uses $y_{i,t-2}$ has no singularities and much smaller variances. Arellano and Bond (1991) proposed a generalized method of moments (GMM) estimator of the first differenced model that brings about significant efficiency gains as compared to the estimator by Anderson and Hsiao (1982) through exploiting additional orthogonality conditions associated with higher lags of the endogenous variable in the set of instruments. Blundell and Bond (1998) show that the lagged-level instruments in the Arellano-Bond estimator become weak as the autoregressive process becomes too persistent or the ratio of the variance of the panel-level effect to the variance of the idiosyncratic error becomes too large. Linear dynamic panel data models include p lags of the dependent variable on covariates and contain unobserved panel level effects, fixed or random. Arellano and Bover (1995) develop a framework for efficient instrumental variable estimators of random effects models with information in levels which can accommodate predetermined variables. Building on the work of Arellano and Bover (1995), Blundell and Bond (1998) proposed a system estimator that uses moment conditions in which lagged differences are used as instruments for the level equation in addition to the moment conditions of lagged levels as instruments for the differenced equation. This estimator is designed for datasets with many panels and few periods. The method assumes that there is no autocorrelation in the idiosyncratic errors and requires the initial condition that the panel-level effects be uncorrelated with the first difference of the first observation of the dependent variable. The system GMM model introduces more instruments and therefore may increase efficiency (Roodman, 2009). This study employs system GMM approach to examine the relationship between diversification and firm performance.

The system GMM model requires test serial correlation in differenced residuals. The Arellano – Bond test for autocorrelation is used to identify autocorrelation of the differenced errors. The null hypothesis of this test is that there is no autocorrelation. In addition, Sargan or Hansen test of overidentifying restrictions is performed to test a null hypothesis that instruments are exogenous, meaning no correlation between the instruments and the disturbances.

6 Data and variables

6.1 Data

The data used to examine the effect of corporate diversification on firm performance is by Vietstock[12] which provides data of all listed firms in Ho Chi Minh Stock Exchange and Hanoi Stock Exchange. We exclude financial firms such as banks, security companies, insurance companies in accordance with earlier studies (Dastidar, 2009; Lien and Li, 2013; Hann et al., 2013; Chen and Yu, 2012; Jiraporn et al., 2008; Lin and Su, 2008; Lins and Servaes, 2002). The financial firms are subject to regulation and financial information that are different to other firms (Jiraporn et al., 2008).

The information of sales segments is collected from annual explanations of financial statement and annual reports of listed companies. In the case of Vietnam stock market, there are no standard requirements for information disclosures. For example, Vietnamese listed firms do not require reporting the segments' sales in industry classification codes. Hence, the information of corporate diversification is only collected from annual explanations of financial statements and annual reports of firms that disclose this information. The sales segments of each company are classified into industries based on Vietnam Standard Industrial Classification 2007 (VSIC 2007).

[12] http://vietstock.vn/

Because of availability of data, this study only focuses on unrelated diversification for which information is available. The data covers financial information of listed firms from 2007 to 2012.

6.2 Variables

Corporate diversification is measured by three approaches: dummy variable, Herfindahl index, and entropy index. Dummy variable equals one if a firm diversifies otherwise it is zero. Chen and Ho (2000) indicate assets-based Herfindahl and sales-based Herfindahl as measures of diversification. Fukui and Ushijima (2007) and Lin and Su (2008) use revenue-based Herfindahl index in their study. Martin and Sayrak (2003) state that entropy measure can capture three aspects of firm's diversification activities i.e. number of industries, distribution of firm revenues/assets over industry segment, and relatedness's degree among industries. Singh et al. (2007) and Lien and Li (2013) use sales-based entropy measure as a measure of corporate diversification.

The Herfindahl index is as follow:

$$H = \sum_{i=1}^{n} S_i^2 \tag{8}$$

where S_i is the i^{th} segment's revenue proportion of the firm's total revenues, and n is the number of segments of the firm.

The entropy index is as follow:

$$E = \sum_{i=1}^{n} S_i \times \ln\left(\frac{1}{S_i}\right) \tag{9}$$

where S_i is the i^{th} segment's revenue proportion of the firm's total revenues, and n is the number of segments of the firm.

Firms are considered as diversified if they have at least one segment's sales that account for at least 90% of total sales (Lin and Su, 2008; Lins and Servaes, 2002).

Firm performance is often measured by Tobin's Q in studies on the relationship between corporate diversification and firm performance (Choe et al., 2014; Lang and Stulz, 1994; Chen and Ho, 2000; Khanna and Palepu, 2000; Fukui and Ushijima, 2007; Lin and Su, 2008). We use Tobin's Q as a proxy for firm performance.

$$Tobin's\ Q = \frac{Share's\ market\ price \times Number\ of\ outstanding\ share + Book\ value\ of\ debt}{Book\ value\ of\ total\ assets} \quad (10)$$

$$Tobin's\ Q = \frac{Share's\ market\ price \times Number\ of\ outstanding\ share + Book\ value\ of\ debt}{Replacement\ value\ of\ assets} \quad (11)$$

In equation (11) of Tobin's Q, replacement value of assets is calculated as in studies of Alberto de et al. (2004) and De Miguel and Pindado (2001). The replacement value of firm's assets (K) is defined as follow:

$$K = KF + KI + (BA - BF - BI) \quad (12)$$

where KF is the replacement value of tangible assets, KI is the replacement value of inventories, BA is the book value of firm's total assets, BF is the book value of tangible assets, and BI is the book value of inventories.

$$KF = KF_{t-1} \times (1 + a)/(1 + b) + I \quad (13)$$

where a is the ratio of depreciation over book value of tangible assets, b is the annual growth of capital good prices (this data is collected from annual Vietnam yearbook of statistics), KF_{t-1} is the lagged value of replacement value of tangible assets and $KF_0 = BF_0$. I is investment which is defined as change in book value of tangible assets plus depreciation.

$$KI = BI \times 2P_t / (P_t + P_{t-1}) \quad (14)$$

where P is the wholesale price (obtained from annual Vietnam yearbook of statistics).

In accordance with previous studies, we use various control variables to investigate the impact of corporate diversification on firm performance i.e. firm size, profitability, leverage, investment, and dividend yield. Firm characteristics such as firm size, profitability, firm leverage, investment, dividend yield, book to market ratio, firm age and industry and economy characteristics such as fraction of diversified firms in industry and GDP growth rate are included to examine the likelihood of taking corporate diversification in the Heckman selection model.

Firm size is a factor that impacts corporate diversification. It can be argued that when firm size increases, firm tends to diversify its business because it has more resources for expanding. Singh et al. (2004) indicate that firm size and corporate diversification (measured by Herfindahl index) have a positive relationship. Firm size may have positive impact on firm performance (Chen and

Yu, 2012). However, Mansi and Reeb (2002) and Choe et al. (2014) find that firm size and firm performance has a negative relationship. Lang and Stulz (1994) state mixed relationship between firm size and firm performance. In this study, firm size is measured by taking logarithm of total assets (Çolak, 2010; Dastidar, 2009; Chen and Ho, 2000; Berger and Ofek, 1995).

Firm leverage refers to financial leverage used by the firm, which shows to what extent the firm's assets are financed by debt. Firms with high debt ratio may have ability to access more funds for business expansion (Chen et al., 2009). Firm leverage affects firm performance in the context of corporate diversification. He (2009) shows that diversified firms are likely to have higher firm leverage. Mishra and Akbar (2007) contend that it is easier for diversified firms to raise funds from debt. Besides, ability of raising debt funds also help firms to invest more into new industries. However, there are empirical evidence showing a negative effect of firm leverage on firm performance (Chen and Yu, 2012). Firm leverage is ratio of total debt over total assets (Chen et al., 2009; Chen and Yu, 2012; David et al., 2010).

Book to market ratio is a proxy for growth opportunity (Singh et al., 2004). Firms with low growth opportunities tend to expand their operations through diversification and firms with high growth opportunities have low level of corporate diversification. The book to market ratio is calculated by taking book value of firm's equity (or book value per share) divided by market value of firm's equity (or market value per share) (Hann et al., 2013).

Firm age represents the number of years that a firm exists. It can be argued that firms with long history may have capacity to do business in new industries. Besides, old firms may have less growth opportunities, and then they tend to diversify their businesses. There is evidence that shows a positive effect of firm age on corporate diversification in developed market (Denis et al., 1997) and emerging market (Chen and Yu, 2012; Lien and Li, 2013). In this study, firm age is measured by the number of years since a firm registered as corporation (Choi et al., 2012).

Profitability is a firm characteristic that affects corporate diversification decision. It is argued that firms with low profitability tend to expand their businesses through corporate diversification in order to find profitable opportunities (Campa and Kedia, 2002). Profitability influences the way that firms with high profitability tend to be less diversified (Campa and Kedia, 2002). It is also found that multi-segments firms are likely to have poor profitability (Claessens et al., 1999).

In this paper, profitability is measured by the ratio of earnings before tax and interest to sales (Dastidar, 2009; Campa and Kedia, 2002).

Industry characteristic is a factor that influences firm's corporate diversification decision (Maksimovic and Phillips, 2002). Fraction of diversified firms in industry represents for industry characteristic as it shows corporate diversification's trend in industry where firms operate. This variable indicates attractiveness of an industry which implies that a firm which operates in an industry that has a high fraction of diversified firms is likely to diversify (Campa and Kedia, 2002). GDP growth rate indicates macro-economic situation of market. It is argued that high GDP growth encourages firms to diversify businesses (Campa and Kedia, 2002).

Investment is ratio of capital expenditure to total sales (Berger and Ofek, 1995; Campa and Kedia, 2002) or capital expenditure to total assets (Mansi and Reeb, 2002). They indicate that investment has a significant positive effect on firm performance. Campa and Kedia (2002) contend that firms with high level of investment tend to be less diversified.

Dividend yield represents for dividend policy of the firm. Dividend yield is ratio of dividend per share to market price per share (Mishra, 2014; Aggarwal and Samwick, 2003). Manos et al. (2012) argue that compared to single firms, multi segment firms may get benefit from internal capital market and then easily maintain a high dividend policy for investors. Aggarwal and Samwick (2003) document a negative link between dividend yield and firm performance.

7 Summary statistics and correlation matrix

[Table 2]

Table 2 illustrates summary statistics of variables used in this study over the period from 2007 to 2012. The mean value of Tobin's Q of sample firms is 1.083, which is relatively lower than Tobin's Q value of 1.453 in Japan (Fukui and Ushijima, 2007), 1.52 in Singapore (Chen and Ho, 2000) and 2.1725 in China (Lin and Su, 2008). The standard deviation of Tobin's Q is 0.413 which is lower than 0.482 in Japan (Fukui and Ushijima, 2007), and 1.0471 in China (Lin and Su, 2008). The average value of Tobin's Q calculated on the basis of replacement value of assets is 1.041 and standard deviation is 0.407.

The average value of Herfindahl index is 0.841 with standard deviation of 0.208. The mean value of Herfindahl index of listed firms in Vietnam is higher than those of 0.700 in the U.S. (Denis et al., 1997), 0.730 in Singapore (Chen and Ho, 2000), and 0.589 in China (Chen, 2010). The value of standard deviation (0.208) of Herfindahl index in Vietnam is lower than those of 0.253 in China (Chen, 2010), and 0.246 in Japan (Fukui and Ushijima, 2007). The mean value of entropy index of listed firms in Vietnam is 0.271 with standard deviation of 0.343. The mean value of entropy index in Vietnam (0.271) is similar to the value of 0.22 in Taiwan (Chen and Yu, 2012), but lower than those of 0.76 in Spain (Del Brio et al., 2011), and 0.4922 in China (Lu and Yao, 2006). The values of Herfindahl index and entropy reveal that the level of corporate diversification in Vietnam is not as high as in developed markets or other emerging markets[13].

The average value of firm size (natural log of assets) is 26.715 and its standard deviation is 1.291. Profitability of listed firms in Vietnam has an average value of 9.7 percent, with a standard deviation of 0.096. The mean value of profitability is slightly higher than that of 6 percent in the U.S. (Çolak, 2010). Leverage variable shows a mean value of 52.2 percent and a standard deviation of 0.212. The mean value of 52.2 percent is higher than those of 33.2 percent in Japan (Fukui and Ushijima, 2007), and 48 percent in Australia (Chen et al., 2009), but similar to value of 52.1 percent in China (Chen, 2010). The mean value of investment is 0.053 and its standard deviation is 0.094. This average value of investment is lower than that of 0.09 in the U.S. (Çolak, 2010), which implies a low level of investment of listed firms in Vietnam. The dividend yield variable shows a mean value of 7 percent, with a standard deviation of 0.062. This mean value is higher than those of 1.4928 percent in the U.S. (Aggarwal and Samwick, 2003), and 4.8 percent in Hong Kong (Chen et al., 2005). The average firm age of Vietnamese listed firms is 6.352, which is considerably lower than that of 21.63 in the U.S. (Çolak, 2010). The mean value of book to market ratio is 1.366, with a standard deviation of 0.906. The mean value of book to market ratio implies a market to book ratio of 0.732 which is relatively lower than that of the U.S. (2.933) (Franco et al., 2010). The average value of fraction of diversified firms in industry is 33.086 percent. This value is lower than that of 59.48 percent in China (Lin and Su, 2008), and 68 percent in Singapore (Chen and Ho, 2000). The average GDP growth rate of Vietnam over the period from 2007 to 2012 is 5.924 percent.

[Table 3]

[13] A lower value of Herfindahl index means a higher level of corporate diversification, and a higher value of entropy index means a higher level of corporate diversification

Table 3 illustrates correlation matrix of variables. Firm performance (TOB and TOBK) is positively correlated with Herfindahl index corporate diversification variable (DIVH). Firm performance (TOB and TOBK) is negatively correlated with entropy index corporate diversification variable (DIVE). Firm performance is positively correlated with firm size (SIZE), profitability (PROF), investment (INV), and GDP growth rate (GDP) and negatively correlated with firm's leverage (LEV), dividend yield (DIVYIELD), firm age (AGE), book to market ratio (BM), and fraction of diversified firms in industry (NDIV). Level of corporate diversification is positively correlated with firm size, firm's leverage, investment, firm age, book to market ratio, and fraction of diversified firms in industry and negatively correlated with profitability, dividend yield, and GDP growth rate.

8 Empirical results

This section presents empirical results of models investigating effect of corporate diversification on firm performance. Table 4 illustrates results of fixed effect estimation. Table 5 illustrates results of fixed effect with instrumental variable estimation. Table 6 illustrates results of Heckman selection method. Table 7 illustrates results of system GMM estimation. For robustness, two measures for Tobin's Q are used in each estimation approach: (1) total market value of firm divided by book value of total assets as per equation (10), and (2) total market value of firm divided by replacement value of total assets as per equation (11).

[Table 4]

Table 4 presents results of impact of corporate diversification on firm performance after controlling for unobserved heterogeneity. Tobin's Q (TOB), measured by total market value of firm divided by book value of total assets, is dependent variable in columns (1), (2), and (3). Tobin's Q (TOBK), measured by total market value of firm divided by replacement value of total assets, is dependent variable in columns (4), (5), and (6). Herfindahl index is used in columns (1) and (4), entropy index is used in columns (2) and (5), and dummy variable is used in columns (3) and (6) as corporate diversification variables. Corporate diversification significantly shows a negative impact on firm performance i.e. increase in level of corporate diversification leads to a decrease in firm performance. In columns (2) and (4), as Herfindahl index increases (decrease in level of corporate diversification), there is an increase in Tobin's Q. Entropy index in columns (2) and (5) is negative and significant which implies that as corporate diversification increases, Tobin's Q decreases. Dummy variable in columns (3) and (6) is negative and significant which indicates that when firms diversify, Tobin's Q is lower. The result implies that diversified firms inefficiently conduct corporate diversification strategy (Berger and Ofek, 1995), and firms' managers do not operate these firms with best interest of shareholders, especially in markets with weak shareholder protection (Lins and Servaes, 2002).

[Table 5]

Table 5 illustrates results of effect of corporate diversification on firm performance after controlling for unobserved heterogeneity and endogeneity caused by correlation between diversification variable and error terms. The sign and significance of corporate diversification variable is similar as in Table 4. However, the magnitude of effect of corporate diversification level on firm performance in instrumental variable fixed effect estimation is higher. The instruments for corporate diversification variable are fraction of diversified firms in industry and fraction of sales of diversified firms in industry. The Hansen J test of over identification is provided to show that these instruments are valid.

[Table 6]

Table 6 illustrates result of firm performance on corporate diversification by using Heckman selection estimation. This table provides results from both two steps and maximum likelihood estimations using two measures of Tobin's Q as per equation (10) and (11). The table also reports first step of Heckman selection estimation (probit model of corporate diversification propensity). As shown in the table, after controlling for endogenous self-selection; corporate diversification dummy variable is negative and significant, indicating that corporate diversification impair firm performance. Lambda values from models are positive and significant, implying that features affecting corporate diversification decision are positive correlated with firm performance and relationship between corporate diversification and firm performance suffers from selection bias (Dastidar, 2009). This implies that coefficient of corporate diversification variable is corrected for selection.

[Table 7]

Table 7 illustrates results of system GMM estimation of firm performance on corporate diversification. In this table, corporate diversification measured by Herfindahl index, entropy index, and dummy variable shows negative and significant impact on firm performance. Arellano – Bond tests for serial correlation at second order and Sargan or Hansen tests for over identification of the models are satisfied, indicating that the models are appropriately specified.

In Table 4, Table 5, Table 6, and Table 7, firm size variable shows mixed results. Fukui and Ushijima (2007) find firm size as negative and insignificant. Campa and Kedia (2002), Lins and Servaes (2002) and Chen and Yu (2012) find firm size as positive. Profitability variable is positive and significant in accordance with Campa and Kedia (2002), Çolak (2010) and Choe et al. (2014). Leverage variable shows mixed results. This contradicts with Fukui and Ushijima (2007), George and Kabir (2012), and Chen and Yu (2012) who find a negative relationship between leverage and firm performance. Firms can lower cost of capital and agency problem with high debt ratio (Bae et al., 2008). Investment variable is negative and significant, which contradicts positive and significant result of investment as per Campa and Kedia (2002), Mansi and Reeb (2002), and Lins and Servaes (2002). This result may imply that that diversified firms in Vietnam may invest efficiently and hence decrease firm performance. Dividend yield variable is negative and significant, implying that listed diversified firms in Vietnam are likely to pay more dividend (Manos et al., 2012), which may have a negative impact on firm performance (Aggarwal and Samwick, 2003).

9 Conclusion

The paper investigates impact of corporate diversification level on firm performance of listed firms in Vietnam over the period from 2007 to 2012. We find that that corporate diversification impairs firm performance in listed firms in Vietnam.

Findings are as per previous studies in developed markets (Lang and Stulz, 1994; Berger and Ofek, 1995; Bae et al., 2011) and developing markets (Claessens et al., 1999; Singh et al., 2007; Boubaker et al., 2008; George and Kabir, 2012). Corporate diversification decreases firm performance because diversified firms invest inefficiently into new segments (Berger and Ofek, 1995), and have to financially support these unprofitable segments (Lins and Servaes, 2002). Weak protection mechanism in emerging markets also encourage firms' managers engage in corporate diversification in order to benefit themselves, warranting their jobs (Jiraporn et al., 2006).

The negative impact of corporate diversification on firm performance implies that Vietnamese government should pay attention to expansion operations of firms, especially in firms which have high level of state ownership. Lack of efficient corporate governance system and law enforcement may encourage firms to take corporate diversification strategy, which leads to value discount of firms. This implies that the state may conduct diversification through a portfolio investment instead of letting firms engage in corporate diversification strategy.

Support Activities for Transportation	12	3100.0	3	461.6	14.9
Telecommunications	13	2000.0	8	1900.0	95.0
Transit and Ground Passenger Transportation	6	953.8	3	136.3	14.3
Truck Transportation	6	273.4	2	22.5	8.2
Warehousing and Storage	1	558.4	0	0.0	0.0
Water Transportation	17	5000.0	10	4200.0	84.0
Water, Sewage and Other Systems	2	289.2	0	0.0	0.0
Wholesale Trade	44	17000.0	18	12000.0	70.6
Wood Products	1	70.8	0	0.0	0.0
All	625	490000.0	233	160000.0	32.7

Note: The table illustrates listed diversified firms by industry in Vietnam at the end of 2012. Column (1) shows the number of listed firms within industry. Column (2) indicates the total market capitalization (MCAP) of listed firms, in billions of Vietnam dongs. Column (3) presents the number of diversified firms. Column (4) illustrates market capitalization of diversified firms. Column (5) presents the percentage of market capitalization of diversified firms relative to market capitalization of industry. Diversified firms are firms that have at least one segment's sales account for equal or less than 90% of total sales.

Table 2: Descriptive statistics of variables

Variable	Observations	Mean	Standard deviation	Minimum	Maximum
TOB	2677	1.083	0.413	0.602	2.252
TOBK	2672	1.041	0.407	0.568	2.208
DIVH	2696	0.841	0.208	0.349	1.000
DIVE	2696	0.271	0.343	0.000	1.136
DDIV	2696	0.331	0.471	0.000	1.000
SIZE	2678	26.715	1.291	24.353	29.191
PROF	2678	0.097	0.096	-0.052	0.345

NDIV	2696	33.086	20.515	0.000	100.000
GDP	2696	5.924	0.577	5.250	7.130

Note: The table reports summary statistics of variables over the period from 2007 to 2012 for Vietnamese listed firms. TOB is Tobin's Q, measured as ratio of total market value of firm divided by book value of total assets. TOBK is Tobin's Q calculated as the ratio of total market value of firm over replacement value of assets. DIVH is sales-based Herfindahl index. DIVE is sales-based entropy index. DDIV is dummy variable of corporate diversification. Dummy equals one if a firm diversifies otherwise it is zero. SIZE is firm size i.e. natural log of assets. PROF is firm profitability i.e. ratio of operating income and sales. LEV is firm leverage, measured as ratio of total debt over total assets. INV is firm investment, computed as ratio of capital expenditure over sales. DIVYIELD is dividend yield ratio. AGE is firm age, the natural log of number of year since firm registered as corporation. BM is book to market ratio. NDIV is fraction of diversified firms in industry. GDP is GDP growth rate.

Table 3: Correlation matrix of variables

Note: The table presents the results of fixed effect estimation of panel data (2007 to 2012). Tobin's Q (TOB), proxy for firm performance, is dependent variable and measured by total market value of firm divided by book value of total assets. Tobin's Q (TOBK), proxy for firm performance, is dependent variable and measured by total market value of firm divided by replacement value of total assets. Herfindahl index is used as corporate diversification measure (DIV) in column (1) and (4). Entropy index is used as corporate diversification measure (DIV) in column (2) and (5). Dummy variable is used as corporate diversification measure (DIV) in column (3) and (6). SIZE is firm size, calculated as the natural log of assets. PROF is firm profitability, equals operating income over sales. LEV is firm leverage, measured by the ratio of total debt over total assets. INV is firm investment, computed by the ratio of capital expenditure over sales. DIVYIELD is dividend yield ratio. p-value in parentheses, standard error in bracket. *, ** and *** represent significance at 10%, 5% and 1% levels respectively.

Section 304 of the Sarbanes-Oxley Act of 2002 (SOX) sets forth a clawback provision that enables a publicly traded company to recover bonuses and other performance-based compensation from the chief executive officers (CEOs) if their company is required to restate financial statements due to material noncomplicances, as a result of misconduct, with financial reporting requirements under the security laws. In this paper we examine the effect of regulatory changes on the sensitivity of CEO bonus to earnings in the cases of good news and bad news in the periods before and after SOX. We find that asymmetric sensitivity of bonus to earnings exists before SOX but disappears in the post-SOX period. This is consistent with the reduced impact of settling up problems due to the clawback provision. This finding shows that regulatory changes affect compensation contracts and has implications for regulators, managers, politicians, investors, and academics in their assessment of the equitable relationship between executive efforts and executive bonus compensation.
Keywords: Executive Compensation, Sarbanes-Oxley, Ex Post Settling Up, Clawback Provision, Asymmetric Sensitivity

Data Availability: Data used in this study are available from public sources identified in the paper

JEL classification: J33; L2; M41

1. Introduction

A line of research examines the sensitivity of executive compensation to performance, which is usually measured by accounting and stock return. Examining the sensitivity of pay to performance around the 1993 enactment of Section 162(m) that limits the corporate tax deduction for executive compensation to $1 million per individual for the top five executives but provides an exception for compensation in excess of $1 million if it qualifies as "performance-based," Johnson et al. (2001), Perry and Zenner (2001), and Balsam and Ryan (2001) find some evidence of an increased sensitivity of compensation to performance after 1993. Carter et al. (2009) examines the relation between earnings and bonuses changes after Sarbanes-Oxley finding firms placing more weight on earnings.

Leone et al. (2006) document that CEO cash compensation is twice as sensitive to negative stock returns as it is to positive stock returns. They attribute this difference in sensitivity to boards of directors structuring cash compensation to mitigate the *ex post* settling up problem so that CEOs are rewarded less for unrealized gains than they are penalized for unrealized losses.[1] They do not, however, pursue similar predictions on the potential asymmetric association between CEO cash pay and accounting earnings for two reasons. First, earnings-based bonus contracts are often piece-wise linear plans containing lower and upper bounds, implying reduced sensitivity of executive bonus pay to earnings when earnings are either very high or very low. Second, conservative accounting constrains managerial opportunistic behavior, offsets managerial biases with its asymmetrical verifiability requirement, and generally excludes unrealized gains from earnings and recognizes unrealized losses in a timely manner (Watts 2003). Therefore, if the accounting system were designed solely for use in executive compensation contracts, there would be no asymmetry in the relationship between bonus pay and accounting earnings, as in the case of stock returns.[2]

In the past two decades, investors, analysts, and other market participants have increasingly been monitoring the extent to which a firm's earnings met or exceeded analyst forecasts. Missing the analysts' forecasts can result in a large decline in stock prices (Barth, Elliott, and Finn 1999; Skinner and Sloan 2002), while firms that meet forecasts enjoy a return premium, even when they meet forecasts through earnings management (Bartov, Givoly, and Hayn 2002). Skinner and Sloan (2002) demonstrate that the market penalizes firms that fall short of expectations by more than it rewards firms that exceed them. More specifically, they find that the negative share returns for firms that failed to meet earnings expectations were significantly greater in magnitude than the positive returns for firms that exceeded market expectations. Since the decrease in a firm's market value with bad earnings news is greater than the increase in the firm's market value due to good earnings news, the compensation committee of a firm should map this asymmetry in compensating CEOs so we predict that the compensation committee penalizes executives' bad performance when the firm's earnings expectations are not met more than it rewards executives' good performance through the payments of executive bonuses.

When earnings expectations are not met, the compensation committee is also likely to penalize the manager more severely under the financial reporting environment that supports greater financial reporting flexibility and offers greater managerial discretions than under the environment that permits less financial reporting flexibility because the manager with greater financial reporting flexibility and managerial discretion is expected to have more means to avoid missing his/her firm's earnings

[1] Leone et al. (2006) further note that the *ex post* settling up problem also exists in other types of CEO compensation, although it is likely to be more severe when payments are made in cash. This is because the unrealized gain may evaporate before equity claims vest when payments are made in the form of stock options.

[2] Of course the degree of accounting conservatism can be also affected by debt contracts, litigation concerns, tax strategies, as well as executive compensation contracts (Watts 2003, Leone et al. 2006).

expectations. Failing to meet earnings expectations leads the compensation committee to believe that the firm's earnings outlook is indeed bleak and thus it has more justifications to penalize the manager with lower bonus pay.

Section 304 of SOX includes a clawback provision that requires reimbursement by CEOs and CFOs of bonuses and other incentive compensation if their company is required to restate financial statements due to material noncompliances, as a result of misconduct, with any financial reporting requirement under the securities laws. Because of this provision, the impact of ex post settling up problem is reduced, i.e., the probability of shareholders incurring costs because future cash flow do not materialize is reduced. Therefore, we expect to see that the sensitivity of executive bonus pay to negative changes in earnings is greater in the pre-SOX period than in the post-SOX period.

CEOs have the greatest level of influence on the firm's financial reporting decisions, and we use CEO compensation data from ExecuComp for the period from 1993 to 2005 to investigate pay-for-performance sensitivity. We find that: first, the sensitivity of executive bonus compensation to accounting earnings is greater for bad news (market-adjusted returns are negative) than for good news (market-adjusted returns are zero or positive).[3] Second, accounting conservatism is positively associated with changes in bonus compensation. Third, the asymmetric sensitivity of executive bonus compensation to accounting earnings in the cases of good news and bad news exists in the period before SOX but disappears after SOX.

These findings are based on both pooled and Fama-Macbeth regression tests using White's (1980) heteroskedasticity-consistent covariance estimator, rather than the ordinary least squares (OLS) estimator that tends to overstate standard errors and thus understate t-statistics in the existence of heteroskedasticity. The findings are also obtained after controlling for most of the variables that have been identified, in prior executive compensation studies, to influence the sensitivity of executive bonus compensation to earnings and stock returns. They remain robust after extreme values of all the variables in the regression tests are eliminated.

This study is expected to make the following contributions to the literature on compensation, earnings management, and conservatism. First, the evidence of a greater sensitivity of executive bonus compensation to changes in earnings with bad news than to changes in earnings with good news further refines the argument of Healy (1985) and Murphy (1999) that earnings-based bonus contracts often contain lower (bogey) and upper (cap) bounds, which suggests reduced sensitivity of cash pay to earnings when earnings are either very high or very low. In other words, this paper's evidence that a more significant increase in the sensitivity of executive bonus compensation to changes in earnings with bad news relative to changes in earnings with good news is consistent with the following argument: when earnings expectations are not met, the manager of a firm suffers a decrease in not only share price but also bonus pay by more than the manager enjoys an increase in share price and bonus pay when earnings expectations are met.

Second, a strong, positive association between the level of conservatism and the change in bonus pay implies the need to control for levels of conservatism in all the regression tests that examine the sensitivity of executive compensation to earnings.

Third, significant reductions in the asymmetric sensitivity of executive bonus compensation to earnings changes after the Sarbanes-Oxley Act of 2002 implies that the less flexible financial reporting environment in the post-SOX period resulted in lower levels of earnings management and conservatism, and the compensation committee of a firm penalizes its manager less in the post-SOX period than in the

---

[3] As in Leone et al. (2006), negative (positive) market-adjusted stock returns are used as a proxy for unrealized losses (gains) or bad (good) news. Therefore, market earnings expectations are assumed not to be met when there exist negative market-adjusted stock returns.

pre-SOX period when earnings expectations are not met. In particular, the evidence of the effects of Sarbanes-Oxley and other concurrent reforms on the sensitivity of executive bonus compensation to earnings changes is likely to be useful information for regulators, managers, politicians, investors, and academics in their assessment of the equitable relationship between executive efforts and executive compensation for the firms affected by the Act.

Fourth, very recently, Shaw and Zhang (2010) demonstrate using a three-way performance partition that an *ex post* settling up in CEO cash compensation based on poor firms performance does not systematically occur.[4] This is in stark contrast to the empirical evidence documented in Leone et al. (2006). The results of this paper also support the Shaw and Zhang's finding, even using the same two-way performance partition as the one used in Leone et al. (2006), because when more control variables are added in the regressions that examine the relation between executive bonus compensation and firm performance, executive bonus compensation is not more sensitive to negative stock returns than to positive stock returns, throwing doubt on the *ex post* settling up claim made in Leone et al. (2006).

The remainder of this study is organized into six sections. The second section develops the hypotheses by exploring and discussing previous relevant research. The third section describes sample selection procedures and research design. Section four presents the results of empirical tests on the sensitivity of executive compensation to earnings and stock returns. The fifth section describes the sensitivity tests and alternative specifications. Concluding comments are provided in the final section.

2. Hypothesis Development

Leone et al. (2006) note that managers, like shareholders, have limited tenure and limited liability, which creates a situation of costly *ex post* settling up when managers are paid for unrealized gains that evaporate. Recovery of excess compensation payments and reparation for excess investments is difficult when the manager leaves the firm before the cash flows materialize (Watts 2003).[5] On the other hand, CEO pay should be reduced for unrealized losses, so the CEO cannot avoid the consequences of poor performance. A higher sensitivity of cash compensation to negative stock returns than to positive stock returns reflects a more severe punishment for poor performance.

Leone et al. (2006), however, do not make similar predictions on the potential asymmetric relationship between CEO cash pay and accounting earnings for the following two reasons. First, the reduced sensitivity of CEO cash compensation to accounting earnings when earnings are either very high or very low has been suggested in prior research (Murphy 1999, Healy 1985, Leone et al. 2006). As reported in Murphy (1999), earnings-based bonus contracts usually contain bogeys and caps, and most bonus plans use accounting earnings in a piecewise linear fashion. Second, conservative accounting generally excludes unrealized gains from earnings and recognizes unrealized losses in a timely manner. Therefore, there would be no asymmetry in the relationship between bonus compensation and accounting earnings, as in the case of stock returns. The above discussions imply that if we can control extreme values of accounting earnings and the levels of accounting conservatism, executive bonus compensation should be more sensitive to negative earnings changes than it is to

[4] Dechow (2006) also suggests that what appears to be *ex post* settling up enforced by compensation committees upon pooly performing executives could in fact reflect the result of compensation committees mechanically applying bonus contract formulas to earnings.

[5] Leone et al. (2006) also indicate that if the firm pays the executive a cash bonus for an unrealized gain, but that gain does not later materialize, the executive can quit the firm and the shareholders will have difficulty recovering the cash paid for that unrealized gain.

positive earnings changes, consistent with the positive correlation between unexpected earnings and abnormal stock returns documented in the famous 1968 Ball and Brown study.

In recent years, investors, analysts, and other market participants have been closely monitoring the extent to which a firm's earnings meet or exceed analyst forecasts. Executives have incentives to use discretionary accruals to achieve the earnings benchmark, since significant economic benefits potentially accrue to firms when earnings meet or beat analysts' forecasts. Missing the analysts' forecasts can result in a large decline in stock prices (Barth, Elliott, and Finn 1999; Skinner and Sloan 2002), while firms that meet forecasts enjoy a return premium, even when they meet forecasts through earnings management (Bartov, Givoly, and Hayn 2002). Skinner and Sloan (2002), in a study that covers a sample period of 1984-1996, demonstrate that the negative share returns for firms that failed to meet earnings expectations were significantly greater in magnitude than the positive returns for firms that exceeded expectations. As Scott (2006) observes, the market penalizes firms that fall short of expectations by more than it rewards firms that exceed them. The compensation committee of a firm is expected to penalize its executives' bad performance by more than it rewards its executives' good performance when a cash bonus is paid. Therefore, this paper's first hypothesis in its alternate form is constructed as follows:

H1: Ceteris paribus, the sensitivity of CEO bonus compensation to accounting earnings is greater for bad news than for good news.

Watts (2003) defined conservatism as "the asymmetrical verification requirements for gains and losses." The greater the difference in the degree of verification required for gains versus losses, the greater the conservatism that exists.

Watts (2003) also observes that in practice, conservatism more than offsets managerial bias, and on average defers earnings and understates cumulative earnings and net assets. In contracts, such as debt, executive compensation, and employment contracts, these conservative effects increase firm value because they constrain management's opportunistic payments to themselves and other parties, such as shareholders. The increased firm value is shared among all corporate stakeholders, increasing everyone's welfare.

Specifically, in debt covenants, conservative accounting reduces the likelihood of management paying excessive dividends by introducing a persistent downward bias into retained earnings [Scott (2006)]. In compensation contracts, conservatism reduces the likelihood of overpayments to managers by constraining premature revenue recognition and asset overvaluation. In sum, conservative accounting can contribute to efficient contracting, which leads to lower cost of capital for the firm and an increase in firm value.

As Watts (2003) indicates, in the bonus compensation case, without verifiable earnings measures, the manager receives overpayments that leave shareholders with a lower share value, even after adjusting for the value increase through the efforts of the manager. Furthermore, the shareholders are unable to recover the overpayment because of the manager's limited liability. The compensation committee of a firm is expected to reward managers through an incentive compensation instrument (e.g., bonus pay) if managers adopt more conservative accounting policies because it will significantly reduce such overpayments to managers. We expect, therefore, a positive correlation between conservatism and bonus pay. Based on the above arguments, this paper's second hypothesis in its alternate form is constructed as follows:

H2: Ceteris paribus, accounting conservatism is positively associated with changes in bonus compensation.

Cohen et al. (2008), Lobo and Zhou (2006), Li et al. (2006), and Carter et al. (2009) demonstrate that the reforms associated with the Sarbanes-Oxley Act (SOX) of 2002 have considerably altered the financial reporting environment in which managers operate, and find an increase in accounting conservatism, a decrease in financial flexibility in financial reporting, and an ensuing decrease in earnings management after the implementation of Sarbanes-Oxley.

As we discussed in the development of hypothesis 1, the results of prior research generally suggest that the capital market penalizes firms that fall short of investors' earnings expectations by more than it rewards firms that exceed them. As a result, managers have a strong incentive to ensure that earnings expectations are met. One way to do this is to manage earnings upwards. Scott (2006) notes, "Rational investors will be aware of this incentive, of course. This makes meeting expectations all the more important for managers. If these are not met, the market will reason that if the manager could not find enough earnings management to avoid the shortfall, the firm's earnings outlook must be bleak indeed, and/or the firm is not well managed since it cannot predict its own future. Consequently, the manager's reputation suffers as well as share price."

Accordingly, when earnings expectations are not met, the compensation committee of a firm has more incentives to penalize the manager in a financial reporting environment that supports less conservative financial reporting, more flexible financial reporting, or higher levels of earnings management than in an environment that mandates more conservative financial reporting, less flexible financial reporting, or lower levels of earnings management, because the manager who has greater flexibility in financial reporting and more earnings management instruments is expected to do better at avoiding missing his/her firm's earnings expectations. In other words, the sensitivity of executive bonus pay to changes in earnings with bad news is less in the post-SOX period than the sensitivity of executive bonus pay to changes in earnings with bad news in the pre-SOX period.

More importantly, Section 304 of the SOX includes a clawback provision that requires reimbursement by CEOs and CFOs of bonuses and other incentive compensation if their company is required to restate financial statements due to material noncompliances, as a result of misconduct, with any financial reporting requirement under the securities laws. Because of this provision, the impact of ex post settling up problem is reduced, i.e., the probability of shareholders incurring costs because future cash flow do not materialize is reduced. This discussion leads to the formation of this paper's third hypothesis as follows:

H3: Ceteris paribus, the level of asymmetric sensitivity of CEO bonus compensation to accounting earnings decreases after SOX.

3. Sample Selection and Methodology

3.1. *Sample Selection*

Table 1 provides the sample selection process. Financial data are obtained from COMPUSTAT, stock return data from CRSP, and executive compensation data from ExecuComp. The sample period begins in 1992 because that is the first year for which detailed compensation information is available from ExecuComp. The initial sample consists of 25,653 firm-year observations with available CEO bonus and stock compensation data. From this initial sample we delete data lost when computing the change form of compensation, missing CRSP, COMPUSTAT and institutional ownership data. We also delete financial institutions (SICs between 6000-6999) and utilities (SICs between 4400 and 5000).[6] The final sample includes 5,332 firm-year observations. Of these, 3,557 (1,775) observations are good (bad) news firms when we measure good/bad news using annual raw return. When we use annual abnormal return to classify good/bad news firms, the sample consists of 2,766 (2,566) good news (bad news) firms.

[Insert Table 1 here]

3.2. *Methodology*

3.2.1. *Performance Measures*

Different measures of accounting performance are used in prior research, including Sloan (1993), Baber, Janakiraman, and Kang (1996), Gaver and Gaver (1998), Baber, Kang, and Kumar (1998), Baber, Kang, and Kumar (1999), and Leone, Wu, and Zimmerman (2006). We adopt four different measures of accounting performance – changes in return on assets (ΔROA), changes in return on equity (ΔROE), changes in earnings per share excluding extraordinary items & discontinued operations (ΔEPSP), and changes in earnings per share including extraordinary items & discontinued operations (ΔEPSEIP), in order to add generality to the analysis.

<u>*Change in Return on Assets (ΔROA)*</u>

$\Delta ROA_t = ROA_t - ROA_{t-1}$

where ROA = Net Income before extraordinary items (EI) and discontinued operations (DO) / Total Assets;

<u>*Change in Return on Equity (ΔROE)*</u>

$\Delta ROE_t = ROE_t - ROE_{t-1}$

where ROE =Net Income before EI and DO / Average Common Equity;

<u>*Change in Earnings per Share, excluding EI and DO (ΔEPSP)*</u>

$$\Delta EPSP_t = \frac{\Delta\left(\text{Earnings per share excluding EI and DO}\right)_t}{\left(\text{Stock Price}\right)_{t-1}}$$

<u>*Change in Earnings per Share, including EI and DO (ΔEPSEIP)*</u>

$$\Delta EPSEIP_t = \frac{\Delta\left(\text{Earnings per share including EI and DO}\right)_t}{\left(\text{Stock Price}\right)_{t-1}}$$

We use two measures of stock performance: Annual market-adjusted returns (Leone, Wu, and Zimmerman 2006) and annual raw returns as used in most prior compensation studies:

<u>*Annual Market-Adjusted Return (ANNMAR)*</u>

---

[6] These firms are excluded because Cheng and Warfield (2005) and Burgstahler and Eames (2003) show that managers in these regulated industries may have different incentives to manage earnings.

ANNMAR is cumulative monthly returns for the fiscal year t, where monthly return is computed by subtracting value-weighted market index from monthly return obtained from the CRSP monthly returns file.

$$\text{ANNMAR}_t = \prod_{\tau=1}^{12}(\text{ARET}\,\tau + 1) - 1$$

where ARET = monthly raw return – value-weighted market index.

<u>*Annual Raw Return (ANNMRR)*</u>

Annual Raw Return (ANNMRR) is cumulative monthly returns for the fiscal year t obtained from the CRSP monthly returns file.

$$\text{ANNMRR}_t = \prod_{\tau=1}^{12}(\text{RET}\,\tau + 1) - 1$$

where RET = monthly raw return

3.2.2. *Regression Models*

We investigate the effect of conservatism on compensation, as well as difference in the relationship between earnings and compensation between good news firms and bad news firms using the following pooled regression model:

$$\begin{aligned}\Delta BON_{i,t} = {} & \beta_0 + \beta_1 D_{i,t} + \beta_2\, ANNMRR_{i,t} + \beta_3\, D_{i,t}*ANNMRR_{i,t} + \beta_4\, \Delta EPS_{i,t} + \\ & \beta_5\, D_{i,t}*\Delta EPS_{i,t} + \beta_6\, SALE_{i,t} + \beta_7\, SALE^2_{i,t} + \beta_8\, FAGE_{it} + \beta_9\, LEVERAGE_{i,t} + \\ & \beta_{10}\, MTB_{i,t} + \beta_{11}\, PERS_{it} + \beta_{12}\, LOSSDUM_{i,t} + \beta_{13}\, EQUITYINC_{it} + \\ & \beta_{14}\, LMVE_{,it} + \beta_{15}\, EPSSTD_{i,t} + \beta_{16} RETSTD_{i,t} + \beta_{17}\, INST_{i,t} + \\ & \beta_{18}\, EAGE_{it} + \beta_{19}\, IOS_{it} + \beta_{20}\, NOAA_{it} + \Sigma\gamma_j YEAR_j + \varepsilon_{i,t} \qquad (1)\end{aligned}$$

$$\begin{aligned}\Delta STOCK_{i,t} = {} & \beta_0 + \beta_1 D_{i,t} + \beta_2\, ANNMRR_{i,t} + \beta_3\, D_{i,t}*ANNMRR_{i,t} + \beta_4\, \Delta EPS_{i,t} + \\ & \beta_5\, D_{i,t}*\Delta EPS_{i,t} + \beta_6\, SALE_{i,t} + \beta_7\, SALE^2_{i,t} + \beta_8\, FAGE_{it} + \beta_9\, LEVERAGE_{i,t} + \\ & \beta_{10}\, MTB_{i,t} + \beta_{11}\, PERS_{it} + \beta_{12}\, LOSSDUM_{i,t} + \beta_{13}\, EQUITYINC_{it} + \\ & \beta_{14}\, LMVE_{,it} + \beta_{15}\, EPSSTD_{i,t} + \beta_{16} RETSTD_{i,t} + \beta_{17}\, INST_{i,t} + \\ & \beta_{18}\, EAGE_{it} + \beta_{19}\, IOS_{it} + \beta_{20}\, NOAA_{it} + \Sigma\gamma_j YEAR_j + \varepsilon_{i,t} \qquad (2)\end{aligned}$$

where for firm i in year t,

BON=BONUS$_t$/SALARY$_{t-1}$;

STOCK= (Restricted stock grants$_t$ + Black-Scholes value of option grantss$_t$)/ SALARY$_{t-1}$;

ΔBON=BON$_t$ – BON$_{t-1}$;

ΔSTOCK = STOCK$_t$ – STOCK$_{t-1}$;

ANNMRR = Annual raw returns for fiscal year t from CRSP;

D = 1 if the annual market-adjusted return (ANNMAR) is negative, and 0 otherwise;

EPS = alternatively measured as ROA, ROE, EPSP, or EPSEIP;

ROA = Net income before EI and DO$_t$ /Total Assets$_t$;

ROE = Net income before EI and DO_t /average common equity for year t and t-1;

EPSP = EPS excluding EI and $DO)_t$/(Stock $Price)_{t-1}$;

EPSEIP = (EPS including EI and $DO)_t$/(Stock $Price)_{t-1}$;

ΔROA = $ROA_t – ROA_{t-1}$;

ΔROE= $ROE_t – ROE_{t-1}$;

ΔEPSEIP = $EPSEIP_t – EPSEIP_{t-1}$;

ΔEPSP = $EPSP_t – EPSP_{t-1}$;

SALE = Net $Sales_t$ (Compustat item SALE);

FAGE= Firm age, calculated as year t minus the first year the firm appeared on CRSP;

LEVERAGE = (Long-term $debt_t$ + the current portion of long-term $debt_t$) / total $assets_t$

MTB = Market value of $equity_t$ /book value of common $equity_t$

PERS = Persistence proxies such as IMA or ARI;

IMA = Persistence measure calculated based on the Integrated Moving Average model;

ARI = Persistence measure based on the Integrated Autoregressive model;

LOSSDUM = 1 if net income including EI and $DO_t < 0$ and 0 otherwise;

EQUITYINC = ($RSHN_t$ + $OPTIONN_t$ + $EOPN_t$ + $UEOPN_t$ + $SHOWN_t$)/($SHOUT_t$ *1,000), where RSHN = Restricted stock holdings (thousands of shares), OPTIONN = Options granted (thousands of shares), EOPN=Exercisable options (thousands of shares), UEOPN = Unexercisable options (thousands of shares), SHOWN = Shares owned with options excluded (thousands of shares), and SHOUT = Common Shares Outstanding (millions of shares);

LMVE = Log(market value of equity from ExecuComp);

EPSSTD = Earnings volatility in year t, measured by standard deviation of annual basic earnings per share over the past 7 years;

RETSTD = Stock return volatility in fiscal year t, measured by standard deviation of monthly returns over the prior 60 months;

INST = % of Institutional Ownership in fiscal year t from the TFSD Ownership Database;

EAGE = Age of the CEO in fiscal year t;

IOS = Investment Opportunity Set composite, computed by performing principal component analysis on the four IOS measures (Kwon and Yin 2006), from all available observations for the period from 1993 to 2005;

NOAA = nonoperating accruals / total assets; and

YEAR = 1 if fiscal year t and 0 otherwise.

We deflate year t change in executive compensation by prior year (t-1) base salary to control for size-related factors that vary cross-sectionally and to minimize the effect of year t-1 performance on compensation metrics (Baber et al. 1996). Control variables including sales (SALE), the square of sales ($SALE^2$), firm age (FAGE), leverage (LEVERAGE), and market-to-book (MTB) are identified in Leone et al. (2006) as those that are potentially correlated with the pay-performance sensitivity. Francis and Schipper (1999, p. 342) indicate that market-to-book ratios have been used in prior research as a proxy for unrecognized intangible assets. Givoly and Hayn (2000) demonstrate that to the extent that equity valuation by investors is based on the present value of future cash flows, the market-to-book ratio as well as earnings multiples would tend to be higher when the accounting measurement is more conservative.[7] This suggests that the market-to-book ratio (MTB), measured by the value of the equity divided by the book value of the equity, can also be used as a proxy for accounting conservatism, and may affect the sensitivity of CEO compensation to market and accounting performance.

Baber et al. (1998) demonstrate that the sensitivity of compensation to earnings varies directly with earnings persistence. Therefore, a proxy for earnings persistence (IMA), measured by MA1 based on an IMA(1,1) time-series characterization of earnings, is also included as a control variable in the regression analysis. A detailed description of the computation of earnings persistence measures is made in section 3.2.3. *LOSSDUM*, which takes a value of 1 if net income with EI and DO is less than 0 and 0 otherwise, is included to control for earnings persistence when earnings are negative.

Cheng and Warfield (2005) find that managers with high equity incentives are more likely to sell shares in the future, and this motivates these managers to engage in earnings management to increase the value of the shares to be sold. Earning management can affect the level of earnings persistence and quality, which in turn can affect the sensitivity of compensation to earnings. We thus include *EQUITYINC* to proxy for the effect of equity incentives for earnings management. The log of the market value of equity (*LMVE*) is included to control for the firm size effect (Dikolli et al. 2005; Garvey and Milbourn 2006).

Banker and Datar (1989), Lambert and Larcker (1987), Sloan (1993), and Leone et al. (2006) demonstrate that earnings volatility and stock return volatility influence the sensitivity of executive cash compensation to market and accounting performance. We measure earnings volatility by the standard deviation of annual basic earnings per share over the last 7 years and stock return volatility by the standard deviation of monthly returns over the prior 60 months, similar to those used in Dikolli et al. (2005).

Other control variables that are expected to influence the sensitivity of executive compensation to executive performance measures include institutional ownership (INST) (Dikolli et al. 2005, 2006) and the age of the executive (*EAGE*) (Garvey and Milbourn 2006, Dikolli et al. 2006), Finally, year dummies (YEAR) are included to capture time-specific factors. We run the two models separately using both pooled and Fama-MacBeth regressions.

Baber et al. (1996) show that there are stronger associations between compensation and performance measures for firms with greater investment opportunities. Following Baber et al. (1996) and Kwon and Yin (2006), we include the investment opportunity set variable (IOS), measured by the principal component of four IOS proxies – Investment Intensity, Geometric Mean Annual Growth Rate of Market Value of Total Assets, Market-to-Book Value of Total Assets, and Research and Development Expenditure to Total Assets, as defined in Table 3 of Kwon and Yin (2006), as a control variable for the regression analysis.

Leone et al. (2006) assert that if the accounting system were designed solely for use in compensation contracts (unrealized gains are excluded from income and unrealized losses are recognized immediately), there would be no asymmetry in the relationship between cash compensation and accounting earnings, as in the case of stock returns. Their claim implies that accounting conservatism can affect the sensitivity of executive compensation to earnings. Therefore, we include two conservatism proxies into the regression analysis: the aforementioned market-to-book value of equity (MTB) and non-operating accruals (NOAA). Khan and Watts (2009), Kwon et al. (2006), and

[7] Also see Feltham and Ohlson (1995) and Ohlson and Zhang (1998).

Givoly and Hayn (2000) document that conservative firms have more negative periodic non-operating accruals (NOAA). Since Khan and Watts (2009) warn that the direct positive relationship between MTB and conservatism is not observed due to the "buffer problem" (Roychowdhury and Watts 2007), we rely more on NOAA as a proxy for conservatism.[8]

Fama-MacBeth Regression Model

We also estimate regression equations (1) and (2) using the Fama-MacBeth (1973) procedure, which has the advantage of controlling for cross-sectional correlation in the residuals by assuming independence through time.[9] The presence of a positive cross-sectional correlation in the residuals in the pooled regression would understate standard errors and overstate the t-statistics. Reported coefficients, adjusted R^2s, and number of observations will be the means of 13 annual regressions from 1993-2005. In addition, the standard errors will be the time-series standard deviations of the coefficients divided by the square root of 13. T-statistics will be accordingly computed as follows:

$$t(Y_j) = \frac{Y_j}{s(Y_j)\big/\sqrt{n}} \tag{3}$$

where Y_j = the mean coefficient of 13 annual cross-sectional regressions from 1993 through 2005 for variable j;

$s(Y_j)$ = the time-series standard deviations of the 13 coefficients divided by the square root of 13; and

n = the number of years tested.

3.2.3. *Earnings Persistence Measures*

A recent study by Baber et al. (1998) demonstrates that the sensitivity of executive cash compensation to earnings varies directly with earnings persistence. Earnings persistence is defined as the degree to which future earnings are induced by a $1.00 increase in current earnings. Valuation theory suggests that analysts and investors should put greater emphasis on forecasting high-persistence earnings than low-persistence earnings, because a given amount of the former has a greater valuation impact than the same amount of the latter. This time series property of earnings (earnings persistence) is positively related to ERC, the magnitude of the relationship between earnings and returns (Kormendi and Lipe 1987, Easton and Zmijewski 1989, Collins and Kothari 1989).

The role of persistence can be explained by comparing the values of an unexpected dollar of permanent earnings and transitory earnings. Prior empirical studies predict that transitory earnings surprises have an empirical ERC of one, while the ERC of permanent earnings is one plus the inverse of the discount rate, so that analysts and investors are relatively uninterested in transitory earnings because the trading profits that could be earned from private foreknowledge of a dollar of transitory earnings are smaller than the profits from private foreknowledge of a dollar of permanent earnings (Freeman and Tse 1992).

---

[8] Khan and Watts (2009) note, "The buffer problem is that over a short horizon beginning MTB is negatively correlated with conservatism flows due to prior unrecognized increases in asset values reducing the necessity to recognize asset value losses. Since ending MTB is a function of beginning MTB, this induces a negative relation between ending MTB and conservatism at the annual horizon. Over longer horizons (three years or more), the beginning MTB effect is reduced and ending MTB (in year t) is positively correlated with conservatism over years t-3 to t as shown in Roychowdhury and Watts (2007)."

[9] Leone et al. (2006) and Herrmann et al. (2001), among others, used the Fama-MacBeth procedure in their empirical analyses. Theil (1971, p. 160) discusses a theoretical aspect of correlated residuals (disturbances) in a panel data regression.

Since earnings follow a non-stationary process, the persistence can be better measured with a first differenced time-series model. In order to estimate firm-specific persistence levels, we adopt an *ARIMA (1, 1, 0*) *or ARI (1,1,0)* (Kormendi and Lipe 1987), Easton and Zmijewski 1989) and an *IMAMA (0, 1 1) or IMA (0,1,1)* (Beaver 1970, Beaver et al. 1980, Collins and Kothari 1989, Ali and Zarowin 1992, and Baber et al. 1998) time-series characterization of quarterly earnings, each of which considers seasonality of quarterly earnings and facilitates parsimonious empirical specifications of both earnings innovations and earnings persistence.

The *ARI (1, 1, 0*) model or the first differenced AR (1) model with seasonality can be expressed as follows:

$$(1-\phi B)(1-B^4)X_t = a_t$$

X is quarterly actual earnings, ϕ is the persistence parameter, B is the backshift operator and a_t is white noise. This can also be represented as

$$X_t = X_{t-4} + \phi(X_{t-1} - X_{t-5}) + a_t$$

$$\Delta X_t - \phi \Delta X_{t-1} = a_t$$

ϕ is a firm-specific persistence level estimate similar to the autocorrelation of seasonally differenced earnings over the 32 quarters that end in each year of the sample period 1993-2005.

We can easily see that if ϕ is low, then current-earnings innovation would be more transitory. On the other hand, if ϕ is high, then current-earnings innovation would be more permanent. Thus, parameter ϕ measures the extent to which earnings innovations are permanent rather than transitory and quantifies the notion of earnings persistence.

The *IMA (0, 1, 1*) model with seasonality can also be expressed as follows:

$$(1 - B^4)X_t = (1 - \theta B^4)a_t,$$ where $(1 - \theta)$ is the persistence parameter.

$$X_t = X_{t-4} - \theta a_{t-4} + a_t$$

If θ=1, then earnings follow a mean reverting process, and all earnings innovations are expected to be transitory. In contrast, when θ=0, earnings follow a random walk process, and all earnings innovations are expected to be permanent. Thus, parameter $(1 - \theta)$ measures the persistence level.

3.2.4. *Modified Jones Model and Performance-matched Discretionary Accruals*

We compute discretionary accruals using the cross-sectional modified Jones model estimated by industry and year. The cross-sectional approach has the advantage of controlling for the effects of industry-wide economic changes on total accruals and allowing the coefficients to change across years due to possible structural changes.[10]

$$TACCR_{i,t} / A_{i,t-1} = a_t (1/A_{i,t-1}) + b_{1t} (\Delta REV_{i,t} - \Delta REC_{i,t}) / A_{i,t-1} + b_{2t} (PPE_{i,t} / A_{i,t-1}) + \varepsilon_{i,t}$$

where for firm i at time t,

[10] Guay, Kothari, and Watts (1996) investigate the relative merits of various discretionary accrual models and conclude that the cross-sectional Jones and cross-sectional modified Jones models are the most effective in identifying discretionary accruals. DeFond and Jiambalvo (1994), Subramanyam (1996), Bartov, Gul, and Tsui (2000), and Gul, Leung, and Srinidhi (2000) further support the adoption of the cross-sectional modified Jones model.

$TACCR_{i,t}$ = total accruals, see footnote[11];

$A_{i,t-1}$ = lagged total assets (item #6);

$\Delta REV_{i,t}$ = change in sales (item #12);

$\Delta REC_{i,t}$ = change in accounts receivable (item #2);

$PPE_{i,t}$ = gross property, plant and equipment (item #7); and

$\varepsilon_{i,t}$ = error term.

Discretionary accruals are estimated as the difference between reported total accruals and fitted values of total accruals (nondiscretionary accruals) using coefficient estimates from equation (3) for the period 1993-2005:

$$DA_{i,t} = TACCR_{i,t}/A_{i,t-1} - [a_t\,(1/A_{i,t-1}) + b_{1t}\,(\Delta REV_{i,t} - \Delta REC_{i,t}) / A_{i,t-1} + b_{2t}\,(PPE_{i,t} / A_{i,t-1})]$$

where $DA_{i,t}$ is discretionary accruals and $\Delta REC_{i,t}$ is the change in accounts receivable (item #2). We adjust discretionary accruals for performance and industry effects, as suggested by Kothari, Leone, and Wasley (2005), because potential measurement errors in discretionary accruals may correlate with industry membership, growth, or performance. We calculate performance-matched discretionary accruals for firm i as discretionary accruals of firm i minus discretionary accruals of the firm j that exhibits the closest ROA in the same industry.

4. Empirical Results

4.1. *Descriptive Statistics*

Table 2 shows means, medians, and standard deviations of compensation variables, performance measure variables, other financial variables, time-series variables, an investment opportunity set proxy variable, conservatism proxy variables, and earnings management proxy variables for all firm-year-observations. The financial and time-series variables are assumed to influence the sensitivity of executive incentive compensation to earnings and stock prices, as documented in prior research.

As in Leone et al. (2006), we compare descriptive statistics between bad news firms and good news firms using parametric (two sample t) and nonparametric (Wilcoxon rank-sum) tests. Table 2 shows that all incentive compensation variables are different between the bad and good news sub-samples at the statistically significance levels of 5% or 1%, with the exception of equity-based compensation (STOCK), which is not significant in the parametric test; changes in equity-based compensation (ΔSTOCK), which is positive but insignificant in the parametric test; and changes in total compensation (ΔTCOG), which is insignificant in the parametric test. As expected, good news firms outperform bad news firms in all performance measures except for ROE, which is not statistically different in parametric tests.

As indicated in Table 2, in general, bad news firms show higher leverage, lower market-to-book value of equity, higher earnings persistence, smaller firm size, lower earnings and stock variability,

[11] $TACCR_{i,t} = \Delta CA_{i,t} - \Delta CL_{i,t} - \Delta Cash_{i,t} + \Delta STD_{i,t} - Dep_{i,t}$, where, for firm i at time t, $\Delta CA_{i,t}$= change in current assets (item #4); $\Delta CL_{i,t}$ = change in current liabilities (item #5); $\Delta Cash_{i,t}$ = change in cash and cash equivalents (item #1); $\Delta STD_{i,t}$ = change in debt included in current liabilities (item #34); and $Dep_{i,t}$ = depreciation and amortization expense (item #14).

lower institutional ownership, older CEOs, less accounting conservatism, and lower cash flows from operations than good news firms.

[Insert Table 2 here]

Panel A of Table 3 reports Spearman correlations among the variables used in the multiple regression tests. Performance metrics (ANNMRR, ΔROA, and ΔEPSP) are significantly and positively correlated with changes in bonus compensation (ΔBON).[12] The correlations between the performance metrics and changes in equity-based compensation (ΔSTOCK) are not statistically significant. The insignificant correlations may imply that equity grants are awarded for reasons other than rewarding managers for past performance, e.g., incentives for future performance [Core and Guay (1999)].

Firm-year observations (5,332) are split into bad news and good news groups based on negative and non-negative values of ANNMAR. Panels B (bad news) and C (good news) of Table 3 reveal Spearman correlations between the two compensation variables (ΔBON and ΔSTOCK) and the performance metrics (ANNMRR, ΔROA, ΔROE, ΔEPSP, and ΔEPSEIP), along with a proxy for conservatism (NOAA). Consistent with the results of Panel A, ΔBON is positively and significantly associated with all performance variables. The correlations are statistically significant at the 1% level without exception. In addition, the negative correlation for the conservatism proxy (NOAA) is significant at the 5% level, which suggests that accounting conservatism increases executive bonus pay. As expected from the results of Panel A and prior research, ΔSTOCK is not significantly associated with any of the performance variables, with the exception of ANNMRR in the case of good news. Unlike the case of ΔBON, the conservatism proxy (NOAA) is significantly and positively correlated with ΔSTOCK in both Panels. This implies that when a firm adopts more conservative financial reporting, the compensation committee penalizes its manager with less equity-based pay.

[Insert Table 3 here]

4.2. *Regression results*

Table 4 reports results from estimating equation (1) for bonus compensation using pooled regressions (Panel A) and Fama-MacBeth regressions (Panel B). In column (1) of Panel A, the sensitivity of bonus compensation to stock returns (ANNMRR) and to change in ROA (ΔROA) are both significant at the 1% level. The coefficient on D*ANNMRR is positive and significant, indicating that bonus compensation is more sensitive to stock returns when returns contain unrealized losses (ANNMAR< 0) than when returns contain unrealized gains (ANNMAR $\geq$ 0), consistent with Leone et al. (2006) conclusion that boards of directors exercising discretion to reduce costly *ex post* settling up in cash compensation paid to executives. The coefficients on D*ΔROA, SALE and $SALE^2$, are statistically insignificant, similar to what Leone et al. (2006) reported. In general, the results presented in the second column of Panel A or Panel B (a short version of ΔROA regression without various control variables) are consistent with those of the third column in Table 4 in Leone et al. (2006).

When we include a comprehensive set of control variables that have been identified in prior research in estimating equation (1), we find the following results. First, the coefficients on stock returns (ANNMRR) and four different types of accounting performance variables — ΔROA, ΔROE, ΔEPSP,

[12] Although not shown in the table, other performance variables, such as ANNMAR, ΔROE, and ΔEPSEIP, are also significantly and positively correlated with ΔBON.

are ΔEPSEIP — are statistically significant at the 1% level in both Panel A and Panel B. Second, the coefficient for D*ANNMRR becomes either insignificant in Columns (2) and (5) or significant at the 10% level at best in Columns (3) and (4). This coefficient is insignificant across board in Penal B using the Fama-MacBeth regression tests.[13] When more control variables are included in equation (1), the asymmetric sensitivity of executive cash compensation to stock returns almost disappears. Note that when Leone et al. include CEO horizon, a proxy for the severity of the *ex post* settling up problem in the model, they failed to document cross-sectional variations in the asymmetric relationship between cash compensation and stock returns. Along with Shaw and Zhang (2010), we failed to find evidence of an asymmetric sensitivity of bonus to stock returns.

This paper's first hypothesis, that the sensitivity of executive bonus compensation to changes in accounting earnings is greater for bad news (market-adjusted returns are negative)

than for good news (market-adjusted returns are zero or positive), is supported by Table 4 when proxies for changes in accounting earnings are ΔROE, ΔEPSP, and ΔEPSEIP in pooled regression tests (Panel A) and ΔEPSP and ΔEPSEIP in Fama-MacBeth regression tests (Panel B). Their coefficients are all statistically significant at the 5% or higher levels. The results imply that, as is done by the capital market, the compensation committee of a firm penalizes its executives' bad performance by more than it rewards its executives' good performance through executive cash bonus pay when the executive performance is measured by changes in earnings.

The regression results of Table 4 are also consistent with this paper's second hypothesis that accounting conservatism is positively associated with changes in bonus compensation.

The proxy for accounting conservatism (NOAA) has significant negative coefficients across all different measures of changes in earnings (ΔROA, ΔROE, ΔEPSP, and ΔEPSEIP). Specifically, t-statistics for the NOAA variable in regressions that include ΔROA, ΔROE, ΔEPSP, and ΔEPSEIP are -4.71 (-4.96), -4.44 (-4.16), -4.40 (-3.55), and -4.16 (-3.34), respectively in pooled (Fama-MacBeth) regression tests and are statistically significant at the 1% level without exception.[14] The compensation committee indeed rewards managers through an incentive compensation instrument (e.g., bonus pay) if managers adopt more conservative accounting policies because it significantly increases contract efficiency and, thus, firm value by reducing unnecessary overpayments to managers.

Other significant coefficients in both pooled and Fama-MacBeth regression tests in Table 4 are those of LOSSDUM, EQUITYINC, and INST. Specifically, when a firm reports a net loss (LOSSDUM = 1), the manager of the firm is penalized with a significant reduction of his or her bonus pay. Executives with higher equity incentives (EQUITYINC) are rewarded with higher bonus pay. Cheng and Warfield (2005) document that managers with high equity incentives are more likely to sell shares in the future, and this motivates these managers to engage in earnings management to increase the value of the shares to be sold. If the compensation committee of such a firm cannot completely see through this earnings management behavior, executives of the firm are likely to receive higher bonus pay based on the increased share value. Executives of firms with higher levels of institutional ownership (INST) are rewarded with higher bonus pay than executives of firms with lower levels of institutional ownership. This evidence of higher executive compensation associated with higher levels of institutional ownership is consistent with the results of Smith and Swan (2008).

[Insert Table 4 here]

---

[13] Leone et al.(2006) present their empirical results based only on Fama-MacBeth regression tests.

[14] Since NOAA becomes more negative with more conservative financial reporting, the negative coefficient of the NOAA variable means more cash bonus pay.

Table 5 reports results from estimating equation (2) for equity-based compensation using pooled regressions (Panel A) and Fama-MacBeth regressions (Panel B). As in Leone et al. (2006), all of the coefficients on stock return variables (ANNMRR and D*ANNMRR) are statistically insignificant when a more comprehensive set of control variables is included. In addition, a weaker association exists between changes in accounting earnings and equity-based executive compensation. There are also no signs of asymmetric sensitivity of executive equity-based compensation to accounting earnings, as in the case of executive bonus compensation.

Other significant coefficients in both pooled and Fama-MacBeth regression tests in Table 5 are those of FAGE, MTB, IMA, LMVE, EPSSTD, RETSTD, INST, EAGE, and IOS. Specifically, as firm age (FAGE) and executive age (EAGE) increase, the level of executive equity-based compensation increases. As market-to-book value of equity (MTB), earnings persistence (IMA), firm size (LMVE), earnings volatility (EPSSTD), stock returns volatility (RETSTD), the level of institutional ownership (INST), and the level of investment opportunities (IOS) increase, the level of executive equity-based compensation decreases.

Interestingly, the MTB variable, which is a proxy for either unrecognized intangible assets or accounting conservatism, is significantly and negatively correlated with changes in executive equity-based compensation in Table 5, whereas the variable is insignificantly associated with changes in executive bonus compensation in Table 4. This implies that accounting conservatism leads to lower equity-based pay.

[Insert Table 5 here]

In order to confirm evidence in prior research that a change took place in the financial reporting environment in the post-SOX period, we test whether conservatism increases (Table 6) and earnings management decreases (Table 7) after the Sarbanes-Oxley Act of 2002 and other concurrent reforms.[15] Lobo and Zhou (2006) examine the change in managerial discretion over financial reporting following the Sarbanes-Oxley Act and document an increase in conservatism in financial reporting following SOX and the resulting requirement by the SEC that financial statements be certified by firms' CEOs and CFOs. They find that firms report lower discretionary accruals after SOX than in the period preceding SOX. In addition, based on the Basu (1997) measure of conservatism, they demonstrate that firms incorporate losses more quickly than gains when they report income in the post-SOX period. Lobo and Zhou's (2006) empirical evidence suggests that SOX and the resultant SEC certification requirement may have altered management's discretionary reporting behavior towards greater conservatism.

In Table 6, the results show that conservatism, measured by cumulative nonoperating accruals, increases after SOX. In the full (constant) sample, the t-statistics are 2.46 (2.01) and 4.87 (2.60) in parametric and non-parametric tests, respectively. They are significant at least at the 5% level. Since the association between the market-to-book value of equity (MTB) variable, another proxy for conservatism, and the changes in bonus pay (ΔBON) is not strong in both pooled and Fama-MacBeth regression tests, we do not include it in the analysis of the change in the level of conservatism following SOX.

[Insert Table 6 here]

[15] For example, as shown in Carters et al. (2009), the NYSE proposed significant rule changes in its listing standards aimed at ensuring independence of directors and strengthening corporate governance practices of listed companies. In October 2002, the NASDAQ followed suit with a similar proposal to strengthen board independence and committee independence (SEC 2003a).

In Table 7, absolute values of modified Jones discretionary accruals and performance-matched discretionary accruals in the pre-SOX period from 1997 through 2000 are compared to those in the post-SOX period from 2002 through 2005.[16] In this comparison, we implicitly assume, as in prior research, that the higher the absolute value of these accruals, the higher the magnitude of earnings management. Although three of the two t-statistics and two Wilcoxon Z statistics are not sufficiently statistically significant, all four statistics are positive. Moreover, the non-parametric Wilcoxon Z statistic (2.57) in the case of modified Jones discretionary accruals is significant even at the 1% level. Therefore, we conclude that there is some evidence that earnings management in the post-SOX period is smaller in magnitude than earnings management in the pre-SOX period.

[Insert Table 7 here]

The results of Table 8 show that the asymmetric sensitivity of executive bonus compensation to changes in earnings is significantly reduced in the post-SOX period relative to the pre-SOX period. The coefficients on ΔROA, ΔROE, ΔEPSP, and ΔEPSEIP when there is bad news (market-adjusted stock returns are negative) are generally significant in the pre-SOX period, but become insignificant in the post-SOX period. The t-statistics of the coefficients on ΔROA, ΔROE, ΔEPSP, and ΔEPSEIP are 0.62 (-0.46), 2.33 (0.31), 1.98 (1.49), and 1.69 (1.18), respectively in the pre-SOX (post-SOX) period in the pooled regression tests, whereas those on ΔROA, ΔROE, ΔEPSP, and ΔEPSEIP are 0.65 (-0.49), 3.89 (-1.24), 3.99 (1.77), and 1.86 (1.05), respectively in the pre-SOX (post-SOX) period in the Fama-MacBeth regression tests. The empirical evidence of Table 8 is consistent with this paper's third hypothesis that the sensitivity of executive bonus pay to changes in earnings when market-adjusted stock returns are negative (bad news) is less under the post-SOX period than in the pre-SOX period.

This reduced asymmetry implies that when earnings expectations are not met (bad news), the compensation committee has greater incentive to penalize its executive under the financial reporting environment that allows for less conservative accounting, more flexible financial reporting or greater earnings management than under the environment that requires more conservative accounting, less flexible financial reporting or less earnings management, because the executive who has greater flexibility of financial reporting and with more earnings management instruments is expected to do better at avoiding missing his/her firm's earnings expectations. When the executive fails to do this, he or she deserves more of a decrease in bonus pay in the more flexible financial reporting environment vis-à-vis the less flexible financial reporting environment.

Cohen et al. (2008), Lobo and Zhou (2006), Li et al. (2006), and Carter et al. (2009) observe that the Sarbanes-Oxley Act of 2002 and other concurrent reforms decreased the flexibility executives had in financial reporting and increased the risk that CEOs and CFOs assume for the accuracy of the reported numbers. Therefore, the degree of asymmetric sensitivity of executive bonus pay to earnings could be less in the post-SOX period, compared to the pre-SOX period.

[Insert Table 8 here]

5. Sensitivity Tests and Alternative Specifications

[16] Since the accounting scandal involving Enron that prompted the US Senate to enact the Sarbales-Oxley Act in 2002 took place in 2001, we intentionally omit 2001 in order to mitigate any noise problem in the comparison analysis as a result of the inclusion of 2001 in the pre-SOX period.

5.1. *Annual Raw Returns (ANNMRR) replaces Annual Market-Adjusted Returns (ANNMAR)*

We replace annual market-adjusted returns (ANNMAR) with annual raw returns (ANNMRR) to proxy for unrecognized losses (ANNMRR < 0) or unrecognized gains (ANNMRR ≥ 0) in both the pooled and Fama-MacBeth regression tests. The results were qualitatively the same as before.

5.2. *Integrated Autoregressive Model (ARI) vs. Integrated Moving Average (IMA)*

We replace the Integrated Moving Average time series model with the Integrated Autoregressive Model to measure earnings persistence. The results are similar to those based on IMA.

5.3. *Extreme Values*

For all regression analyses in this study, we use several methods of truncation: deletions of observations outside mean ± 3 std, mean ± 4 std, and mean ± 5 std; deletion of extreme 1% of variable distributions; and deletion of extreme 2% of variable distributions. The results presented in Tables 4, 5, and 7 are robust to such alternative treatments.

6. Concluding Remarks

This paper examines the asymmetric sensitivity of the CEO bonus to earnings, the association between conservatism and bonus pay, asymmetric sensitivity of CEO bonus compensation to earnings before and after SOX. In line with recent developments in theoretical models and empirical findings, we posit that the sensitivity of executive bonus compensation to earnings with bad news (market-adjusted stock returns are negative) will be larger than the sensitivity of executive bonus compensation to changes in earnings with good news (market-adjusted stock returns are either positive or zero). We also posit that accounting conservatism will be positively correlated with changes in executive bonus pay. Based on the results of prior research that documents an increase in conservatism, a decrease in flexibility in financial reporting, and an ensuing decrease in earnings management following the Sarbanes-Oxley Act of 2002, this paper further posits that the asymmetry of the sensitivity of executive bonus compensation to changes in earnings will be reduced in the post-SOX period.

We find empirical evidence consistent with the above hypotheses. Specifically, first, the sensitivity of CEO bonus compensation to earnings with bad news is greater than the sensitivity to earnings with good news. Following prior research, negative (nonnegative) market-adjusted stock returns are used as proxies for bad (good) news. Second, the accounting conservatism, measured in cumulative nonoperating accruals, indeed increases bonus pay. Third, a significant reduction in the asymmetry of the sensitivity of executive bonus compensation to changes in earnings is found in the post-SOX period. We attribute this to the clawback provision set forth by SOX. Fourth, this paper's primary findings are based on both pooled and Fama-Macbeth regression tests using White's (1980) heteroskedasticity-consistent covariance estimator, rather than the ordinary least squares (OLS) estimator that tends to overstate standard errors and thus understate t-statistics in the presence of heteroskedasticity. Fifth, the empirical results are also robust to a variety of extreme value treatments and alternative specifications of bad news. Finally, this paper attempts to incorporate the effects of most, if not all, of the control variables (19 independent variables) that have been identified in the executive compensation literature.

Given that the issue of executive compensation has been a longstanding one in the United States and Canada because many feel that executives are excessively paid, this paper's evidence of asymmetric sensitivity of executive compensation to earnings and a positive role of accounting conservatism in connection with executive bonus pay, along with a significant reduction of the asymmetry in the relationship between executive bonus compensation and earnings in the post-SOX period is likely to be useful information for managers, politicians, investors, and academics in their assessment of the equitable relationship between executive efforts and executive bonus compensation.

Acknowledgments

We'd like to thank Steve Balsam, Patrice Gelinas, Gerry Lobo, and Inho Suk, for their helpful comments.

[a] The variables are defined in Table 2. The symbols *, **, and *** indicate statistical significance levels of 10%, 5%, and 1%, respectively, in two-tailed tests.
[b] White's (1980) heteroskedasticity tests for violations of assumptions of homoskedastic errors and independence between the errors and regressors. Whenever violations occur at 10% or higher levels, White's t values replace Student's t values.
[c] See Table 2 for variable definitions.

Influence of financial decisions on financial performance is critical issue for academic researcher and investors since past few decades in developing economic. The purpose of this paper is to examine the impact financial leverage on financial performance from sugar manufacturing section in Vietnam. Sugar manufacturing companies have listed on Ho Chi Minh City Stock Exchange (HOSE) and Hanoi Stock Exchange (HNX). For measuring the performance of the firms Return on Assets (ROA), Return on Equity (ROE), Net Profit Margin (NPM) and Earning per Share Growth (EPSG) are used as proxies. Debt to Equity Ratio (DER) is variables for the capital structure. Controlled variables installed in the research as firm's age (AGE), size (SIZE) impact on relationship between financial leverage and financial performance. Surveyed companies are six. Data is taken from period 2009 to 2013. The panel data is analysed by using the Pooled regression model, Fixed Effect Model (FEM), Random Effect Model (REM) and Generalized Least Square (GLS). The result shows the negative impact and significant of financial leverage on financial performance as Earnings Per Share Growth, Net Profit Margin and Return On Assets. Firm's age negatively impacts and significant on financial performance as Earnings Per Share Growth, Net Profit Margin. Firm size negatively impacts and significant on financial performance as Return on Equity. The conclusion, limitation and recommendation area of research are also discussed at the end of the research. The research provides useful recommendations for policy direction and management of Vietnamese listed sugar companies.

Keywords: Financial leverage, financial performance, sugar companies, Vietnam, panel data, firm's age, firm size, FEM, REM, GLS.

1. Introduction

Financial leverage plays an important role in corporate finance. Financial leverage is a measure of how much firms use equity and debt to finance its assets. Firm finances its operation and investment by multiple financing resources. The financing resources classify into two main categories. First, the internal financing includes common stock issuance, reserves, retained earnings, and preferred stocks. Second, resource identify the external financing which consisting the short-term, long-term debt and the issuance of bonds. Firm often likes to finance by debt because firm can deduct interest expenses when calculating taxable income. The financial leverage employs by a firm is intended to earn more on the fixed charges funds than their costs. Moreover, stockholders can maintain control of a firm without increasing their investment. When debt increases, the financial risk of the company also increases, make firm bankruptcy. But, it increases the opportunity for the firm to earn more by efficiently utilization of these resources. Balancing between benefit and cost associated with debt financing are right decision, avoid affecting shareholder's benefit. Due to purpose of financial management is to maximum shareholder's wealth. Therefore, the capital of any organization is a significant dynamic for firm's existence and growth as well as it has key roles in the financial performance of the firm to achieve the long-term goals and objects of the organization.

Vietnam's sugar industry really takes shape in southern Vietnam in the early 20th century, and concentrates in the central and Mekong river delta regions. Products of sugar industry mainly supply to the domestic demand. But, most of Vietnamese listed sugar firms' after – tax profit declines in 2013. Losses resulted is mentioned is the low sugar price and high interest rates (Hung, 2014). Vietnamese firm's financial leverage increases high. According to Son (2012) in recent years, the debt to equity ratio of local firms is 120%, higher than regional average is 45%. High leverage affects how firm's financial performance ratio? When financial performance is decreased, it is signal for shareholder, investor and creditor. And the market will reflect stock price on the stock exchange. Their price/earnings ratios based on 2013 numbers are between 5X and 10X. Some of the companies are trading 20% below their book values and the dividend yields are around 8-12% (AFC, 2014). Therefore, the importance of financial leverage for Vietnamese listed sugar companies is necessary. The companies needs the optimal financing resources towards reaching the optimal capital structure intended for to consistency with firm's requirements towards making suitable financing decisions and followed by return significantly on their financial performance as firms output.

The objective of the research is empirically investigate the main role of financial leverage, firm's age, firm size on the firm's financial performance of Vietnamese listed sugar companies for the period 2009 – 2013 in Ho Chi Minh City Stock Exchange (HOSE) and Hanoi Stock Exchange (HNX).

This research aims to answer the question is: what is the impact of financial leverage on financial performance of listed sugar companies in Vietnam?

This research has important decision-making implications for the manager, academic researchers, shareholders with reason that the quality accounting information has become very important in current situation, with the purpose of such benefits it is very important in

Vietnam. Now, financial leverage, firm's age, firm size, and financial performance have to be converted into important decisions. They are assumed that there is strong and critical relationship among financial leverage, firm's age, firm size, and financial performance. In this research examines new evidences on the linkages among financial leverage firm's age, firm size, and financial performance.

Content of this paper is structured as follows: introduction, literature review and hypothesis, research methodology, data analysis and discussion, conclusion and future research.

2. Literature review and hypotheses

Structure of this section consists of seven parts. The first and second sections are popular definitions of financial leverage and financial performance. The third one presents the relationship between financial leverage and financial performance. The fourth one presents the empirical evidences. The fifth one presents the relationship among financial leverage, firm's age, firm size and financial performance. The sixth one is hypothesis development. The last is conceptual model.

The concept of financial leverage

Financial leverage shows the amount of debts representing in capital structure of the company (Mehta, 2014). Firm uses debt financing due to some benefits as 1) By raising funds through debt, stockholders can maintain control of a firm without increasing their investment, 2) If the firm earns more on investments financed with borrowed funds than it pays in interest, then its shareholders' returns are magnified (Brigham et al., 2011). Besides, financial leverage increases with the increase in the percentage of debts which causes to increase the risk as liquidation and even bankruptcy.

There are many measures of financial leverage as total debt ratio, debt to equity ratio and market debt ratio. Total debt ratio measure the percentage of funds provided by current liabilities and long-term debt. Debt to equity ratio indicates what proportion of equity and debt in firm is using to finance its assets. Market debt ratio reflects a source of risk that is not captured by the conventional book debt ratio (Brigham et al., 2011). Among them, debt to equity ratio is an important tool of financial analysis to evaluate the financial structure of firm. It basically indicates the relative proportion of debt and equity in financing the assets of the firms.

The choice of financial leverage measurement depends on research objective. Financial leverage in this analysis is assumed to arise as firms venture to borrow capital when they expect to earn more than the cost of debt capital. So, the research uses debt to equity ratio.

The concept of financial performance

Financial performance generally measures of a firm's overall financial health over a given period of time (Gweyi et al., 2014). Financial performance provides a subjective measure of how well a company can use assets from its primary mode of business and generate revenues. A number of different accounting measures for calculating firm performance. Financial performance indicators in the form of ratios include profitability, utilization financial structure and investment – shareholder ratio (Brigham et al., 2011). Measure of profitability is by Net Profit Margin (NPM), Earnings Per Share Growth (EPSG). Net Profit Margin shows how much each sales dollar shows up as net income after all expenses are paid. This ratio might be the most important for shareholders and investors, as it give them a tough view of how well their businesses are at the last. EPS Growth is defined as the percentage change in normalised earnings per share over the previous 12 month period to the latest year end. It gives a good picture of the rate at which a company has grown its profitability per unit of equity. The performance of the sugar companies will be measured by Return On Assets (ROA). ROA is defined as net income divided by total assets. ROA shows the efficiency with the company is managing its investment in assets and using them to generate profit. Another measure of profitability is the Return On Equity (ROE). Return On Equity measures the rate of return on the ownership interest of the common stock owners. ROE shows how well a company uses investment funds to generate earnings growth.

These indicators are the most popular to measure financial performances and used in many researches such as Pratheepkanth (2007), Rehman (2013). So, these financial performance indicators are focused in this research.

Theory about financial leverage and financial performance

Many researchers have focused on the relationship between financial leverage and financial performance. Some of these researches are:

Modigliani and Miller (1958) published a paper about capital structure. They concluded capital structure had no influence on firm value. It was irrelevance and argument result, but it contributed important for developing capital structure theory.

Modigliani Miller (1963) found that in the presence of corporate income taxes but in the absence of the bankruptcy risk, there was a linear relationship between the value of the levered firm and that of its debt. This implied that a firm should maximize it used of debt in order to enjoy the benefit of tax subsidy on interest payments.

Kraus and Litzenberger (1973) suggested that trade-off theory. The theory referred to the optimal capital structure was determined by balancing benefits and cost associated with debt financing. Debt financing benefits included tax savings, reducing agency cost and the financial distress cost, and the cost associated to debt financing was direct and indirect bankruptcy costs.

According to Myers (1977), the cost of high leverage could lead to a negative relationship between leverage and firm performance. Debt overhang problems created underinvestment problems and cause poor firm performance. Even if firms with high leverage had new investment projects that generated positive net present values, they couldn’t issue new junior debt. Because the earnings generated by new investment projects were used to pay off debts to existing debt holders, new junior debtors did not obtain adequate payments from the earnings of new projects. Therefore, banks and other creditors did not offer credit for new projects with positive net present values. As highly leveraged firms couldn’t obtain enough credit, they could lose potential profits from profitable investment opportunities of which they were unable to take advantage.

Myers and Majluf in (1984) suggested pecking order theory. This theory stated that because of information asymmetry between firms managers and investors it was probable that investors would under value the new issued stock, so to avoid this problem the company first priority was to use its internal sources “retained earnings” to finance its investments, if they were not sufficient then debt was issue and when it was not useful to issue any more debt, then equity is issue. So they could conclude that if firm was profitable its retained earnings would be high and it would use its retained earnings for its financial needs, so it employed that there is negative relationship between leverage and firms profitability

Jensen (1986) argued the threat of defaulting on debt payments makes firms more efficient. As highly leveraged firms that had large amounts of debt have to pay off debts and make interest payments, they had an incentive to earn more cash from efficient investments and to enhance their performance. Furthermore, because of the threat of default on debt payments, they did not increase their debts and finance profitable investment opportunities without using debt.

To sum it up, theoretical literature provides opposite arguments on the relationship between leverage and corporate performance. Therefore, has empirical literature decided between theories?

The empirical evidences

The empirical studies have been performed to analyse the relationship between leverage and corporate performance.

Pratheepkanth (2007) researched the impact capital structure and financial performance of business firm listed at Colombo Stock Exchange during the study period (2005 - 2009). The result of study showed that the leverage finance impacted negatively on financial performance of small business. The capital structure indicator was measured by debt equity ratio. The financial performance indicators were used in the study such as Return On Assets, Return On Investment, Net Profit Margin, Gross Profit. The sample size consisted of 30 business companies listed at Colombo Stock Exchange. They used descriptive statistics to describe and summarize the behaviour of the variables in a study. And correlation analysis was used to find out the relationship between capital structure and financial performance. And regression mode was used to analyse the impact of financial leverage. Business firm depended on debt capital.

Singapurwoko et al. (2011) studied the impact of financial leverage to profitability study of non-financial companies listed in Indonesia Stock Exchange during the study period (2003 - 2008). The results of the study showed debt, firm size, and operational decision affected positively significant, and macroeconomics affected insignificantly towards profitability. And, industry factor was found to affect companies’ profitability. They used debt and combined other factors such as operational decision, macroeconomics, firm size, and industry to understand the effect of debt to profitability. The profit indicator was Return On Equity. The financial leverage was measured by using Equity Multiplier. The operational decision was measured by Total Assets Turnover. The macroeconomics indicator was measured by Bank Indonesia rate. Firm size was measured by the value of asset. The industrial indicator was qualitative measures. The sample size consisted of 48 listed non-financial companies in

Indonesian Stock Exchange. Regression and chi square analysis were used to find out the impact of financial leverage to profitability.

Ojo (2012) examined the effect of financial leverage on corporate performance in Nigeria. Data consisted of 17 firms were randomly selected and studied for a period ranging from 1993 to 2005. Financial leverage on Earnings Per Share indirectly affected the Net Assets Per Share of firms as the bulk of the shocks on the Net Assets Per Share was received from Earnings Per Share of the firms. Financial leverage indicator was Debt Equity Ratio. The corporate performance indicators were used in the study such as Earnings Per Share, Net Assets Per Share. He employed econometric technique of Vector Auto Regression (VAR) model. Financial leverage had substantial effect on corporate performance especially when the Net Assets Per Share was used as an indicator of corporate performance in Nigeria over the period covered by the study.

Rehman (2013) investigated relationship between financial leverage and financial performance of listed sugar companies in Pakistan during the study period. The results of the study showed that positive relationship of Debt Equity Ratio with Return On Assets and Sales Growth, and negative relationship of Debt Equity Ratio with Earnings Per Share, Net Profit Margin and Return On Equity. Financial leverage was measured by using Debt to Equity Ratio. Financial performance was measured by using five indicators including Return On Assets, Return On Equity, Earnings Per Share After Tax, Net Profit Margin, Sales Growth. The sample size consisted of 35 listed companies from sugar companies of Karachi Stock Exchange in period from 2006 to 2011. Descriptive statistics are used to describe and summarize the behaviour of the variables in a study. Correlation analysis was also used to find out the relationship between financial leverage and financial performance. The use of debt might make a positive or negative impact on financial performance.

Wabwile et al. (2014) researched the effect of financial leverage and financial performance of Tier 1 Commercial Banks Listed on Nairobi Security Exchange Kenya. The result of study showed that total debt to equity, debt to asset, have a negative effect on return on assets and return on capital employed, but none of them are significant. There was a positive correlation between financial leverage and EPS. Financial leverage was measured by using Debt to Equity Ratio, Debt to Asset ratio, Times interest earned ratio. Financial performance was by using four indicators including Return On Assets, Return on capital employed (ROCE), growth of the firm Earnings per share (EPS) and Dividend yield (DY) and value of the firm Price book value (PBV). The sample data was 6 commercial banks listed on Nairobi Security Exchange from the period 2007-2011. They collected data from financial statement of companies (2010-2012). Person correlation analysis and regression analysis were used to test correlation of data were used to find out the relationship between financial leverage and financial performance.

Gweyi et al. (2014) tested the effect of financial leverage and financial performance of Deposit Taking Savings and Credit Co-operative in Kenya. Financial leverage was measured by using Debt to Equity Ratio. The result of study showed that strong positive correlation between Debt Equity Ratio with Return On Equity and Net Profit Margin and a weak positive correlation between Debt Equity Ratio with Return On Assets and Income Growth. Financial performance was by using four indicators including Return On Assets, Return On Equity, Net Profit Margin, Income Growth. The sample data was 40 Savings and Credit Co-operative

Societies from the period 2010 to 2012. They collected data from financial statement of companies (2010-2012). Descriptive statistics and correlation analysis were used to find out the relationship between financial leverage and financial performance. They concluded that a strong correlation between financial leverage and financial performance of Deposit Taking Savings and Credit Co-operative in Kenya.

Akeem et al (2014) examined the effect of capital structure on firm's performance with a case study of manufacturing companies in Nigeria from 2003 to 2012. Capital structure measured by total debt and debt to equity ratio. Firm's performance measured by Returns on asset (ROA), Returns on equity (ROE). Panel data for the firms were generated and analysed using fixed effects, random effects and Hausman Chi Square estimations to test the relationship between the firm leverage and firm performance. The result of study showed that capital structure measures are negatively related to firm performance. The study recommended that firms should use more of equity than debt in financing their business activities, in as much as the value of a business could be enhanced using debt capital.

In summary, the results of empirical research are mixed relationship between of financial leverage and financial performance: positive and negative. As the portion of debts is increased the financial leverage and financial risk are also increased. If the economic condition is good, financial leverage can increase financial performance. If the economic condition is bad, financial leverage can decrease financial performance. Vietnam economy declines in recent years and firms' debt ratio is high, alarm lever (Son, 2012).

So, the research is expected a negative impact of financial leverage on financial performance.

The relationship among financial leverage, firm's age, firm size and financial performance

Firm's age is an important determinant which contributes into relationship between financial leverage and financial performance. Firm age can be defined in terms of years of formation, incorporation or listing. Bulan and Yan (2009) concluded that older firms are more leveraged than younger firms. They argued that mature firms are older, more stable and more highly profitable, with fewer growth opportunities and good credit histories. Due to these characteristics, mature firms are able to borrow more easily and at a lower cost. But, younger firms are more dynamic and more volatile in their growth experience than older firms (Evan 1987). Maturity bright stability in growth as firms learn more precisely their market positioning, cost structures and efficiency levels, are less frequently surprised by profit outcomes, and consequently are less likely to revise their investment plans. Warusawitharana (2011) studied documented firms' average profitability changes systematically with age. He regarded that between 5 and 10 years, the firm's profitability stabilised. After 10 years, the profit started to decline slowly. So, firm's age affects to relationship between financial leverage and financial performance is negative.

Firm size plays important role in defining the capital structure of a firm. Natural log of total sales or natural log of total assets can be used as proxy for size of the firm. As larger firms have an advantageous position in capital markets to raise external funds, they are less dependent on internal funds. Larger firms are more diversified and hence have lower variance of earnings, making them able to tolerate high debt ratios (Wald, 1999). Larger firms are less asymmetrical information. On the other hand, smaller firms may find it relatively more costly to resolve information asymmetries with lenders, may present lower debt ratios (Castanias, 1983). But, Audia et al (2000) highly structured that the large size firms had to encounter with the greater difficulty for highly sensitive organizational structure towards maintain resourcefulness, entrepreneurship and innovativeness to overcome an impediment to growth, good quality performance be supposed to accordingly leads to a reducing in leverage ratios. Intended for large size firms the effects of performance on leverage is negative. Ezeoha (2008) explained that the pecking order theory has an imperious consequence in the financing patterns of the Nigerian listed firms by considering some other variables constant. The result of study illustrated a highly significant negative relationship between financial leverage and profitability indicators.

Thus, firms' age and size have an important influence on capital structure decisions and choices of debt and equity. For firm's age and firm size, the effect of leverage on performance is expected negatively in this research.

Hypothesis development

According to pecking order hypothesis firms tend to use internally generated funds first and then resort to external financing. This shows that profitable firms will have less amount of leverage. There is negative relation between financial leverage and financial performance. Based on the literature review, there are hypothesis that are needed to be proved. Since the main reason of this research is to find out the impact of financial leverage on financial performance, then:

H1: A firm‘s Debt to Equity Ratio has a negative impact on its Earnings Per Share Growth.

H2: A firm‘s Debt to Equity Ratio has a negative impact on its Net Profit Margin.

H3: A firm‘s Debt to Equity Ratio has a negative impact on its Return On Assets.

H4: A firm‘s Debt to Equity Ratio has a negative impact on its Return On Equity.

Conceptual model

Based on literature review and hypothesises the conceptual model is formulated and presented in Figure 1 and consisted of four hypothesises from H1 to H4.

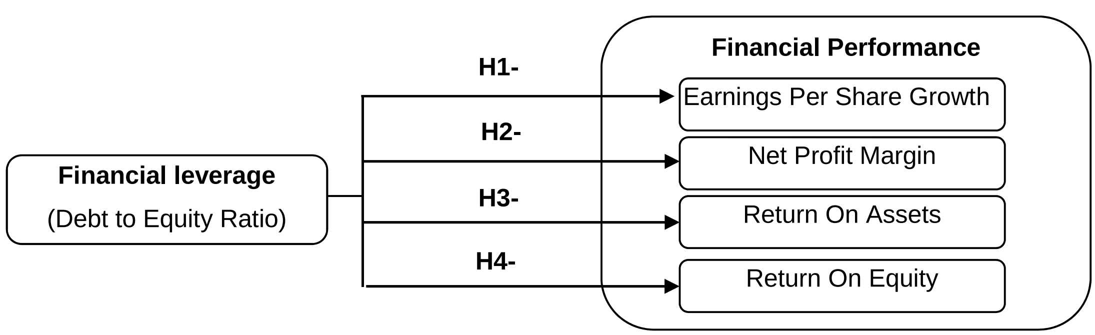

Figure 1: Conceptual model

The research is based on a standard multiple linear regression analysis with the following specification:

$Y_{it} = \beta_0 + \beta_1 DER_{it} + \beta_2 Z_{it} + \varepsilon_{it}$

With: Y is Financial performance variable as mentioned.

DER is Financial leverage (Debt to Equity Ratio)

Z is controlled variables.

β_i are the coefficients of the explanatory and controllable variable.

ε is the error term

3. Research methodology

Data collection

The research collects data from annual audited financial statement of listed sugar companies in HOSE and HNX. This publication provides useful information on key accounts of the financial statements of all listed firms of HOSE and HNX. The sample size consists of 6 listed sugar companies from food producer sector of HOSE and HNX from the period 2009 – 2013 and before Dec 31, 2007. Type of data structure used in this research is panel data.

Variable of Interest

Financial performance (Dependence variable)

Performance of the firms can be calculated by using accounting measure using firm's financial statements. According to Rehman (2013), Wabwile et al. (2014), financial performance indicators are Return On Assets (ROA), Return On Equity (ROE), Earnings Per Share Growth (EPSG), Net Profit Margin (NPM). So, this research uses most commonly used accounting based proxy for performance that is Return On Assets (ROA), Return On Equity (ROE), Earnings Per Share Growth (EPSG), Net Profit Margin (NPM) to evaluate the financial performance as dependent variable.

Financial performance indicators are calculated as:

Return On Assets = Net Income to common stockholders/ Total Assets

Return On Equity = Net Income common stockholders / Total equity

Net Profit Margin = Net Income common stockholders / Sales

Earnings Per Share Growth = (Current year EPS - last year EPS) / last year EPS

Financial leverage (Independence variable)

This research uses accounting measure for financial leverage as independent variable. Gweyi et al. (2014) used debt to equity ratio to measure financial leverage in their research on the relationship between financial leverage and financial performance. It has important implication from the viewpoint of creditors, and owner of business and the firm itself.

Financial leverage as calculated: Financial leverage (DER) = Total debt/ Total equity.

Control variables

The research examines the impact of two control variables impact on relationship between financial leverage and financial performance: firm's age and firm size:

Firm's age (AGE): The number of years since the inception of the firm to the observation date.

Firm size (SIZE): Natural logarithm of total assets.

Method of data analysis

The study uses panel estimation technique in analysing independent variables to the dependent variables. The panel data analysis uses the effect of time as much as it uses the effect of the cross sections (Wooldridge, 2002). The technique helps to control the covert effects which may be related the parameters within the set-up capital structure model. Furthermore, it is expected that modelling the financial data set such that it will have both the time dimension and the cross section dimension will lead more accurate results (Bayrakdaroğlu, 2013). The most common models of this kind are the Pooled regression model, Fixed effects model (FEM) and Random Effects mode (REM) (Gwatidzo et al, 2009).

Pooled regression model approach is to disregard the space and time of the pooled data and estimate the usual OLS regression. In particular, a pooled regression assumes that the estimated coefficients are the same for each cross-section (firms) and over the years.

Fixed Effect method is used to control all the stable characteristics of the companies included in the study over a fixed period of time (Yaffee, 2003). This method provides statistically better results by removing the biases from the data and explains only within the sample variations.

The random effects model (REM) was developed to overcome the loss of the degree of significance in the fixed effects model (Bayrakdaroğlu, 2013). Random Effect method is applied when characteristics of sample differs. As the characteristics of companies are different in terms of size, age etc. so this method is suitable to explain variations between the companies.

The most common way to decide choosing FEM or REM are used Hausman Test. The choice of the model is supported by Hausman test results which indicated a p-value of less than 0.05 hence supported the use of fixed regression model as against random effect model (Hausman and Taylor, 1981).

Finally, the financial performance should vary across firms and over time. Since capital structure itself may also change move over time for the same firm. These models can supply statistical information among groups of variables and among time periods.

4. Data analysis and discussion

This section includes the statistical analysis of financial leverage and the financial performance in listed sugar and companies of HOSE and HNX in Vietnam.

Data analysis technique includes five steps. Firstly, descriptive statistics are used to describe and summarize the behaviour of the variables in the research. Secondly, Person correlation analysis is also used to find out the relationship between financial leverage and financial performance. Thirdly, Pooled regression model, Fixed effects model (FEM) and Random effects model (REM) are used to examine find out the impact of financial leverage on financial performance. Since the study is cross- sectional across the Vietnamese listed firms, hence the FEM and REM' specifications to differ significantly. And Hausman test will be run to test whether model is FEM or REM (Greene, 2008). Fourthly, testing multi-collinearity, heteroskedasticity, autocorrelation violation. Finally, Generalized Least Square which is used by Gill et al. (2010) is fixed heteroskedasticity, autocorrelation. STATA is used software to describe and correlation and regression analysis the impact of financial leverage on financial performance of the listed companies.

Descriptive Statistics

Descriptive statistic is used to describe the nature of data. Table 1 presents the descriptive statistics for all variables, which are used in this research. The total number of observations is 30 firm-years.

DER has a standard deviation of 0.591 lesser than its mean of 0.903, maximum one is 2.68, minimum one is 0.93.

EPSG has a mean of about 0.306 and a standard deviation of 0.986 in which the lowest number is -0.921 and the highest one is 3.649.

The average Net Profit margin is 0.138 and bigger than a standard deviation of 0.084, maximum one is 0.031, minimum one is 0.012.

ROA has a standard deviation of 0.086 lesser than its mean of 0.140, maximum one is 0.379, minimum one is 0.013.

ROE has a mean of about 0.246 and a standard deviation of 0.135 in which the lowest number is 0.028 and the highest one is 0.606.

The average firm's age is 14.5 and a standard deviation of 2.861, maximum one is 20, minimum one is 8.

Table 1: Descriptive Statistics

	Observation	Mean	Std. Dev.	Min	Max
DER	30	0.903	0.591	0.93	2.68
EPSG	30	0.306	0.986	-0.921	3.649
NPM	30	0.138	0.084	0.012	0.031
ROA	30	0.140	0.086	0.013	0.379
ROE	30	0.246	0.135	0.028	0.606
AGE	30	14.5	2.861	8	20
SIZE	30	13.597	1.005	11.486	14.994

The average firm size is 13.597 and a standard deviation of 1.005, maximum one is 14.994, minimum one is 11.486. The mean value for size is high which shows that companies are growing according to total assets.

Correlation analysis

Table 2 shows Pearson correlation between variables. The correlation matrix result shows that there is negative correlation between performance and leverage.

The result shows negative relationship of Debt to Equity Ratio with Net Profit Margin, firm's age at high significance at α =1% level and Return On Assets margin at high significance at α =5%. The result shows the relationship of Debt to Equity ratio with Earnings Per Share Growth, Return On Equity and firm size at no significance. This shows that if performance of the firm is decreasing, its profitability will also increase.

The result shows negative relationship of firm's age and Earnings Per Share Growing, Return On Equity at high significance at α = 5% level. There is negative correlation between size and performance this means that old companies don't have a competitive advantage and get experience new things with the passage of time. So, companies' performances are declined.

The result shows negative relationship of firm size and Return On Asset, Return On Equity at high significance at α = 1% level. There is negative correlation between size and performance this means that larger firms, invest their assets, but old companies' performances aren't improved and decreased.

Table 2: Correlation Analysis

	DER	EPSG	NPM	ROA	ROE	AGE	SIZE
DER	1						
EPSG	-0.2021	1					
NPM	-0.5644 ***	0.4208 **	1

Note: *, **, and *** denote significance at 10%, 5% and 1% levels

Pooled regression model, Fixed Effects Model (FEM) and Random Effects Model (REM)

As the results of Hausman test, the Random Effects Model will choose to regress the relationship of Debt to Equity Ratio and financial performance indictors as Return On Assets, Return On Equity because Prob> chi2 is 0.324; 0.24 which is higher than 0.05 in Table 4. While the Fixed Effects Model is better with Earnings Per Share Growth and Net Profit Margin because Prob> chi2= 0 in Table 3.

Table 3: Pooled regression model, Fixed Effects Model (FEM) and Random Effects Model (REM) of EPSG, NPM and DER, AGE, SIZE

	EPSG			NPM		
	Pooled	REM	FEM	Pooled	REM	FEM

Autocorrelation	0.006			0.024		
Hausman test	0.002			0.000		

Note: *, **, and *** denote significance at 10%, 5% and 1% levels

Table 4: Pooled regression model, Fixed Effects Model (FEM) and Random Effects Model (REM) of ROA, ROE and DER, AGE, SIZE

	ROA			ROE		
	Pooled	REM	FEM	Pooled	REM	FEM
DER	-0.068 ***	-0.068 ***	-0.027	-0.014	-0.014	047
AGE	-0.000	-0.007	-0.026	-0.011	-0.011	-0.051 **
SIZE	-.031 **	-.031 **	-0.013	-0.061 ***	-0.061 ***	-0.012
R-square	0.438	0.438	0.138	0.368	0.368	0.152
Heteroskedasticity	0.16			0.210		
Autocorrelation	0.001			0.011		
Hausman test	0.324			0.24		

Note: *, **, and *** denote significance at 10%, 5% and 1% levels

Multi-collinearity test result:

All of factors in Table 5 are smaller than 10, so all Independence variables aren't be multi-collinearity.

Table 5: Multi-collinearity test result

	VIF	1/VIF
DER	1.20	0.830
AGE	1.36	0.736
SIZE	1.20	0.834
Mean VIF	1.25	

Heteroskedasticity Test Results

The study tests for panel level heteroskedasticity using White's test .The null hypothesis of this test is homoskedasticity. The p-value of NPM, ROA, ROE and DER, AGE, SIZE is 0.223; 0.16; 0.21 is statistically significant at 5 percent level in Table 3, 4. Hence, the null hypothesis of NPM, ROA, ROE and DER, AGE, SIZE is rejected existence of heteroskedasticity.

The p-value of EPSG and DER, AGE, SIZE of 0.008 is not statistically significant at 5 percent level in Table 3 and hence the null hypothesis of EPSG and DER, AGE, SIZE is accepted of existence of heteroskedasticity. The study consequently employs the GLS estimation technique to take care of this problem.

Autocorrelation Test Results

The study uses the Wooldridge test to test the presence of autocorrelation. The null hypothesis of this test is that there is no first order autocorrelation in the data. The p-value of the F test between EPSG, NPM, ROA, ROE and DER, AGE, SIZE is 0.006; 0.024; 0.001; 0.011 in Table 3, 4. They implies that the F test is not statistically significant at 5 percent level. Hence, the null hypothesis of EPSG, NPM, ROA, ROE and DER, AGE, SIZE is not rejected autocorrelation in the data. Subsequently, the study employs the GLS estimation technique to take care of this problem.

Generalized Least Square Regression Result

The results for GLS method between EPSG and DER -0.693 at significant levels 1% in Table 6.

So, financial leverage (Debt to Equity Ratio) has a negative and significant impact on its Earnings Per Share Growth of Hypothesis 1 is accepted.

The results for GLS method between NPM and DER is -0.064 at significant levels 1% in Table 6. So, financial leverage (Debt to Equity Ratio) has a negative and significant impact on its Net Profit Margin of Hypothesis 2 is accepted.

Table 6: Generalized Least Square Regression Result

	EPSG	NPM	ROA	ROE
DER	-0.693 ***	-0.064 ***	-0.057 ***	-0.020
AGE	-0.255 ***	-0.012 *	-0.004	-0.008
SIZE	-0.255	0.003	-0.039	-0.079 ***

Note: *, and *** denote significance at 10% and 1% levels

The results for GLS method between ROA and DER is -0.057 at significant levels 1% in Table 6. So, financial leverage (Debt to Equity Ratio) has a negative and significant impact on its Return on Assets of Hypothesis 3 is accepted.

Besides, the result for GLS method between ROE and DER is -0.020 at no significant level in Table 6. So, financial leverage (Debt to Equity Ratio) has a negative and no significant impact on its Return on Equity of Hypothesis 4 is rejected.

Overall two control variables show result of relationship with firm's performance. The firm's age shows a negative and significant levels 1%, 10% in relationship between AGE and EPSG and NPM is -0.255, -0.012. The firm's age shows a negative and insignificant in relationship between AGE and ROA, ROE.

The firm size shows a negative and significant level 1% with Return on Equity is -0.079. The firm size shows negative and insignificant levels in relationship between SIZE and EPSG, NPM, ROA.

All of hypotheses are summarized in Table 7.

Table 7: Hypotheses result

	Hypotheses	
H1	A firm's Debt to Equity Ratio has a negative impact on its Earnings Per Share Growth	Accepted
H2	A firm's Debt to Equity Ratio has a negative impact on its Net Profit Margin	Accepted
H3	A firm's Debt to Equity Ratio has a negative impact on its Return On Assets	Accepted
H4	A firm's Debt to Equity Ratio has a negative impact on its Return On Equity	Rejected

5. Conclusion

Findings

The objective of this research is an attempt to examine the impact of financial leverage on financial performance of listed sugar companies in HOSE and HNX and explores the impact of firm's age, firm size in the period 2009 – 2013. The research uses four measures which are used as the proxies for firm's age, firm size, leverage and firm performance on behalf of emerging economy conditions.

The study affirms that leverage has a significant negative effect on financial performance such as financial leverage (DER) negatively impacts and significant of on financial performance as Earnings Per Share Growth, Net Profit Margin and Return On Assets. The results are compatible with Pratheepkanth (2007) as they found a negative impact as well. On other hand, the result is matched with concluding of Wabwile et al. (2014) and consistent with trade-off theory (Kraus and Litzenberger, 1973), pecking order theory (Myers and Majluf, 1984). Based on the trade-off theory for capital structure, an optimal level of leverage can enable a firm to improve its financial performance as it can accrue tax advantage (tax shield) associated with optimum level of debt. The finding is clear evidence to conclude that as the firm increases debt beyond the optimum level. Vietnam economy is recession in recent years. Food manufacture industry is affected in economic condition, and sugar companies' output decrease. Sugar firms rely on borrowing extreme, they will not achieve tax shields and then it lead to increase borrowing cost of which the firm exposes to the bankruptcy risks and reduce the return. This research result shows that use of debt decrease EPSG, NPM, ROA and the results were consistent with the pecking order theory that firm prefer internal financing on external financing and thus enhance performance.

The finding shows that Return On Equity (ROE) is not insignificantly affected by financial leverage (DER). The result is same with result of Abdullah (2012). It can explain that shareholder of sugar company would have no concerned with the debt levels and sources which are used to raise more capital.

Based research finding, the firm's age negatively impacts and significant on financial performance as Earnings Per Share Growth (EPSG), Net Profit Margin (NPM). Sugar firm's age has shown a negative relation with financial performance in the research. The negative of age is due to the fact that firms don't learn with the passage of time and don't get experienced and they can't tackle the problems easily as compared to the new firms. As the age of the sugar firm increases, it doesn't lead to lower debt ratios. As the age of the sugar firm increases, it doesn't increase experience of the firm due to which over the time managers don't learn that what should be done to improve its performance.

And, the firm's size negatively impacts and significant on financial performance as Return on Equity (ROE). Large sugar companies aren't found to have a competitive advantage over small firms as large firms have a wide array of resources and also enjoy economies of scale, hence aren't in a better position to compete in the market.

Managerial implications

The manager should ensure that financial decisions made by them are in consonance with shareholder's wealth maximization objective which encompasses the profit maximization objective of the firm.

Firstly, based on the trade-off theory for capital structure, firm can take advantage of debt to make a better return on equity which ultimately influences firms' profitability. Manager should determine an optimal debt level that balances the benefits of debt against the costs of debt. Manager should avoid situations where they are highly leveraged since this may lead to bankruptcy if they are unable to make payment on their debt.

Secondly, the pecking order theory states that firms' managers prefer to finance new investments first internally with retained earnings, second with debt, and last by issuing new equity. The finding of study, listed sugar used high leverage, so financial performance decreased. Therefore, the order of preferred finance methods for listed sugar firms could first be internal funds, second issuing equity, and last by using debt, enhances firm's performance. Thus, firms' manager of Vietnamese listed sugar follow the Pecking Order Theory.

Thirdly, the management should monitor the interest charged on debt financing to avoid liquidation of the company. It helps the firm avoids the bankruptcy risks, which effect inversely on firm performance.

Fourthly, the manager should employ financial leverage in a way that enhances value for their company owners leading to an increase in returns to equity holders. The debt creates for the managers an incentive to work hardly and actively in spite of the decrease the increments that may make it, but this will encourage them to utilize the best invested opportunities. And a firm will achieve tax shields, and then reflect positively on their performance such as increase EPSG, NPM, ROA.

Fifthly, the result is found that using debt affect the performance in case of ROA in a negative direction which means that listed sugar firms in Vietnam inefficiently use their assets. Manager should invest and manage the company's asset efficiently. The company uses them to generate profit, as a measure of performance.

Sixthly, old companies stabilize on performance whereas new firms should have strategies in place to market and stabilize in order to have a competitive advantage over old companies. The manager should learn and get experience new things with the passage of time. The manager shouldn't carry heavy burdens from the past and are thus more flexible in adjusting to dynamic market trends.

Finally, a firm expands beyond the optimum size diseconomies of scale will set in and this can result in a decline in the financial performance of the firm. Manager should expand in a controlled way with the aim of achieving an optimum size so as to enjoy economies of scale which will ultimately result in higher level of financial performance.

6. Limitation and further research

Although this study produced some interesting and meaningful findings, there are some limitations as well. This study investigates 6 listed sugar companies in the HOSE and HNX for period (2009 – 2013). This is restricted research. The future research will take unlisted companies to increase the sample size and enlarge the time period (2006 – 2013).

Moreover, the study is only limited to three factors that affect the financial performance of the listed sugar companies in the stock market. Thus, more research should be carried out to determine other factors that affect financial performance such as market indicator.

And the research can be conducted comparative study by taking data from different sectors to check the relationship between financial leverage and financial performance.

Despite the implementation of many large scale projects (project 1547 and project 752) involving in controlling urban flooding in Ho Chi Minh City, the issue of urban flooding has been a long-lasting issue for inhabitants in HCMC. There are many causes for the problem, both objective and man-made. This study conducts a contingent valuation (CV) study to find out the willingness to pay (WTP) for the controlling of urban flooding issue. The CV survey was done with the direct survey instrument on 180 households in HCMC. The hypothetical scenario of elicitation was the project 1547 and project 752 upon completion. Double-bounded dichotomous choice question was also employed. The results found some disparities in the tendency of voting for the scenario between some areas in HCMC. Non-parametric and parametric estimates for mean WTP are VND 464,654 and VND 380,000 per each household respectively. Bootstrapping procedure further solidifies these results.

Keywords: Contingent valuation method, WTP, bootstrap, urban flooding.

1. INTRODUCTION

Ho Chi Minh City (HCMC) is one of the largest city and an important economic center in Viet Nam. With the population of 7.8 million people and density of 3,721 people per kilometer square (Wikipedia, 2011), the development of infrastructure cannot catch up with the rapid urbanization rate of HCMC. The inconsistency in the urban development in HCMC caused various problems, one of which is the exceedance in capacity of the urban sewer and drainage system, one of the causes for major urban flooding (Hoc, 2008). Moreover, the instability of the weather also further aggravates the flooding issue through the heavy rainfall and high rainfall level.

In the effort to address the flooding circumstance, the Government has approved two major plans. The first one is the plan of urban drainage improvement and sewer development of HCMC, which was approved by Decision 752 in 2002. The second is the MARD[1] construction plan, which was approved by Decision 1547 in 2008. Both projects have the same goal to help alleviate the flooding in HCMC, but they solve in different approaches. While the former focuses on rehabilitating and developing the inner urban drainage system, the latter seeks to build large scale hydraulic constructs around the city. However, due to the diversity in causes of flooding in HCMC, in order to completely solve the problem, the combination of both projects is required.

Research problem and objectives

In summary, to deal with the urban flooding issue, not to mention other smaller projects, there are two main projects have been approved and in the process of implementing, which are urban drainage improvement and sewer development of HCMC (project 752) and hydraulic construction plan (project 1547). However, project 1547 is facing difficulties in appealing investment and cost underestimating, which may delay the project until 2025. Although a specific number of expected

[1] MARD stands for Ministry of Agriculture and Rural Development.

outcomes of the two projects were not given, CBA of these projects expected to relieve all the tangible damage caused by flood in 50 years, which means no heavy flooding will be occurring in the next 50 years (Steering Centre for Urban Flood Control Program, 2013).

Are all the aforementioned measures effective or not? Inspection of the all the projects upon completion will be required to answer the question in the future. Although a CBA analysis for project 1547 has already been conducted. However, the estimating of the benefit of the project in the CBA is based on the 'flood risk approach' which did not consider the demand and willingness to pay (WTP) of the inhabitants in HCMC. In addition, the results of the study may serve as a guide for making decisions involving potential urban flooding project implementation and fee collection in HCMC as well as in other areas. Furthermore, potential projects involving flood control in HCMC may also require WTP as an important indicator to estimate the benefit of the project. Therefore, this study intents to:

- Evaluate inhabitants' level of awareness about flood risks in HCMC
- Determine the aggregate WTP for a hypothetical anti-flooding project
- Find out the factors governing the WTP of HCMC inhabitants.

In order to answer these questions, Contingent Valuation Method (CVM) will be applied in conjunction with the direct interview survey instrument to measure the willingness to pay for the elimination of urban flooding in HCMC. The result in the study may be used in policy making for deciding whether or not a project would be feasible to be conducted in the future. It may be also helpful for the process of inspecting the effectiveness of the project 1547 and 752.

2. LITERATURE REVIEW

Benefits and costs of a public good or an environmental good are difficult to determine since public goods or environmental goods usually do not have a price. Moreover, the costs and benefits are mostly dependent on individuals' preferences. Given a public good is provided, the individual's benefit can be measured by measuring how much that individual is willing to give up to obtain that public good. On the contrary, the individual's cost when a public good is lost is measured by the value of something else that individual would accept to compensate for the loss.

In terms of welfare, money is usually used as a standard measure. In that case, the measure of benefit is the willingness to pay (WTP) to obtain the benefit or willingness to accept (WTA) to compensate for the lost. The measure of cost is WTP to avoid the cost and WTA to tolerate the same.

2.1 Willingness to pay and willingness to accept

Pearce (1997) defined willingness to pay is the monetary valuation that was placed by an individual for a good or service. WTP is constrained by ability to pay so that any people with higher income will value goods or services more highly than that with lower income.

According to Bateman et al. (2002), the concept of WTP and WTA can be graphically illustrated using indifferent curve. The vertical axis represents the expenditure in money unit of an individual on the private good (y). The horizontal axis represents the quantity of a public good (x). The indifferent curve I and I' represent two linked combinations which have the same level of utility of two distinct individuals, with I has a lower level of utility than I'.

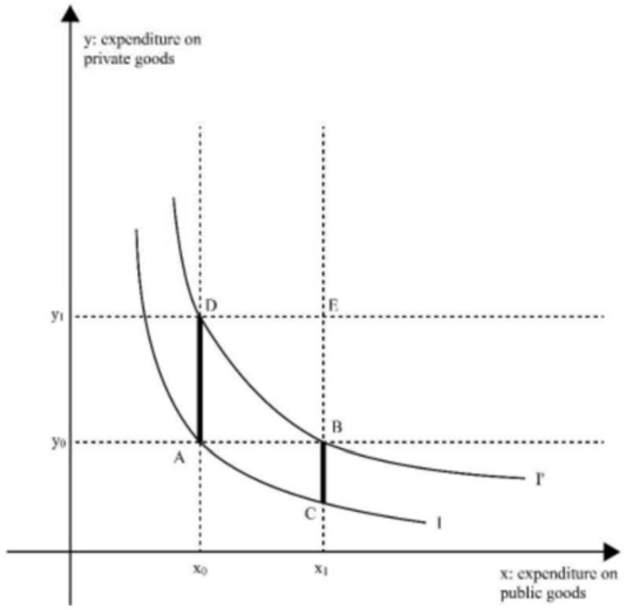

Figure 1 Measure of change in human welfare
Source: Bateman et al., 2002

With the increase in the quantity of public good, the individual can enjoy x_1 of the public good, but the private consumption is reduced by BC, in other words, the new consumption point is now C. The amount BC is defined as the WTP for the increase in the public good (or the compensating variation for the increase in the public good).

If the initial consumption of the individual is at B and there is a *decrease* in quantity of public goods from x_1 to x_0, but the individual enjoys a higher level of private consumption, y1, moving the consumption point from B to D. The amount DA is the amount of private consumption needs to be compensated for the loss in the public good, specifically in this case, the WTA for the reduction in the public good is DA (or the compensating variation for the reduction in the public good).

2.2 Total Economic Value

The net sum of all relevant WTAs and WTPs is defined as the total economic value (TEV) of any change in welfare from a policy or a project. The TEV is commonly classified into use and non-use value. Use value is classified into actual value and option value, non-use value can be disaggregated into existence value, bequest value and altruism value. The following figure demonstrates TEV and its categories.

First, use value consists of two components. Actual use relates to the actual use of the good or service (for example, a visit to a park, the prevention of potential damage of an urban flooding prevention project). Option value refers to the willingness to pay to preserve the good for using it in the future. Amongst stated and revealed preference techniques, there are two commonly used techniques to value the use value of an environmental good, Travel cost method and Hedonic pricing method.

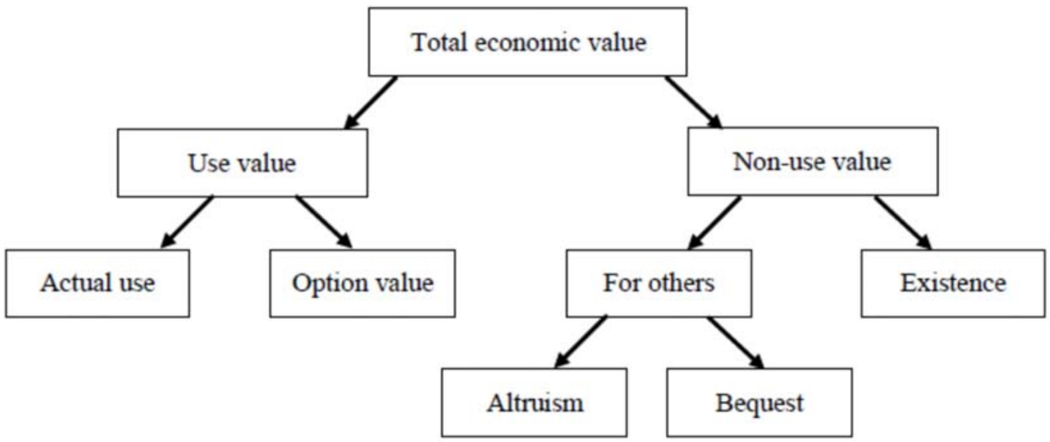

Figure 2 Total economic value
Source: Bateman et al., 2002

Second, the non - use value relates to WTP to keep some good exists, though there is no actual or possible use. The non - use value consists of existence, altruism and bequest value. Existence value refers to the WTP to have a good exists and the individual eliciting WTP has no use for himself or for someone else. The reasons for maintaining the good could be the 'feeling of responsibility' for the good or the 'concern' for the existence of a good (for instance, a rare species of animal). Altruistic value relates to the WTP to keep the good maintained to others in the current generation. Similarly, bequest value may come when the person concerns that the good should be available to others in future generations.

Covering TCM and HPM weakness of not being able to measure non-use value, Contingent Valuation Method (CVM) is one of the methods used to value the non-use value. According to Mitchell and Carson (1989), CVM has many advantages over other methods, one of which is the ability to capture the existence value. CVM involves in describing a hypothetical scenario for the respondent to state their WTP for it. Therefore, it is suitable for the valuation of environmental goods with an easy-to-perceive aspect, such as the cleansing of a river or the provision of electricity in a remote area. Due to the difficulty in capturing the actual use value of such goods, plus respondents of a CVM study rely on their own preferences, which is 'contingent' upon the hypothetical good, to give out their WTP, CVM is unable to capture the use value of the good. However, CVM can be used to measure the non-use value effectively.

2.3 Utility Theory and the Utility Difference Approach

Following economic theory, Bateman et al. (2002) defined the general form of indirect utility function as:

$$V(Y, P, S, Q)$$

The function V(.) can be described as the utility a household can acquire from the income (Y) with the prices of goods (P) (Higher or lower prices enable households to have more goods and thus, raise the utility) and the level of non-market good (Q) (Higher or lower level of non-market good represent an improvement or a decline). The utility is also assumed to be dependent on other socioeconomic factors (S).

Assuming there is a provision of non-market good that raise the level of non-market good from initial Q_0 to Q_1. The household's utility will be pushed up to a higher level:

$$V(Y, P, S, Q) < V(Y, P, S, Q_1)$$

With a higher level of non-market good, the household has to pay an amount to achieve a better well-being, but the higher the amount, the less utility the household will enjoy due to the reduction in dispensable income. So the maximum amount the household willing to pay for the improvement can be described as the amount that will bring the household's utility back to the state without the improvement, or mathematically:

$$V(Y, P, S, Q_0) = V(Y - C, P, S, Q_1)$$

With C is the household's maximum WTP, or in other words, the compensating variation for the change in the well-being. C can be written as a function of other parameters in the model. Moreover, C is constrained by the income, which means the maximum WTP cannot exceed income:

$$C = C(Q_0, Q_1, Y, P, S) = WTP \leq Y$$

Assuming a household indirect utility function has the linear form. With the assumption of the price of market goods and socioeconomic factors of that household fixed. The function of the household utility before the change (status quo) in the non-market good can be written as follows:

$$v_0 = \alpha_0 + \beta y + \gamma p + \gamma s + \gamma q_0 + \mu_0$$

μ_0 represents the unobservable factors that may influence the utility of the household. With the provision of the non-market good, the new indirect utility function will be:

$$v_1 = \alpha_1 + \beta y + \gamma p + \gamma s + \gamma q_0 + \mu_1$$

Note that the change in the utility in the latter equation due to the change in q will be captured in α_1. As mentioned, with the improved welfare, the household is expected to pay a monetary amount from their income that solves:

$$v_0 = v_1$$

$$\beta y + \alpha_0 + \mu_0 = \beta(y - C) + \alpha_1 + \mu_1$$

$$C = \frac{\alpha_1 - \alpha_0 + \mu_1 - \mu_0}{\beta}$$

The amount $\alpha_1 - \alpha_0 + \mu_1 - \mu_0$ can be interpreted as the utility difference that comes from the provision of the non-market goods. This observable portion of the utility difference can be further parameterized as a function of household other socioeconomic characteristics ($X_1, X_2, \ldots, X_k$) in a simple linear form:

$$\alpha_1 - \alpha_0 = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \cdots + \beta_k X_k$$

3. METHODOLOGY

Based on the referred literature, this chapter will present the context in which the study is conducted, the application of CVM in the context of valuing the WTP for controlling urban flooding, some justifications about selecting the appropriate elements in CVM, the main contents of the questionnaire, description of the hypothetical scenario, and lastly, the estimation and bootstrap techniques used in the study will also be introduced.

3.1 Survey procedure of the study

Although there are many methods to evaluate public good, such as hedonic pricing and travel cost, CVM is especially suitable in the case of studies involved in non-marketed goods and services, which exists in this study (Bateman et al., 2002). Moreover, the CVM is more feasible when implementing in developing countries, where the response rate is high compared to developed countries (Grosh & Glewwe, 2001). According to Mitchell and Carson (1989), CVM has many advantages over other methods, one of which is the ability to capture the existence value, which mean the individual willingness to pay to preserve the good or service. In addition, there has not been any study measuring the WTP for urban flooding prevention in Vietnam yet. Therefore, the CVM will be used to measure the WTP for HCMC flooding prevention.

The actual survey will be in face-to-face interview format. After providing information about the flooding situation in HCMC, question about characteristics of the respondent and the house, household expectation about flood situation will be asked, then a hypothetical project will be set up. The proposed hypothetical project will be the project 1547 upon completion, which was approved in 2008 by the HCMC People's Committee and the Government plus some brief explanation of the project 752 involving rehabilitating the urban sewer and drainage system will also be given. Although these projects have actually been implemented already, but due to their slow progress, the completed projects are still chosen for the hypothetical scenario. The hypothetical scenario will be described as having the capabilities of alleviating the urban flooding completely when finished. After describing the hypothetical project, the respondents will be given an opportunity to question about the project. Then the bid question is given, in which respondents will be asked how much he/she willing to pay if the project need contributions from HCMC residents.

Regarding the survey mode, the study applied was the direct in-home face-to-face interview mode. Bateman et al. (2002) introduced seven advantages of the face-to-face mode over other modes of survey, which are (i) the assurance of the household members stated, (ii) the order of information unfolding to the respondent, (iii) the assistance of the interviewer to the respondent, (iv) the correction of interviewer with misunderstanding to the questionnaire, (v) the motivation of the interviewer, (vi) the recording of verbatim comments made by the respondents and finally, (vii) the interviewer can monitor the respondents' confidence to the important questions, this is especially useful in question regarding attitude of the respondent to a specific disaster in this study. In addition, computer-assisted personal interviewing (CAPI) was also implemented. Specifically, an electronic tablet with the built-in questionnaire will be brought to each household and will be used by the interviewer to record the answer. This will help cutting down the time spent on data entering and minimize the possibility of error due to entering mistake if the survey was done by traditional paper-survey mode.

For the bid question, the study uses double-bounded dichotomous contingent valuation to ask for the amount that the respondents are willing to pay for the hypothetical project. Then from the data, the WTP for the HCMC flooding prevention is inferred. The double-bounded dichotomous bid question is chosen due to the high statistical efficiency could be achieved compared to open-ended or single-bounded dichotomous-choice method according to Bateman et al. (1999). This type of bid question requires each respondent to identify two pre-specified amount that bound their maximum WTP (one amount is higher and one amount is lower than their maximum WTP). Specifically, each respondent will be asked an initial amount (initial bid), if the answer 'yes' / 'no' is given, a higher/lower amount (higher/lower bid) will be asked. From the answers (yes-no, yes-yes, no-yes, no-no) and corresponding bounds, the WTP interval from each individual is inferred in the data analysis.

The payment vehicle of choice is also crucial to a CVM study (Morrison, Blamey, & Bennett, 2000). Payment vehicle is the method by which the money will be hypothetically collected from the respondents. Two payment vehicles were put into consideration, one-time voluntary payment and one-time mandatory payment in electricity bill of the household. Although a mandatory increase in electricity bills seems to be a more convenient method than a voluntary donation for urban households, Morrison, Blamey & Bennett (2000) pointed out that one of the reasons for the occurrence of vehicle bias is respondents' doubts about payment being one-off. The request for an increase electricity bill may raise doubts to the respondent that, although being clearly stated, that increase will not be charged one time. Furthermore, Ryan (2006) also stated collective payment mechanism usually results in a somewhat higher estimate of WTP compare to voluntary mechanism. To avoid bias, one time voluntary payment vehicle was chosen in this study.

To address hypothetical bias. In the context of the study, three solutions were chosen. The first remedy used was giving the respondents the certainty that the hypothetical project has actually been implemented by project 1547 and project 752 (Cummings et al., 1995; Landry and List, 2007; Mitani and Flores, 2010), the survey will give some information regarding the year of starting, the scale of these actual projects.

However, due to the actual slow progress of these projects, the current progress of these projects was not given the respondents to avoid protest bids. The second solution was the use of vocal confirmation message after the respondents have completed the bid question. More specific, the respondents will be asked whether they are certain about the bid or not, if they are not, they will be required to rethink and change their bid answers. And finally, several emphasis will be made by the interviewer throughout the survey reminding the respondents to answer the questions honestly.

At the beginning of the study, a focus group discussion is conducted, the main purpose of the focus group discussion is to gain insights about the issue of urban flooding, what has to be considered in the questionnaire and basic bid range suggestions. The focus group consists of 6 people who have resided in HCMC for more than 10 years. Participants are asked to give an opinion on the understandability of the proposed scenario and decide whether a specific question is appropriate or not.

After the questions in the questionnaire have been constructed and revised by the focus group. To pre-test the questionnaire, a pilot survey whose main purpose is to determine the bid levels and check the validity of the questions was initiated. 20 random households were selected and surveyed, they were asked to give the specific bid (open bid) on the scenario instead of choosing dichotomous yes-no. According to the collected pilot-survey data, 18 sets of bid were designed, these sets of bids would be used in the final survey.

Table 1 Details of 18 sets of bid used in the survey

Set #	Initial bid (VND)	Lower bid (VND)	Higher bid (VND)	Number of households
1	50,000	20,000	250,000	10
2	50,000	20,000	450,000	10
3	50,000	20,000	1,000,000	10
4	50,000	20,000	3,000,000	10

5	250,000	50,000	450,000	10
6	250,000	50,000	1,000,000	10
7	250,000	50,000	3,000,000	10
8	450,000	50,000	1,000,000	10
9	450,000	50,000	3,000,000	10
10	450,000	250,000	1,000,000	10
11	450,000	250,000	3,000,000	10
12	1,000,000	50,000	3,000,000	10
13	1,000,000	250,000	3,000,000	10
14	1,000,000	450,000	3,000,000	10
15	3,000,000	50,000	5,000,000	10
16	3,000,000	250,000	5,000,000	10
17	3,000,000	450,000	5,000,000	10
18	3,000,000	1,000,000	5,000,000	10

Finally, the sample is chosen based on the two-stage sampling design. More specifically, four districts were chosen at random (District 6, Thu Duc District, Binh Tan District and Binh Thanh District), then in every district, one area was chosen to survey. In each area, the survey process will be accompanied with one area-leader person, the leader will assist in the survey process and ensure the honesty of the responses. Households are notified in advance by telephone by the leader and the family member who takes the survey will have their age to be restricted in working age (18 or older). The total sample size is 180 (not counting pilot observations) which is distributed across areas as following.

Table 2 Distribution of observations across areas

District	Area	Number of observations
District 6	An Duong Vuong Street	30
Binh Tan District	An Duong Vuong, Kinh Duong Vuong Street	45
Binh Thanh District	Nguyen Huu Canh, Nguyen Xi Street	53
Thu Duc District	Kha Van Can Street	52

After the survey has been conducted, the mean and the WTP would be computed using two methods, non-parametric estimation and parametric estimation. For non-parametric estimation, Bateman et al. (2002) proposed a method to deal with double-bounded data, Turnbull Self Consistency Algorithm (TSCA), which is the method will be used in this study. While parametric estimation will conduct a logistic regression to estimate mean WTP.

3.2 Non-parametric estimation technique

An advantage of non-parametric estimation over parametric regression models is that the former do not make any model assumption. Parametric estimation relies solely on the data on the bid levels offered and households' choices. The double-bounded dichotomous question produces interval data with overlapping interval. Bateman et al. (2002) proposed a solution to deal with this type of data, which is Turnbull Self-Consistency Algorithm (TSCA). The procedure for TSCA is described as follows.

Firstly, interval data from the study will be classified into basic intervals, which are smallest interval division units of WTP data and overlapping intervals, which are intervals that encompass two or more basic intervals. In details, data from the study will be classified as follows, in which 8 first intervals are basic intervals.

Table 3 Interval distribution of WTP responses

Interval code	Lower bound	Higher bound	Number of HHs in interval
A	0	20,000	9
B	20,000	50,000	13
C	50,000	250,000	11
D	250,000	450,000	10
E	450,000	1,000,000	12
F	1,000,000	3,000,000	4
G	3,000,000	5,000,000	3
H	5,000,000	∞	0
CD	50,000	450,000	9
CDE	50,000	1,000,000	11
CDEF	50,000	3,000,000	15
DE	250,000	1,000,000	7
DEF	250,000	3,000,000	10
DEFGH	250,000	∞	1
EF	450,000	3,000,000	8
EFGH	450,000	∞	4
FGH	1,000,000	∞	3
GH	3,000,000	∞	1
AB	0	50,000	17
ABC	0	250,000	14
ABCD	0	450,000	9
ABCDE	0	1,000,000	9
	Total number of households		180

TSCA attempts to calculate the survivor function at each of the boundary values B_j (which are 0; 20,000; 50,000; 250,000; 450,000; 1,000,000; 3,000,000; 5,000,000) by dividing the number of households who have WTP higher than B_j by the total sample size (which is 180). However, that number of households is not certain since some households have their intervals spanned in many basic intervals.

The second step is to calculate probabilities for each basic interval that a household WTP will fall into that interval by subtracting the probability of lower bound to the probability of lower bound of the next higher interval.

For each of overlapping intervals, the number of households in that overlapping interval will be allocated into number of households in basic intervals it spans, according to the calculated probability of lying in each basic interval.

Lastly, with the new set of households which are only lying in basic intervals, the survivor function can now be constructed. Multiple iteration of the whole process may be initiated to get the mean WTP to converge.

3.3 Parametric estimation technique

From the framework of utility difference, clearly:

$$\mathrm{z} = \alpha_1 - \alpha_0 = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \cdots + \beta_k X_k + \beta C - (\mu_1 - \mu_0)$$

The utility difference model yields a logit specification when the probability of a yes response is assumed as the cumulative distribution function of a logistic covariate with the assumption of zero mean error term. The probability of responding a 'yes' answer will be

$$\Pr(yes) = \frac{1}{1 + e^{-z}}$$

Whose coefficients will be estimated by maximizing the likelihood function in a logit model.

In this study, the data on WTP question will be treated as discrete choice data. Specifically, 180 double bounded responses will be treated as 360 binary responses, additionally, a bid variable will be added to the model indicating the bid level that household is faced when elicit the choice.

After estimating the coefficients of the logit model. Then the mean and median of WTP under the assumption of logistic distribution will be computed as follows, according to Haab and McConnell (2002):

$$\text{Mean (median) WTP} = \frac{-\overline{X}\beta'}{\beta_0}$$

In which:

$\overline{X}$ is the row vector of sample mean, including 1 for the constant

β' is the column vector of estimated coefficients excluding the coefficient of bid

β_0 is the coefficient of 'bid' variable.

3.4 Confidence intervals of mean WTP

The estimated WTPs are only estimates of the entire population's WTP based on the sample of households. Different samples could possibly produce different WTPs. Thus, after estimating mean WTP in non-parametric and parametric method in this study, it is required to have an indication of the accuracy of these WTP.

Bateman et al. (2002) generalized two main approaches, which are analytical approach and numerical approach. The latter, is also known as bootstrapping, is proved to be able to achieve a very high degree of robustness and can be applied in many types of estimation techniques and data. Bootstrapping involved in the process of iterated estimation of WTP from a large number of randomly generated datasets whose observations are also randomly drawn from the initial dataset. From the produced WTPs, the confidence interval is then inferred (Krinsky & Robb, 1986).

This study will also apply bootstrapping to produce the 95% confidence interval of the mean WTP. Parametric estimation will bootstrapped with a certain STATA command and non-parametric estimation will be bootstrapped with the Crystal Ball software.

4. ANALYSIS RESULTS

After the survey procedure has been developed. Then actual survey is conducted to gather data. In a CVM study, the crucial requirement is the assurance of data reliability and representativeness because of the complete dependence of WTP estimates on the data. In addition, objective factors such as intentional dishonesty of the respondents, unpatterned responding behaviors or uncontrollable hypothetical bias could also obliquely alter the data. Nevertheless, only with 180 observations compare to the population of over 2 million households in HCMC, the data barely meet the strict requirements of a CVM data quantity. This section holds the purpose of presenting some descriptive statistics of survey data, WTP estimation results with both non-parametric and parametric techniques along with some main findings from the parametric estimation.

4.1 Non-parametric estimation result

After applying TSCA for the sample data, the resulting survivor function is then constructed as follows:

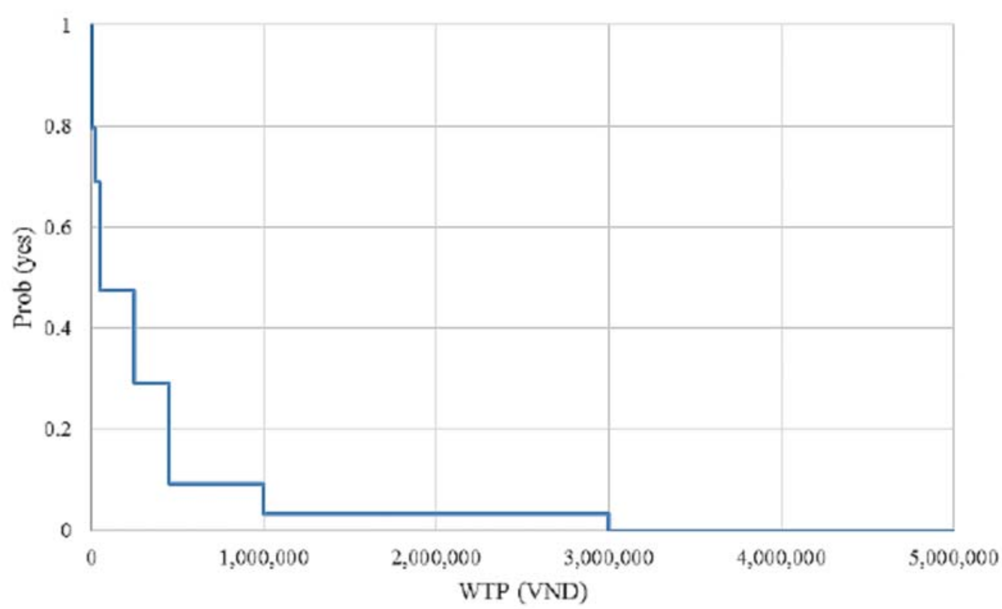

Figure 3 Survivor function of non-parametric estimation

The mean WTP is VND 484,654 while the median of WTP is 250,000. Bootstrapped 95% confidence interval ranges from VND 348,499 to VND 631,757 (for more details on calculating and bootstrapping, see the Appendix). The median WTP in TSCA non-parametric estimation is the value of bid that take the prob(yes) of 0.5, which means it only takes the value of boundary values. Thus, the significant difference between mean and median WTP in this estimator can be explained by the low probability allocation into higher interval and the varied interval distances.

4.2 Parametric estimation results

Parametric estimation in this study involves in logistic regression with the dependent variable of choice (yes/no) with a bid variable indicate the bid offered to the respondents. Since each respondent are asked two times with a double-bounded dichotomous valuation question, the dataset will also be replicated to 360 observations. More specifically, each household will be treated as two different households with the same characteristics but the bid responses.

First, the initial logit model was conducted with all 48 variables included (unrestricted model). However, the unrestricted model failed to give significant result at the 5 % level for 40 variables. Then, by using a stepwise procedure with clustering[2] at 5% level with the unrestricted model, a second logit model with 8 variables was produced (restricted model). A likelihood ratio contrast test between two models also failed to reject the null hypothesis of variables inclusion un-necessity. The result of the restricted model is presented as follows (see the Appendix for the full results of both models):

Table 4 Logistic regression result[3]

Dependent variable: choice	Coef.	Odds ratio	z	p-value
bid_in_million	-3.057	0.047	-6.65	0.00
gender_male	0.098	0.975	0.25	0.80

street_anduongvuong	-2.124	0.119	-4.12	0.00
street_kinhduongvuong	-1.273	0.280	-2.86	0.00
income_in_million	0.347	1.415	7.87	0.00
distance_river_100m_500m	-0.400	0.670	-0.60	0.55
distance_river _1km_2km	0.637	1.891	0.79	0.43
distance_river _500m_1km	0.779	2.179	1.30	0.19
_cons	-0.708	0.492	-0.92	0.36

The distance to the river and canal category, although is not significant in the restricted model, the LR individual test failed to remove it from the model, suggesting that these variables still have significant predicting power in the model. In this category, the sign of the dummy indicating a distance from 100m to 500m is negative while others are positive, this possibly implies that the shorter the distance, the less the respondents are willing to pay. Other variables are statistically significant at the 5 % level.

Bid and income variables have negative and positive signs respectively. This implies a monetary increase in bid/income will lead to a decreased/increased probability of

[3] Bid and income are measured in million VND. Dummy variables are italicized. gender_male and 4 education dummies are in unrestricted model only. Other variables are in the restricted model

voting for the project. This is consistent with common sense and economic theory. Moreover, the effect of each VND increase in bid is eight times stronger than income's, suggesting a greater sensitivity of WTP of respondents to the bid faced than the income sensitivity. The age variable has the negative sign, which means respondents who are older has a lower probability of responding with a 'yes' response, suggesting that people who are younger have a higher tendency to vote for the project than who are older.

However, the surprising discovery is the disparities in the tendency of voting between areas in HCMC. More specifically, negative signs on street_kinhduongvuong and street_anduongvuong dummies imply that households residing on An Duong Vuong Street and Kinh Duong Vuong Street are more reluctant to pay for the project than people residing in other 3 streets. A possible explanation for such low preferring in these streets could be the high frequency of flooding in these areas, leading to the increased level of respondents' uncertainty of the outcome of the hypothetical project when asked. According to Urban Flooding Control Centre (2013), Ward 6, which consists An Duong Vuong Street and Kinh Duong Vuong Street, is one of the areas in HCMC which has been suffering from long-lasting flooding since 2008.

The mean and median WTP calculated by the result of the restricted model with 8 variables is VND 380,000, which is fitted in bootstrapped 95% confidence interval of VND 268,822 to VND 480,079. A further comparison between unrestricted and restricted model is illustrated as follows.

Table 5 Unrestricted model and Restricted model comparison

	Unrestricted model	**Restricted model**
Number of observations	360	360
Included variables	48	8
Number of significant variables at 5%	8	5
Count R-squared	0.85	0.83
Number of variables with VIF >10	6	0
Likelihood Ratio contrast test	Not preferred	Preferred
Mean (median) WTP	400,000	380,000
Bootstrapped 95% conf. interval	290,418 – 499,367	268,822 - 480,079

With the count R^2 of 0.83 compared to 0.85 with the unrestricted model and the advocate from the LR contrast test, it can be said that the restricted model achieves a reasonably equivalent predicting power, which is important to WTP estimating compare to the unrestricted one. Moreover, the unrestricted model is also impaired with serious collinearity issue and there is no significant difference in WTP between two models. Therefore, mean WTP of 380,000 is considered as a consistent parametric estimate for the valuation in the study.

In comparison with non-parametric estimate (VND 484,654), parametric technique produces a more conservative number. Possibly due to the significant drag-down of the variables of the restricted model shown by numerous negatives on the coefficients. However, the non-parametric approach does not take into account the other characteristics, especially income, but WTP choice and bid amount. Although there is no clear evidence supporting the use of either method, conservative principle prefers the use of the approach that produce the lower result (Daniel & Jouni, 2002).

There are also some gaps in WTP between male and female. Recalculation of WTP for male and female group results in the estimate of VND 360,000 and VND 400,000 respectively. This is contrary to the common belief that male tends to pay more than female because of being the main earner in households. However, the gap is not very significant and the phenomena can be explained by the housewives' greater level of concern toward their houses.

5. CONCLUSION

Urban flooding has been risen as a serious problem in HCMC in recent years. Despite efforts of the Government to eradicate the situation through large-scale projects, urban flooding still impairs residents in HCMC. Moreover, due to the economic value diversity of such anti-flooding measures, assessing the value of urban flooding controlling has been challenging for economists not only in HCMC, but also in other metropolises in the world. This study applied Contingent valuation method to find out the WTP for the complete elimination of urban flooding in HCMC. The estimated WTP values may be potentially used in cost-benefits assessments of future projects, or inspection upon completion of current projects. Although the survey has been conducted carefully by direct interview method, there are still potential limitations that may alter the results.

The results show the WTP estimates of VND 484,654 and VND 380,000 for non-parametric TSCA technique and parametric estimation respectively. Further justification has been made between figures and the latter was considered as a consistent estimate for mean WTP for the urban flood control. With the approximated total households of 2 million, the aggregated WTP for the whole city is 760 billion VND. Obviously, this figure is extraordinarily low compared to the enormous scale of the hypothetical project and the actual expected investment cost for project 752 and project 1547. However, despite the results, it is still uncertain to conclude about the feasibility of these projects due to the fact that total economic value may not be fully captured by the contingent valuation method, only the non-use value. Thus, further studies using various methods are required in order to fully give out a best estimate for the evaluation of use value of these plans.

The study also points out that, the level of flooding impact, which is reflected through location variable in the study, possibly plays an important role for the respondents to decide whether or not they should accept the bid. More specifically, this suggests that people living in An Duong Vuong and Kinh Duong Vuong streets are less willing to pay for the flood prevention than people living in other 3 streets in the study. Even though another study which encompasses a greater number of streets and districts in HCMC may be required to further solidify this point, this finding still gives some insights for policy makers about the seriousness of flooding in these two areas and the priority of controlling the flooding situation in HCMC.

APPENDIX

APPENDIX 1: The questionnaire

Question 1. Year of birth

Question 2. Gender

Question 3. Number of family members

Question 4. Monthly income of household

Question 5. How many members in your household is currently working?

Question 6. How long have your family been in HCMC?

Question 7. Education level

- ◯ High School
- ◯ Vocational training
- ◯ College
- ◯ University
- ◯ Post-graduate

Question 8. House condition:	Total square (m2)	No. of floors
◯ Semi-concrete house		
◯ Concrete house		
◯ Temporary house		
◯ Villa		

Question 9. House ownership

- ◯ Rent house
- ◯ Private house
- ◯ State-provided house

Question 10. Distance to the nearest canal or river:

- ◯ Under 100m
- ◯ From 100m to 500m
- ◯ From 500m to 1km
- ◯ From 1km to 2km
- ◯ Higher than 2 km

Question 11. House address

	Yes	No
Question 12. Have your family been affected by urban flooding before?	◯	◯
Question 13. In your opinion, would the urban flooding controlling be improved in the future?	◯	◯
Question 14. Do you concern about the current urban flooding consequences?	◯	◯

Question 15. On average, how many times have your house been affected with urban flooding?

Question 16. In your opinion, what natural disaster do you concern the most? (From 1 to 4 scale)

Hurricane	①	②	③	④
Flooding	①	②	③	④
Earthquake	①	②	③	④
Thunderstorm	①	②	③	④

Question 17. In your opinion, what environmental issue do you concern the most? (From 1 to 4 scale)

Air pollution	①	②	③	④
Water pollution	①	②	③	④
Noise pollution	①	②	③	④
Soil erosion	①	②	③	④
Greenhouse effect	①	②	③	④
Extinction of rare species	①	②	③	④
Illegal logging	①	②	③	④
Natural resources exhaustion	①	②	③	④

Question 18. In your opinion, what urban issue do you concern the most? (From 1 to 4 scale)

Robbery	①	②	③	④
Traffic accident	①	②	③	④
Fire hazard	①	②	③	④
Urban flooding	①	②	③	④
Traffic congestion	①	②	③	④

Question 19. Is your family currently using any private anti-flooding measures?

- ◯ No measures taken
- ◯ Floor elevation

HCMC has been facing with the urban flooding for a long time, especially in the rain season from May to November. Moreover, in October, the situation will be further aggravated by the river tide.

There are three main causes for urban flooding in HCMC: flooding from upstream, high tide and heavy rain. Moreover, the rapid urbanization also pushes canals, rivers and urban drainage system into overload condition.

According to Steering Centre for Urban flooding, In 2013 and 2014, it is expected to have 11 impaired street routes in the city suburban areas remains and there will be no flooding in the city center. Most significant flooding points are:

- Around Phu Lam Circus (District 6) in the city western gateway. Specifically, Hau Giang Street, Hung Vuong Street, Kinh Duong Vuong Street, Minh Phung Street.
- In Binh Tan District, which has the fast urbanization and unorganized city planning, leads to the exceedance in drainage system.
- Some other areas such as Thanh Da (Binh Thanh district), Kha Van Can Street (Thu Duc district) is also affected heavily with flooding.

With the flooding situation. I would like to propose a project which will help alleviating the flooding problem in HCMC. This project is actually approved and implemented in 2008 by the Government but it has not been completed yet. First, the HCMC will be divided into 3 zones (see figure).

- Zone I (yellow zone): contains all of the left-hand side of Saigon river plus Nha Be District (central HCMC districts and a part of Long An Province)
- Zone II (red zone): contains the area around Saigon river – Dong Nai river tri-fork (District 2, 9 and Thu Duc District)
- Zone III (blue zone): contains Can Gio district only.

The project focuses on protecting zone I and zone II, zone III is consider to be an important ecological and vulnerable area. So no measures is implemented in zone III in the project.

Second, the protection for zone I consists of 172 km of dykes and 12 sluice gates, protecting urban and rural areas of HCMC, more specific, zone I, against tidal flooding and river discharges. It also serves the role of controlling the water level in the protected area by enhancing the outer drainage system. Furthermore, the inner urban drainage will also be enhanced by rehabilitate 186 urban drainage routes.

Third, the protection for zone II focuses on the raising of the embankment of lowlands and building smaller dykes to enclose ecological and tourism areas. Canals and main rivers will also be dredged to improve drainage capacity.

Upon completion, this project is expected to eliminate completely the urban flooding in HCMC. Do you have any questions regarding this project?

Question 20. Assuming if there is a call for contribution to the implementation of this project. Each household in HCMC will be requested to contribute an amount of <initial_bid> as voluntary donation. Will you accept to contribute?

◯ Accept	→	If the amount is now <*higher_bid*>, will you accept?	◯ Accept ◯ Reject
◯ Reject	→	If the amount is now <*lower_bid*>, will you accept?	◯ Accept ◯ Reject

Questions regarding belief	Yes	No
Question 21. Do you think this project can effectively reduce the urban flooding problem?	◯	◯
Question 22. Do you think this project may contaminate the surroundings in the implementation process?	◯	◯
Question 23. Do you believe the Government will make a good use of your contribution?	◯	◯

APPENDIX 2: Non-parametric WTP calculation and bootstrap

At the beginning, the number of households will be distributed into intervals. First, TSCA will calculate the probability of having WTP greater than boundary values by dividing the number of households who have WTP higher than boundary values by the total sample size (180) the results are presented in column 5 in the table below

Second, the probability for having WTP range from an interval's lower bound and higher bound is then calculated for basic intervals by subtracting aforementioned figures. For overlapping intervals, the probability is calculated by adding corresponding basic interval probability. Detailed calculation is presented in column 6 in the table below.

Interval code	Lower bound	Higher bound	Number of HHs in interval	Probability WTP > lower bound	Probability lower b < WTP < higher b
A	0	20,000	9	180/180 = 1.00	1.00 – 0.67 = 0.33
B	20,000	50,000	13	122/180 = 0.67	0.67 – 0.60 = 0.07
C	50,000	250,000	11	109/180 = 0.60	0.60 – 0.35 = 0.25
D	250,000	450,000	10	63/180 = 0.35	0.35 – 0.19 = 0.16
E	450,000	1,000,000	12	35/180 = 0.19	0.19 – 0.06 = 0.13
F	1,000,000	3,000,000	4	11/180 = 0.06	0.06 – 0.02 = 0.04
G	3,000,000	5,000,000	3	4/180 = 0.02	0.02 – 0.00 = 0.02
H	5,000,000	∞	0	0/180 = 0.00	0.00 – 0.00 = 0.00
CD	50,000	450,000	9		0.25+0.16
CDE	50,000	1,000,000	11		0.25+0.16+0.13
CDEF	50,000	3,000,000	15		0.25+0.16+0.13+0.04
DE	250,000	1,000,000	7		0.16+0.13
DEF	250,000	3,000,000	10		0.16+0.13+0.04
DEFGH	250,000	∞	1		0.16+0.13+0.04+0.02+0.00
EF	450,000	3,000,000	8		0.13+0.04
EFGH	450,000	∞	4		0.13+0.04+0.02+0.00
FGH	1,000,000	∞	3		0.04+0.02+0.00
GH	3,000,000	∞	1		0.02+0.00
AB	0	50,000	17		0.33+0.07
ABC	0	250,000	14		0.33+0.07+0.25
ABCD	0	450,000	9		0.33+0.07+0.25+0.16
ABCDE	0	1,000,000	9		0.33+0.07+0.25+0.16+0.13

Third, the number of households in each basic interval will be recalculated by adding the initial number of households with the probability-weighted number of households in overlapping intervals. The result is shown in the column 4 at the table below

Interval code	Lower bound	Higher bound	Number of HHs in interval (Recalculated)	Probability WTP > lower bound (Recalculated)
A	0	20,000	36.52	1.00
B	20,000	50,000	19.17	0.80
C	50,000	250,000	39.14	0.69
D	250,000	450,000	32.74	0.47
E	450,000	1,000,000	36.02	0.29
F	1,000,000	3,000,000	10.81	0.09
G	3,000,000	5,000,000	5.61	0.03
H	5,000,000	∞	0.00	0.00
			Mean WTP	484,654

Lastly, the probability of having WTP higher than boundary values will be recalculated with the new numbers of households. The Mean WTP will now be the sum product of newly calculated probabilities with the boundary values (lower bounds).

To calculate the confidence interval, the bootstrapping procedure is applied. More specifically, using Crystal Ball software, multiple randomly generated data sets will be used to calculate different WTPs. The result for the confidence interval of this mean WTP is shown below.

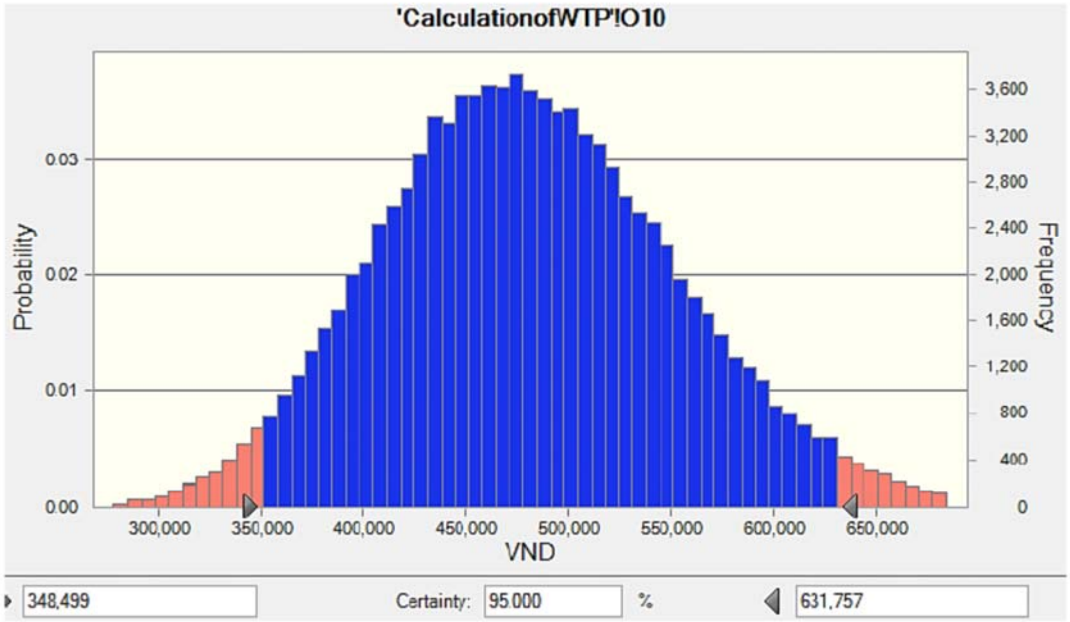

Figure 4 Crystal Ball bootstrapping result for non-parametric WTP
(For even more detailed calculations and bootstrapping instruction, see the Excel file).

Conceptual Framework of Virtual-Team Effectiveness in Vietnam

Huynh T. M. Chau
Ho Chi Minh City University of Technology
htmchau@hcmut.edu.vn

Cao Hao Thi
Saigon Technology University
thi.caohao@stu.edu.vn

With outstanding advantages, teamwork have been increasingly popular in enterprise environment. Improving the effectiveness of team is a solution to help improve the quality of human resources, and thereby promote the general efficiency of companies. In recent days, advances in information systems and communication technology have provided companies with new options for organizing: virtual-team. This is a burgeoning form of organization that allows teams to be composed according to qualifications and expertise, without the limitations of time, space, and the costs and disruptions of relocation.

In Vietnam, companies are more and more investing in virtual-teams to enhance their performance and competitiveness. However, in fact, research on virtual-teams is still in its nascent stages (Badrinarayanan & Arnett, 2008, Prasad & Akhilesh, 2002) and because of the relative newness of virtual-teams, many areas of research have not been examined (Badrinarayanan & Arnett, 2008). Besides, some recent studies also showed that teamwork in Vietnamese companies is not as professional and effective as expected because most managers can't access reliable theoretical framework of team effectiveness (Chau & Anh, 2013).

What are the inputs that influence virtual-team effectiveness? What are the process factors that occur during virtual-teamwork? How can virtual-team effectiveness be measured? To answer these questions, firstly, a review of literature is conducted on background theories and recent studies of teamwork to identify relevant elements in a team effectiveness framework. Once the elements are identified, a qualitative research is carried out on 9 virtual-team managers to indicate which elements are suitable to virtual-team. The number of elements is reduced from 56 to 47. Some elements are removed or classified into other level or divided into specific elements. Some new elements are composed of available elements or brand-new added. After that, a quantitative survey is conducted by using questionnaires via email, Google Docs and hard copies to 259 virtual-team members whose working locations are in the territory of Vietnam.

The research findings help propose a conceptual framework that is particularly suitable to virtual-team effectiveness in Vietnamese enterprise environment. In this framework, (1) **Inputs** include four dimensions: *(i) Team characteristics* (9 factors), *(ii) Individual characteristics* (5 factors), *(iii) Organization characteristics* (5 factors), *(iv) Task characteristics* (4 factors); (2) **Processes** include seven factors: *(i) Coordination, (ii) Connection, (iii) Communication, (iv) Commitment, (v) Flexibility, (vi) Synergy, (vii) Conflict managing*; (3) **Outcomes** include two dimensions: *(i) Performance outcomes* (3 factors), *(ii) Attitude and behavior outcomes* (2 factors) (see Figure 3).

Keywords: Conceptual, effectiveness, framework, team, Vietnam, virtual

1. Introduction

The pressure of global competition, the need to consolidate business models in dynamic, uncertain and complex settings and the need for innovation demand the modification of the structure of work traditionally based around individuals, and the adoption of organizational designs oriented to change and based on teams (West *et al.*, 2004). Teams bring the diversity of knowledge, skills and experience that permits rapid, flexible and innovatory responses to the problems and challenges faced. Hence, the success of organizations and the global production of knowledge depend to a large extent on the effectiveness of teams (Wuchty *et al.*, 2007).

Teamwork goes by many labels, including work teams, work groups, task groups, parallel teams, quality circles, project teams, project groups, cross-functional teams, management teams, etc. With the growth of telework - increasingly called virtual work - is the inevitable growth of virtual-teams, which are teams of people who are geographically dispersed but work together virtually through the use of technology such as teleconferencing and videoconferencing, e-mails, text messages and telephone. Today, we would be hard pressed to find an organization that doesn't have one or more virtual workers and virtual-teams. Virtual-teams are growing in popularity (Cascio, 2000). In the competitive market, virtual-teams represent a growing response to the need for fasting time-to-market, low-cost and rapid solutions to complex organizational problems. Virtual-teams enable organizations to pool the talents and expertise of employees and non-employees by eliminating time and space barriers. Virtual-teams are not only attractive to employers but also green. According to the Telework Research Network, the existing 2.9 million U.S. telecommuters save 390 million gallons of gas and prevent the release of 3.6 million tons of greenhouse gases annually (Lister & Harnish, 2011). In Vietnam, there are many companies which have been using virtual-teams as a modern working form of teamwork. The more companies use virtual-teams, the more knowledge of team effectiveness should be supplied to managers.

However, a representative of General Department of Vocational Training (Ministry of Labor, Invalids and Social Affairs) claimed that one of the most weakness of Vietnamese employees is teamwork (Phuong, 9/2014). Recently, citing from the International Labor Organization, some newspapers reported that the labor productivity of Vietnam belongs to the lowest area, only 1 part 15 of Singaporean, 1 part 5 of Malaysian, 2 part 5 of Thai (Hieu, 9/2014). Performance of Vietnamese employees declines in geometric progression as the number of team members increased in arithmetic progression (Anh, 4/2013). There is a paradox in many Vietnamese companies is the more talented and young the employees are, the easier they lose in activities which require teamwork (Nhat, 6/2011). The experiments suggest that more research is needed to explore the ways to enhance the performance of virtual-teams (El-Tayeh *et al.*, 2008).

Aiming to provide more references for those interested in improving team effectiveness, especially virtual-team effectiveness in Vietnam, this study is carried out in three steps: *(1)* Systematizing background theories and recent studies of teamwork to identify relevant elements in a team effectiveness framework. *(2)* Carrying out a qualitative research on 9 virtual-team managers to indicate which elements are suitable to virtual-team. *(3)* Conducting a quantitative survey among 259 virtual-team members whose working locations are in the territory of Vietnam. These respondents have got themselves involved in virtual-teams with different positions and working locations. The research findings help propose a conceptual framework that is particularly suitable to virtual-team effectiveness in Vietnamese enterprise environment.

2. Literature review

2.1. *Group and team*

A group is two or more individuals who are connected by and within social relationships (Forsyth, 2006). Groups can be classified into two types: *(1)* Informal groups; *(2)* Formal groups (Hiriyapa, 2009; Luthans, 2011; Newstrom, 2007; Schermerhorn *et al.*, 2004). A team is a formal group. It's a group of people holding themselves collectively accountable for using complimentary skills to achieve a common purpose. Teamwork occurs when team members live up to their collective accountability for goal accomplishment (Schermerhorn *et al.*, 2010). Results of teamwork consist of both individual results and what we call "collective work-products" (Katzenback & Smith, 1993). In team, there's no social loafing as group.

Although teamwork is preferred to groupwork, two terms "team" and "group" are used interchangeably in the literature (Guzzo & Dickson, 1996). It is not always beneficial to form groups or teams, under some circumstances one has no alternative (Wagner & Hollenbeck, 2014). In this study, the literature review was carried out on the background theories and recent studies of both "team" and "group", and the term "team" was used for all of the concepts related to "team" or "group".

2.2. *Virtual-team*

Now, due to communication technology improvements and continued globalization, virtual-teams have increased rapidly worldwide (Kirkman *et al.*, 2002). Although virtual-teamwork is a current topic in the literature on global organizations, it has been problematic to define what "virtual" means across multiple institutional contexts (Chudoba *et al.*, 2005). Virtual-teams work across boundaries of time and space by utilizing modern computer driven technologies. The term "virtual-team" is used to cover a wide range of activities and forms of technology-supported working (Anderson *et al.*, 2007). Virtual-teams are comprised of members who are located in more than one physical location. This team trait has fostered extensive use of a variety of forms of computer-mediated communication that enable geographically dispersed members to coordinate their individual efforts and inputs (Peters & Manz, 2007).

Generally, we can differentiate various forms of "virtual" work depending on the number of persons involved, the degree of interaction between them or number of managers, etc. Cascio & Shurygailo (2003) have clarified the difference form of virtual-teams by classifying it with respect to two primary variables namely, the number of location and the number of managers illustrates this graphically. Therefore there are four categories of virtual-teams: *(1)* Teleworkers: A single manager of a team at one location; *(2)* Remote team: A single manager of a team distributed across multiple location; *(3)* Matrixed teleworkers: Multiple manager of a team at one location; *(4)* Matrixed remote teams: Multiple managers across multiple locations.

2.3. *Team effectiveness frameworks*

The success of organizations and the overall production of knowledge depend to a large extent on the effectiveness of teams (Wuchty *et al.*, 2007). Teams are often conceptualized as complex performance systems (Forsyth, 2006). Assuming that variables in the system are linked to one another in simple, one-to-one relationships, systems theory recognizes factors that set the stage for teamwork (*inputs*), that facilitate or inhibit the nature of the teamwork (*processes*), and a variety of consequences that result from the team's activities (*outcomes*). This assumption is the basis of the well-known Input-Process-Output framework of team effectiveness.

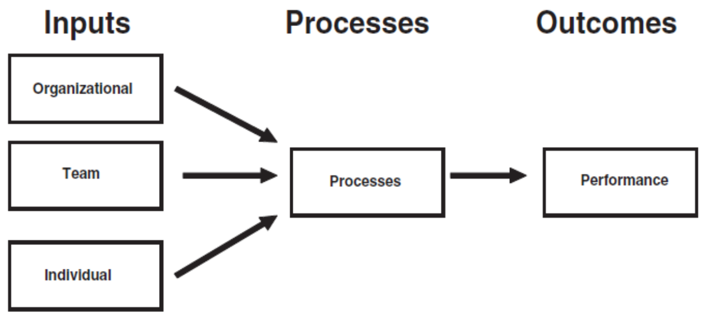
More than 50 years ago, McGrath (1964) developed the first Inputs-Processes-Outcomes (IPO) framework for studying team effectiveness. Since then, the IPO team effectiveness framework has served as a valuable guide for researchers over the years, but it has also been modified and extended in several ways (Cohen & Bailey, 1997; Hackman, 1983; Ilgen *et al.*, 2005; McGrath *et al.*, 2000; Salas *et al.*, 1992). According to Mathieu *et al.* (2008), there are two usual team effectiveness frameworks: *(1)* IPO team effectiveness framework; *(2)* IMO team effectiveness framework.

2.3.1. *IPO team effectiveness framework*

Blendell *et al.* (2001), Driskell *et al.* (1987), Klimoski & Jones (1995), McGrath (1964), Tannenbaum *et al.* (1992), etc., used IPO team effectiveness framework to describe team effectiveness as a system of three stages: Inputs -> Processes -> Outcomes. *(1)* Inputs describe antecedent factors that enable and constrain members' interactions. These include individual team member characteristics (e.g., competencies, personalities), team-level factors (e.g., task structure, external leader influences), organizational and contextual factors (e.g., organizational design features, environmental complexity). *(2)* These various antecedents combine to drive team processes, which describe members' interactions directed toward task accomplishment. Processes are important because they describe how team inputs are transformed into outcomes. *(3)* Outcomes are results and by-products of team activity that are valued by one or more constituencies (Mathieu *et al.*, 2000). Broadly speaking, these may include performance (e.g., quality and quantity) and members' affective reactions (e.g., satisfaction, commitment, viability).

Being considered popular in study, but the IPO team effectiveness framework has been often criticized and modified. Most of the adaptations to the IPO team effectiveness framework have either placed it in a larger context, emphasized a temporal element, or rediscovered more subtle aspects of the model that have gone overlooked. Ilgen *et al.* (2005) noted that many of the meditational factors that intervene and transmit the influence of team inputs to outcomes are not processes. Several other studies showed that during the processes, many mediating factors were formed, such as cognition, motivation, emotion, power, psychological safety, crowd effects, etc. (Cohen & Bailey, 1997; Marks *et al.*, 2001).

Figure 1. Inputs-Processes-Outcomes (IPO) Team Effectiveness Framework



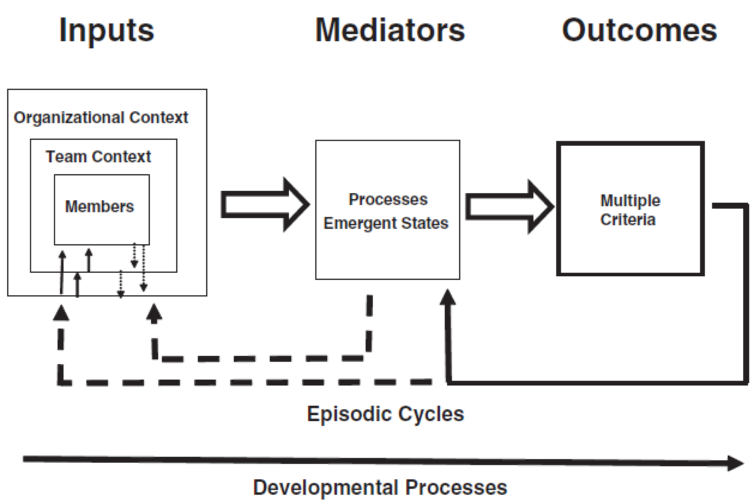
2.3.2. *IMO team effectiveness framework*

In recent years, IMO (inputs-mediators-outcomes) was another outstanding framework of team effectiveness, typically Rasker & Essens (2001), Salas *et al.* (1992), Shanahan (2001), Urban *et al.* (1995), etc. The differences between IMO and IPO team effectiveness frameworks are: *(1)* Inputs are classified into layers, outer layers (higher level factors) and inside layers (lower level factors) influence mutually; *(2)* In teamwork, there appear meaningful mediators that team managers should pay attention to in order to increase the chances of improving team effectiveness. Identifying these mediators also help researchers partly explain the reason why the same inputs make different outcomes; *(3)* Developmental processes of teams unfold over time as teams mature with cyclic loops; *(4)* In a cycle, mediators and outcomes can influence on inputs; *(5)* Feedback loops are episodic processes, while the results of previous cycle affect the inputs of following cycle. Therefore, IMO team effectiveness framework can be displayed as IMOI (Inputs-Mediators-Outcomes-Inputs).

2.4. *Relevant elements in team effectiveness framework*

Not many IMO models were published because of the complexity of relationships between

Figure 2. Inputs-Mediators-Outcomes (IMO) Team Effectiveness Framework



elements in this kind of framework. Hence, by reviewing outstanding studies of teamwork published since the beginning of 20th century, the authors identify relevant elements which probably exist in an IPO framework (not an IMO framework) of team effectiveness.

2.4.1. *Input factors*

Inputs describe antecedent factors that enable and constrain members' interactions. These usually include three main components: individual team member characteristics (e.g., competencies, personalities), team-level factors (e.g., task structure, external leader influences), and organizational and contextual factors (e.g., organizational design features, environmental complexity). According to McGrath (1964), inputs include: *(1)* individual-level factors, *(2)* group-level factors, *(3)* environment-level factors. Gladstein (1984) classified two kinds of inputs: *(1)* group level, *(2)* organizational level. Cohen & Bailey (1997) pointed out four types: *(1)* organization, *(2)* team, *(3)* task, *(4)* individual. According to Rasker & Essens (2001) inputs include: *(1)* environment factors, *(2)* situation factors, *(3)* team factors, *(4)* individual factors, *(5)* task factors.

Analyzing recent studies of teamwork, the authors identify 26 input factors. Cohen & Bailey's review of the work teams literature (1997) has proven to be one of the most influential Journal of Management articles, with more than 545 citations as of 2007 (Harzing, 2007). Referring to Cohen & Bailey (1997), the authors classify these inputs into four kinds (see Appendix 1):

(a) Organization level, including: *(a.1)* Purposes or Goals, *(a.2)* Reward structure, *(a.3)* Resources, *(a.4)* Organizational culture), *(a.5)* Availability of environment, *(a.6)* Work stress, *(a.7)* Climate, *(a.8)* Mutual trust and shared value.

(b) Team level, including: *(b.1)* Leadership, *(b.2)* Norm and procedure*, (b.3)* Team structure or Team design, *(b.4)* Team building, *(b.5)* Relevant members, *(b.6)* Roles and responsibility, *(b.7)* Team size, *(b.8)* Information system, *(b.9)* Relationship.

(c) Task level, including: *(c.1)* Task design or Task structure , *(c.2)* Task strategy, *(c.3)* Task complexity or Work load, *(c.4)* Task characteristic

(d) Individual level, including: *(d.1)* Knowledge, *(d.2)* Attitude, *(d.3)* Skill, *(d.4)* Personality, *(d.5)* Training or Educating

2.4.2. *Process factors*

Team processes have played a central role in most team effectiveness models (Gist *et al.*, 1987; Guzzo & Shea, 1992; Hackman, 1983). Historically, team processes were categorized as either "taskwork" or "teamwork" (McIntyre & Salas, 1995; Oser *et al.*, 1989; Stout *et al.*, 1999). At its essence, taskwork describes functions that individuals must perform to accomplish the team's task, whereas teamwork describes the interaction between team members (McIntyre & Salas, 1995). Marks *et al.* (2001) developed a taxonomy of processes that included three categories: transition, action, and interpersonal.

Analyzing previous studies of teamwork, the authors identify 13 factors that exist or emerge in team processes, notably coordination and communication (see Appendix 2): *(e.1)* Connection, *(e.2)* Flexibility, *(e.3)* Motivation, *(e.4)* Effort, *(e.5)* Synergy, *(e.6)*

Compatibility, *(e.7)* Interdependence, *(e.8)* Commitment, *(e.9)* Coordination, *(e.10)* Assessment – feedback – audit – monitoring, *(e.11)* Decision making, *(e.12)* Communication, *(e.13)* Conflict solving or Problem managing.

2.4.3. *Outcome factors*

Most studies of teamwork concentrate on "who" are team members, "how" they work together, "what" they do to complete tasks. This lead to the obvious bias: many models help clarify the inputs and processes of teamwork, but too few models mentioned outcomes (Beal *et al.*, 2003; Ilgen, 1999). Besides, team effectiveness is often confused with team performance. Although team performance is the most widely criterion in the field of organizational behavior (Bommer *et al.*, 1995), studies of teamwork mostly focuse on human behaviors. Therefore, team performance can not be fully alternative to team effectiveness.

Team effectiveness can be measured in two ways: *(1)* Team effectiveness is an *one-dimensional construct* directly measured by a single variable, usually the team performance (Kolodny & Kiggundu, 1980; Shea & Guzzo, 1987) or the real productivity of team (Steiner, 1972); *(2)* More popularly, team effectiveness is a *multidimensional construct* measured by various criteria (Hackman, 1983; Hackman *et al.*, 1986; Hackman, 2002). For example, according to McGrath (1984) and Sundstrom *et al.* (1990), team effectiveness includes *(i)* team performance and *(ii)* team viability; according to Tannenbaum *et al.* (1992), team effectiveness is viewed as a combination of performance in terms of outcomes and the team's ability to grow and regenerate itself; according to Mohrman *et al.* (1995), team effectiveness is based on three aspects *(i)* team performance, *(ii)* interdependent functioning, *(iii)* team satisfaction; according to Cohen *et al.* (1996), team effectiveness is *(i)* high performance and *(ii)* employee quality of work life; according to Newstrom (2007), team effectiveness includes *(i)* performance or productivity improvements, *(ii)* member behaviors, *(iii)* member attitudes.

Analyzing previous studies of teamwork, the authors identify 17 outcome factors or 17 criteria to measure team effectiveness. Referring to Newstrom (2007), the authors classify these criteria into three kinds (see Appendix 3):

(f) Performance, including: *(f.1)* Productivity, *(f.2)* Cost, *(f.3)* Production, *(f.4)* Quality, *(f.5)* Services , *(f.6)* Safe, *(f.7)* On-time, *(f.8)* Sales, *(f.9)* Plan.

(g) Attitude, including: *(g.1)* Satisfaction, *(g.2)* Satisfaction about job, *(g.3)* Commitment, *(g.4)* Change, *(g.5)* Trust

(h) Behavior, including: *(h.1)* Turnover, *(h.2)* Absence, *(h.3)* Viability

3. Qualitative research

Basing on theoretical basis, a qualitative research is carried on virtual-team managers to indicate which elements are suitable to virtual-team. In order to increase the representation of sample, the authors use *types of virtual-team* as a criterion to choose interviewees: *(i)* teleworkers, *(ii)* remote team, *(iii)* matrixed teleworkers, *(iv)* matrixed remote teams. Sample size is 9 determined by saturation (See Table 1).

Table 1. Information of interviewees

Position – Company	Type of virtual-team
1. Assistant to Project Manager – The Siam Cement Group (SCG)	Teleworkers
2. Operation Specialist – Royal HaskoningDHV	Remote team
3. Exporting Manager – Duytan Plastics Manufacturing Corporation	Matrixed teleworkers
4. Vice Manager of Engineering Department – Southern Vietnam Power Project Management Board	Matrixed remote teams
5. Planning Specialist – Management Board of HCMC Urban Railway	Teleworkers
6. Chief Executive Officer – NMKH Co., Ltd.	Remote team
7. Head of Transaction Banking – Saigon Thuong Tin Commercial Joint Stock Bank (Sacombank)	Matrixed teleworkers
8. Director of Training Center – Viet Capital Bank	Matrixed remote teams
9. Former Associate Creative Director – Chuo Senko Vietnam	Teleworkers

In-depth interview technique (face to face or via telephone) is used. The average time per interview is 60 minutes. Interview protocol is composed of two parts: *(1)* Introduction part: presents the research purposes and questions which help select correct interviewees; *(2)* Discussion part: presents questions which help collect data. Results:

- Not all elements are believed suitable to virtual-team. Because of particular characteristics of virtual-team, especially different working locations, six elements are suggested to be removed: *(a.7*) Climate, *(b.4)* Team building, *(e.6)* Compatibility, *(f.6)* Safe, *(g.3)* Commitment, *(g.5)* Trust.
- One element is suggested to be classified into other level: *(a.1)* Purposes or goals is moved from *(a)* Organization level to *(c)* Task level.
- Two elements are divided into specific elements: *(a.2)* Reward structure = *(OL2)* Reward structure of company & (*TeL8)* Reward structure of team, *(b.1)* Leadership = (*OL7)* Leadership of company & *(TeL7)* Team leadership.
- New elements are composed of available elements: *(OL3)* Resources = *(a.3)* Resources & *(a.5)* Availability of environment, *(TeL2)* Team structure = *(b.3)* Team structure or Team design & *(b.5)* Relevant members, *(PF1)* Connection = *(e.1)* Connection & *(e.7)* Interdependence, *(PF6)* Coordination = *(e.6)* Compatibility & *(e.9)* Coordination, *(Pe4)* Quality = *(f.4)* Quality & *(f.5)* Services, *(Pe5)* On-time = *(f.7)* On-time & *(f.9)* Plan, *(A1)* Satisfaction = *(g.1)* Satisfaction & *(g.2)* Satisfaction about job.
- One brand-new element is added: *(OL1)* Vision and mission.

Besides, in the context of virtual-team, the descriptions of each element are also recorded (see Table 2).

Table 2. Some results of qualitative research

Kinds of factors	Factors	Origin	Descriptions
Input factors			
Organization level	(OL1) Vision and mission	Brand-new factor	Company has clear vision and mission, which are concurred and advocated by virtual-team members.
	(OL2) Reward structure of company	(a.2)	Company applies clear and fair reward structure on virtual-team members.
	(OL3) Resources	(a.3) & (a.5)	Company supplies virtual-team members with sufficient and stable resources, which include anything necessary for virtual-teamwork, such as office equipment, computers, internet, telephone, software, human resources, finance resources, etc.
	(OL4) Organizational culture	(a.4)	Company has strong culture which is suitable to virtual-teamwork.
	(OL5) Work stress	(a.6)	Company puts reasonable work stress to virtual-team members.
	(OL6) Mutual trust	(a.8)	Company successfully builds mutual trust between to virtual-team members and company.
	(OL7) Leadership of company	(b.1)	Leaders of company care about and support virtual-teamwork.
Team level	(TeL1) Norm and procedure	(b.2)	Virtual-team successfully builds internal common rules, norms and procedures.
	(TeL2) Team structure	(b.3) & (b.5)	Virtual-team has relevant members who can minimize weaknesses and maximize strengths of each other.
	(TeL3) Roles and responsibility	(b.6)	In virtual-team, each member is assigned specific and rational roles and responsibilities. All virtual-team members understand, agree and perform their roles and responsibilities.
	(TeL4) Team size	(b.7)	Virtual-team has stable number of members which is suitable to task.
	(TeL5) Information system	(b.8)	Virtual-team has good information system which help team members more efficient in transferring information.
	(TeL6) Relationship	(b.9)	In virtual-team, members have positive relationships.
	(TeL7) Team leadership	(b.1)	Leaders of virtual-team accomplish their tasks in team.
	(TeL8) Reward structure of team	(a.2)	Virtual-team has an internal reward structure which is clear and fair.
Task level	(TaL1) Task goals	(a.1)	Virtual-team's goals are in proportion to tasks. They must be clear and consistent with company's vision and mission.
	(TaL2) Task design	(c.1)	Virtual-team's tasks are scientific.
	(TaL3) Task strategy	(c.2)	Virtual-team has logical strategy to solve particular tasks.
	(TaL4) Work load	(c.3)	Virtual-team is put under suitable and fair work load.
	(TaL5) Task characteristic	(c.4)	Virtual-team's tasks (e.g., types of tasks, requirement of time, skill, ability, etc.) are reasonable.
Individual level	(IL1) Knowledge	(d.1)	Virtual-team members have suitable knowledge (e.g., technical knowledge, specialized knowledge, etc.)
	(IL2) Attitude	(d.2)	Virtual-team members have positive attitudes (e.g., ready to work with distant partners, etc.)
	(IL3) Skill	(d.3)	Virtual-team members have requisite skills, especially teamwork skill (e.g., internet skill, intranet skill, computer skill, stenography skill, etc.)
	(IL4) Personality	(d.4)	Virtual-team members have suitable and reciprocal personalities (e.g., open-minded, flexible, self-aware, self-motivated, active, etc.)

	(IL5) Training	(d.5)	Virtual-team members train themselves to work together effectively (e.g., learning in classes, participating in seminars, etc.)
Process factors			
	(PF1) Connection	(e.1) & (e.7)	Virtual-team members have close connection and interdependence. Virtual-team is a solidary and durable unity.
	(PF2) Flexibility	(e.2)	Virtual-team members respond quickly and flexibly to change.
	(PF3) Motivation	(e.3)	Virtual-team members are motivated by team and company.
	(PF4) Effort	(e.4)	Virtual-team members spend their physical and spiritual efforts on common tasks.
	(PF5) Synergy	(e.5)	Resources in virtual-team are reasonable assigned to tasks.
	(PF6) Coordination	(e.6) & (e.9)	Virtual-team members coordinate closely in order to take full advantage of collective strength. They adjust themselves to become more suitable to each other and to common tasks.
	(PF7) Commitment	(e.8)	Virtual-team members agree and commit to common internal rules.
	(PF8) Assessment – feedback – audit – monitoring	(e.10)	Virtual-team members continuously do the jobs of assessment – feedback – audit – monitoring
	(PF9) Decision making	(e.11)	Virtual-team members join in common decision making processes.
	(PF10) Communication	(e.12)	Virtual-team members communicate effectively. Information is preserved while transferring.
	(PF11) Conflict managing	(e.13)	Virtual-team members proactively plan solutions to conflict.
Outcome factors			
Performance	(Pe1) Productivity	(f.1)	Virtual-team's outcomes are appropriate to inputs.
	(Pe2) Cost	(f.2)	Virtual-team's cost is reasonable and acceptable.
	(Pe3) Production	(f.3)	Virtual-team's production (e.g., products, contracts, projects, etc.) meets the target.
	(Pe4) Quality	(f.4) & (f.5)	Quality of virtual-team's outcomes is acceptable. Quality is increased by plus services (e.g., consulting, promotion, maintenance, warranty, etc.)
	(Pe5) On-time	(f.7) & (f.9)	Virtual-team's outcomes are on-time and conform to plan.
	(Pe6) Sales	(f.8)	Virtual-team's sales and profits meet requirements.
Attitude	(A1) Satisfaction	(g.1) & (g.2)	Virtual-team members have positive thought about each other. Internal conflict is controlled. Virtual-team members are satisfied with work load and results.
	(A2) Change	(g.4)	Virtual-team members positively change. They accept new things and pay attention to team improvement.
Behavior	(B1) Turnover	(h.1)	Virtual-team members don't leave team or stop working because of negative reasons. The number of turnover is within managers' control.
	(B2) Absence	(h.2)	Virtual-team members take part in common working time. They also participate in team-building activities outside working hours. The number of unpermitted absence is decreased.
	(B3) Viability	(h. 3)	Virtual-team is maintained.

4. Quantitative survey

Basing on the results of qualitative research, 47 relevant elements are identified. In order to propose a conceptual framework of virtual-team effectiveness that is particularly suitable to Vietnamese enterprise environment, a quantitative survey using convenient sampling is carried out. The respondents are working in companies in the territory of Vietnam and have participated in virtual-teams with different positions and working locations. Data is collected by questionnaires delivered via email, Google Docs and hard copies. In the first part of questionnaire, some demographic information is collected. In the second part, all scales are scored on a 5-point Likert-scale anchored with strongly disagree = 1 to strongly agree = 5, with 47 indicators. The questionnaire is piloted with a group of virtual-team members before the actual survey. The audit tool is later conducted with a total of 281 respondents, 259 was finally usable (22 invalid respondents). The data is then analyzed by SPSS.

4.1. *Demographic information:*

Gender: 52.9% respondents are woman, 47.1% respondents are man.

Current working location: 68% respondents are in Hochiminh City, 20% respondents are in Hanoi City, 12% are in other places.

The number of virtual-team: 55.1% respondents are participating in 1 virtual-team, 21.5% respondents are participating in 2 virtual-teams, 12% respondents are participating in 3 virtual-teams, 5.8% respondents are participating more than 3 virtual-teams.

Types of virtual-team: 37% respondents have participated in teleworkers, 67.6% respondents have participated in remote team, 36.7% respondents have participated in matrixed teleworkers, 25.9% respondents have participated in matrixed remote teams.

Tools for virtual-teams: 98.8% virtual-teams have used Email, 91.9% virtual-teams have used Telephone, 78.8% virtual-teams have used Instant Messaging and Chat, 59.5% virtual-teams have used Web Conferencing, 50.2% virtual-teams have used File Transfer, 47.5% virtual-teams have used Remote Access and Control, 38.2% virtual-teams have used Groupware.

Positions in current virtual-teams: 24.3% respondents are managers of at least one virtual-team.

The average size of virtual-teams: 17.8% virtual-teams have 2 members, 57.5% virtual-teams have from 3 to 7 members, 24.7% virtual-teams have more than 7 members.

4.2. *Virtual-team effectiveness framework:*

Exploratory Factor Analysis (EFA) using *principal component factor analysis* with *varimax rotation* and *Kaiser normalization* is conducted on observed variables. Firstly, when EFA is conducted on 25 observed variables encoded from 25 input factors, KMO = 0.785 (p = 0.000) and the variable *(TaL3) Task strategy* is removed. Then, EFA is conducted on 24 remaining observed variables, KMO = 0.847 (p = 0.000), two variables *(IL5) Training* and *(TaL5) Task characteristic* are removed. There are four dimensions formed (see Table 3).

Table 3. Results of EFA on input factors

Dimensions	Factors	Factor loadings			
		(1)	(2)	(3)	(4)
Team characteristics	(TeL2) Team structure	0.822			
	(TeL4) Team size	0.804			
	(TeL1) Norm and procedure	0.774			
	(OL6) Mutual trust	0.731			
	(TeL7) Team leadership	0.725			
	(TeL5) Information system	0.674			
	(TeL6) Relationship	0.662			
	(TeL8) Reward structure of team	0.514			
	(PF11) Conflict managing	0.505			
Individual characteristics	(IL2) Attitude		0.804		
	(IL3) Skill		0.703		
	(IL1) Knowledge		0.632		
	(IL4) Personality		0.620		
	(TeL3) Roles and responsibility		0.597		
Organization characteristics	(OL3) Resources			0.787	
	(OL2) Reward structure of company			0.743	
	(OL7) Leadership of company			0.651	
	(OL4) Organizational culture			0.612	
	(OL1) Vision and mission			0.505	
Task characteristics	(TaL2) Task design				0.785
	(TaL4) Work load				0.707
	(OL5) Work stress				0.692
	(TaL1) Task goals				0.650
	Eigenvalue	6.771	2.345	1.692	1.602
	% of Total Variance	29.284	17.552	6.264	5.933
	Cronbach Alpha	0.863	0.754	0.777	0.654

All new constructs are tested by Cronbach's α coefficient (Cronbach's α range is between 0.654 to 0.863). Another EFA is conducted on 11 observed variables which are encoded from 11 process factors, KMO = 0.680 (p = 0.000), 4 variables *(PF3) Motivation*, (*PF4) Effort, (PF8) Assessment – feedback – audit – monitoring , (PF9) Decision making* are removed, and only one dimension is formed (see Table 4).

Table 4. Results of EFA on process factors

Dimensions	Factors	Factor loadings
		(1)
Processes	(PF6) Coordination	0.717
	(PF1) Connection	0.699
	(PF10) Communication	0.689
	(PF7) Commitment	0.621
	(PF2) Flexibility	0.607
	(PF5) Synergy	0.599
	(PF11) Conflict managing	0.555
Eigenvalue		5.332
% of Total Variance		23.764
Cronbach Alpha		0.609

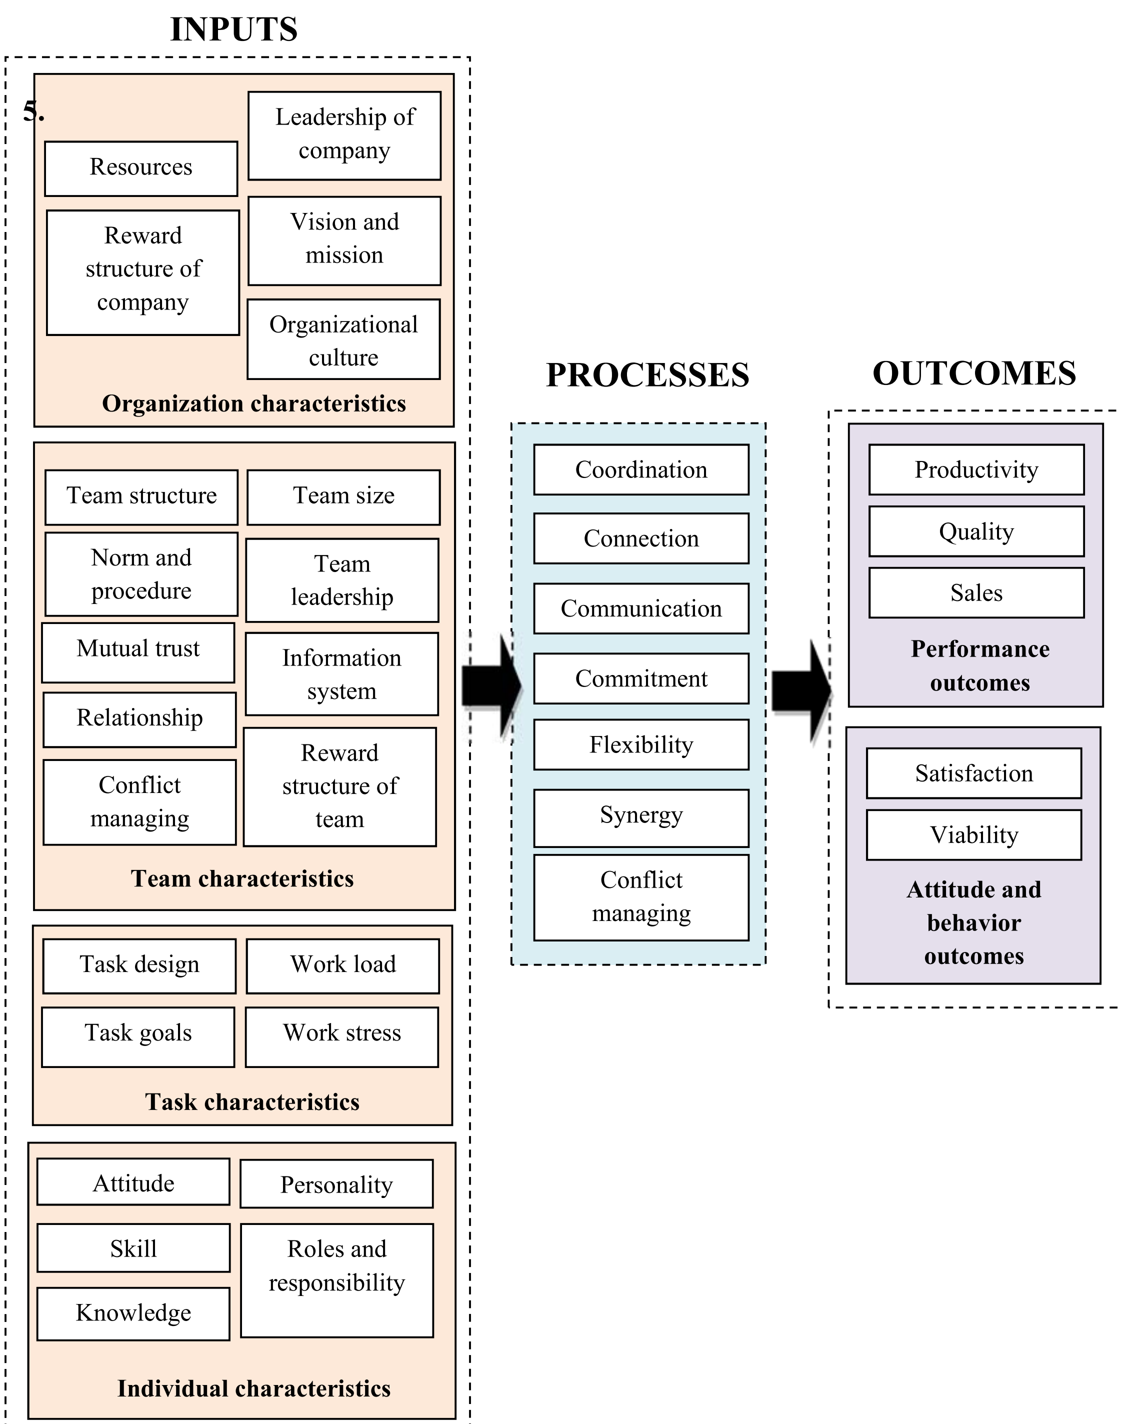
EFA is then conducted on 11 observed variables which are encoded from 11 outcome factors, KMO = 0.740 (p = 0.000), 6 variables (*Pe2) Cost, (Pe3) Production, (Pe5) On-time, (A2) Change, (B1) Turnover, (B2) Absence* are removed, and two dimensions are formed (see Table 5). All new constructs are tested by Cronbach's α coefficient.

Table 5. Results of EFA on outcome factors

Dimensions	Factors	Factor loadings	
		(1)	(2)
Performance outcomes	(Pe1) Productivity	0.767	
	(Pe4) Quality	0.721	
	(Pe6) Sales	0.620	
Attitude and behavior outcomes	(A1) Satisfaction		0.586
	(B3) Viability		0.554
Eigenvalue		2.657	1.369
% of Total Variance		44.281	22.811
Cronbach Alpha		0.623	0.611

The research findings help propose a conceptual framework of virtual-team effectiveness that is particularly suitable to Vietnamese enterprise environment (see Figure 3).

Figure 3. Conceptual framework of virtual-team effectiveness in Vietnam



6. Conclusion

This study is conducted to answer three questions: (1) What are the inputs that influence virtual-team effectiveness? (2) What are the process factors that occur during virtual-teamwork? (3) How can virtual-team effectiveness be measured? To answer these questions, firstly, a review of literature is conducted on background theories and recent studies of teamwork to identify relevant elements in a team effectiveness framework. Once the elements are identified, a qualitative research is carried out on 9 virtual-team managers to indicate which elements are suitable to virtual-team. The number of elements is reduced from 56 to 47. Some elements are removed or classified into other level or divided into specific elements. Some new elements are composed of available elements or brand-new added. After that, a quantitative survey is conducted by using questionnaires via email, Google Docs and hard copies to 259 virtual-team members whose working locations are in the territory of Vietnam.

The research findings help propose a conceptual framework that is particularly suitable to virtual-team effectiveness in Vietnamese enterprise environment. In this framework, (1) **Inputs** include four dimensions: *(i) Team characteristics* (9 factors), *(ii) Individual characteristics* (5 factors), *(iii) Organization characteristics* (5 factors), *(iv) Task characteristics* (4 factors); (2) **Processes** include seven factors: *(i) Coordination, (ii) Connection, (iii) Communication, (iv) Commitment, (v) Flexibility, (vi) Synergy, (vii) Conflict managing*; (3) **Outcomes** include two dimensions: *(i) Performance outcomes* (3 factors), *(ii) Attitude and behavior outcomes* (2 factors) (see Figure 3).

This study contributes to the body of knowledge on virtual-teams, as well as teams, in general. The survey development process used in this study can be utilized by researchers interested in other constructs related to different aspects of team within organization. However, because of convenience sampling method, most respondents are in Hochiminh City, so the results may not highly generalize virtual-team in Vietnam. This study can be pursued by systematizing more theories and studies, extending the scales, carrying out quantitative survey on bigger sample, analyzing data by other techniques.

	a.6 Work stress	(Driskel *et al.*, 1987; Hackman, 1983; Rasker & Essens, 2001; Shanahan, 2001; Tannenbaum *et al.*, 1992)
	a.7 Climate	(Adam *et al.*, 2002; Biech, 2007; Blendell *et al.*, 2001; Hackman, 1983; Klimoski & Jones, 1995; LaFasto & Larson, 2001; Lombardo & Eichiger, 1995; Parker, 2011; Rasker & Essens, 2001; Shanahan, 2001; Tannenbaum *et al.*, 1992)
	a.8 Mutual trust and shared value	(Adam *et al.*, 2002; Blendell *et al.*, 2001; Hackman, 2002; LaFasto & Larson, 2001; Lencioni, 2002; Lombardo & Eichiger, 1995; Mickan & Rodger, 2005; Parker, 2011; Shanahan, 2001; Sharif & Nahas, 2013; Spatz, 2000; West, 2004)
b. Team level	b.1 Leadership	(Rubin *et al.*, 1978; Klimoski & Jones, 1995; Lombardo & Eichiger, 1995; Spatz, 2000; Shanahan, 2001; Rasker & Essens, 2001; Blendell *et al.*, 2001; LaFasto & Larson, 2001; Biech, 2007; Hackman, 2002; West, 2004; Mickan & Rodger, 2005; Mealiea & Baltazar, 2005; Parker, 2011; Van Roosmalen, 2012; Sharif & Nahas, 2013)
	b.2 Norm and procedure	(Blendell *et al.*, 2001; Driskel *et al.*, 1987; Hackman, 1983; Klimoski & Jones, 1995; LaFasto & Larson, 2001; Rubin *et al.*, 1978; Salas *et al.*, 1992; Shanahan, 2001; Sundstrom *et al.*, 1990; Tannenbaum *et al.*, 1992; Urban *et al.*, 1995)
	b.3 Team structure or Team design	(Blendell *et al.*, 2001; Driskel *et al.*, 1987; Hackman, 1983; Klimoski & Jones, 1995; Parker, 2011; Rasker & Essens, 2001; Salas *et al.*, 1992; Shanahan, 2001; Tannenbaum *et al.*, 1992; Urban *et al.*, 1995)
	b.4 Team building	(Hackman, 2002; Mealiea & Baltazar, 2005; Salas *et al.*, 1992; Shanahan, 2001; Sharif & Nahas, 2013; Sundstrom *et al.*, 1990; Tannenbaum *et al.*, 1992; West, 2004)
	b.5 Relevant members	(Hackman, 2002; LaFasto & Larson, 2001; Lencioni, 2002; Mickan & Rodger, 2005; West, 2004)
	b.6 Roles and responsibility	(Adam *et al.*, 2002; Biech, 2007; Blendell *et al.*, 2001; Hackman, 2002; Katzenbach & Smith, 1993; Klimoski & Jones, 1995; LaFasto & Larson, 2001; Lencioni, 2002; Mealiea & Baltazar, 2005; Mickan & Rodger, 2005; Parker, 2011; Rubin *et al.*, 1978; Shanahan, 2001; Sharif & Nahas, 2013; Spatz, 2000; Sundstrom *et al.*, 1990; Tannenbaum *et al.*, 1992; West, 2004)
	b.7 Team size	(Driskel *et al.*, 1987; Katzenbach & Smith, 1993; Klimoski & Jones, 1995; LaFasto & Larson, 2001; Rasker & Essens, 2001; West, 2004)
	b.8 Information system	(Hackman, 1983; LaFasto & Larson, 2001; Salas *et al.*, 1992; Spatz, 2000)
	b.9 Relationship	(Biech, 2007; Hackman, 1983; Hackman, 2002; LaFasto & Larson, 2001; Lencioni, 2002; Mealiea & Baltazar, 2005; Mickan & Rodger, 2005; Parker, 2011; Rubin *et al.*, 1978; Sharif & Nahas, 2013; West, 2004)

c. Task level	c.1 Task design or Task structure	(Hackman, 1983; Hackman, 2002; Parker, 2011; Rasker & Essens, 2001; Salas *et al.*, 1992; Sundstrom *et al.*, 1990; Tannenbaum *et al.*, 1992; Urban *et al.*, 1995)
	c.2 Task strategy	(Hackman, 1983; Katzenbach & Smith, 1993; Klimoski & Jones, 1995; Lencioni, 2002; Salas *et al.*, 1992; Spatz, 2000; Van Roosmalen, 2012)
	c.3 Task complexity or Work load	(Rasker & Essens, 2001; Shanahan, 2001; Tannenbaum *et al.*, 1992; Urban *et al.*, 1995)
	c.4 Task characteristic	(Driskel *et al.*, 1987; Rubin *et al.*, 1978; Tannenbaum *et al.*, 1992; Urban *et al.*, 1995)
d. Individual level	d.1 Knowledge	(Blendell *et al.*, 2001; Hackman, 1983; Klimoski & Jones, 1995; Lombardo & Eichiger, 1995; Mickan & Rodger, 2005; Rasker & Essens, 2001; Salas *et al.*, 1992; Shanahan, 2001; Tannenbaum *et al.*, 1992; Urban *et al.*, 1995)
	d.2 Attitude	(Klimoski & Jones, 1995; LaFasto & Larson, 2001; Parker, 2011; Rasker & Essens, 2001; Shanahan, 2001; Tannenbaum *et al.*, 1992; Urban *et al.*, 1995)
	d.3 Skill	(Driskel *et al.*, 1987; Hackman, 1983; Katzenbach & Smith, 1993; Klimoski & Jones, 1995; LaFasto & Larson, 2001; Lombardo & Eichiger, 1995; Mealiea & Baltazar, 2005; Rasker & Essens, 2001; Salas *et al.*, 1992; Shanahan, 2001; Tannenbaum *et al.*, 1992; Urban *et al.*, 1995; West, 2004)
	d.4 Personality	(Blendell *et al.*, 2001; Driskel *et al.*, 1987; LaFasto & Larson, 2001; Tannenbaum *et al.*, 1992)
	d.5 Training or Educating	(Shanahan, 2001; Tannenbaum *et al.*, 1992)

Appendix 2. Process factors

Factors	**References**
e.1 Connection	(Hackman, 2002; LaFasto & Larson, 2001; Lencioni, 2002; Mickan & Rodger, 2005; Rasker & Essens, 2001; Spatz, 2000; Sundstrom *et al.*, 1990; Tannenbaum *et al.*, 1992; West, 2004)
e.2 Flexibility	(Lombardo & Eichiger, 1995; Mickan & Rodger, 2005; Rubin *et al.*, 1978; Sharif & Nahas, 2013; West, 2004)
e.3 Motivation	(Blendell *et al.*, 2001; Hackman, 1983; Rasker & Essens, 2001; Tannenbaum *et al.*, 1992; Urban *et al.*, 1995)
e.4 Effort	(Hackman, 1983; Klimoski & Jones, 1995; Salas *et al.*, 1992)
e.5 Synergy	(Biech, 2007; Salas *et al.*, 1992; Shanahan, 2001)
e.6 Compatibility	(Klimoski & Jones, 1995; Shanahan, 2001; Spatz, 2000)
e.7 Interdependence	(Adam *et al.*, 2002; Rasker & Essens, 2001)
e.8 Commitment	(Adam *et al.*, 2002; Katzenbach & Smith, 1993; LaFasto & Larson, 2001; Lencioni, 2002; Mickan & Rodger, 2005; Sharif & Nahas, 2013; Spatz, 2000; West, 2004)
e.9 Coordination	(Adam *et al.*, 2002; Biech, 2007; Hackman, 1983; Hackman, 2002; Klimoski & Jones, 1995; LaFasto & Larson, 2001; Lencioni, 2002; Mickan & Rodger, 2005; Rasker & Essens, 2001; Rubin *et al.*, 1978; Shanahan, 2001; Sharif & Nahas, 2013; Spatz, 2000; Tannenbaum *et al.*, 1992; Urban *et al.*, 1995; West, 2004)
e.10 Assessment – feedback – audit – monitoring	(Adam *et al.*, 2002; Blendell *et al.*, 2001; Hackman, 1983; Mealiea & Baltazar, 2005; Mickan & Rodger, 2005; Parker, 2011; Rasker & Essens, 2001; Sharif & Nahas, 2013; Spatz, 2000; Sundstrom *et al.*, 1990; Tannenbaum *et al.*, 1992; Van Roosmalen, 2012; West, 2004)
e.11 Decision making	(Biech, 2007; Hackman, 2002; LaFasto & Larson, 2001; Lencioni, 2002; Lombardo & Eichiger, 1995; Mealiea & Baltazar, 2005; Mickan & Rodger, 2005; Parker, 2011; Rubin *et al.*, 1978; Sharif & Nahas, 2013; Tannenbaum *et al.*, 1992; West, 2004)
e.12 Communication	(Adam *et al.*, 2002; Biech, 2007; Blendell *et al.*, 2001; Hackman, 2002; Klimoski & Jones, 1995; LaFasto & Larson, 2001; Lencioni, 2002; Mealiea & Baltazar, 2005; Mickan & Rodger, 2005; Parker, 2011; Rubin *et al.*, 1978; Shanahan, 2001; Sharif & Nahas, 2013; Tannenbaum *et al.*, 1992; Urban *et al.*, 1995; West, 2004)
e.13 Conflict solving or Problem managing	(Adam *et al.*, 2002; Biech, 2007; Katzenbach & Smith, 1993; LaFasto & Larson, 2001; Lencioni, 2002; Lombardo & Eichiger, 1995; Mealiea & Baltazar, 2005; Mickan & Rodger, 2005; Parker, 2011; Rubin *et al.*, 1978; Sharif & Nahas, 2013; Tannenbaum *et al.*, 1992; West, 2004)

Appendix 3. Outcome factors

Kinds of factors	Factors	References
f. Performance	f.1 Productivity	(Campion *et al.*, 1993; Campion *et al.*, 1996; Cohen *et al.*, 1996; Cohen & Bailey, 1997; Gibson *et al.*, 2003)
	f.2 Cost	(Cohen *et al.*, 1996)
	f.3 Production	(Drach-Zahavy & Somech, 2002)
	f.4 Quality	(Campion *et al.*, 1993; Campion *et al.*, 1996; Cohen *et al.*, 1996; Cohen & Bailey, 1997; Doolen *et al.*, 2003; Gibson *et al.*, 2003)
	f.5 Services	(Gladstein, 1984; Shea & Guzzo, 1987; Campion *et al.*, 1993; Campion *et al.*, 1996; Hyatt & Ruddy, 1997; Gibson *et al.*, 2003)
	f.6 Safe	(Cohen & Ledford, 1994; 1996; Doolen *et al.*, 2003)
	f.7 On-time	(Gibson *et al.*, 2003)
	f.8 Sales	(Gladstein, 1984; Shea & Guzzo, 1987)
	f.9 Plan	(Doolen *et al.*, 2003)
g. Attitude	g.1 Satisfaction	(Gladstein, 1984; Hackman, 1987; Tannenbaum *et al.*, 1992; Campion *et al.*, 1993; Cohen & Ledford, 1994; Jehn, 1995; Klimoski & Jones, 1995; Campion *et al.*, 1996; Cohen *et al.*, 1996; Cohen & Bailey, 1997; Shanahan, 2001; Blendell *et al.*, 2001; Doolen *et al.*, 2003)
	g.2 Satisfaction about job	(Gladstein, 1984; Cohen & Ledford, 1994; Cohen *et al.*, 1996; Cohen & Bailey, 1997; Wageman, 1995)
	g.3 Commitment	(Fry & Slocum, 1984; Cohen & Ledford, 1994; Cohen *et al.*, 1996; Cohen & Bailey, 1997)
	g.4 Change	(Cohen & Ledford, 1994; Cohen *et al.*, 1996; Cohen & Bailey, 1997)
	g.5 Trust	(Cohen *et al.*, 1996; Cohen & Bailey, 1997)
h. Behavior	h.1 Turnover	(O'Reilly *et al.*, 1989)
	h.2 Absence	(Cohen & Ledford, 1994; Cohen *et al.*, 1996)
	h.3 Viability	(Hackman & Walton, 1986)

This paper is conducted to examine the effects of a currency's devaluation on trade balance for the case of Thailand. In this study, these effects are considered in different aspects such as the determinants of a trade balance of Thailand; and the long run relationship between bilateral exchange rate and Thailand's trade balance.

Empirical findings indicate that the exchange rate policy and relative growth rate of incomes play a central role in explaining Thailand's trade balance, and fiscal and monetary policies are beneficial in some cases. Moreover, the panel fully modified OLS (FMOLS) estimations illustrate that a devaluation of Thailand Baht could provide positive effects on its trade balance in the long run, especially for the groups of country with high income, upper middle income, and countries in the America, and Europe. The individual FMOLS regressions between Thailand and each of her 62 trading partners indicate that the devaluation of Thailand's currency would stimulate Thailand's trade performance with over 20 trading partners, but hurt its performance with the other 10 countries and inconclusive conclusion for the others.

Keywords: Exchange rate, trade balance, currency depreciation, instrumental variable (IV), fully modified ordinary least square (FMOLS)

1. Introduction

Exchange rate has always been one of the most attractive subjects among academics, exporters, importers, investors as well as policy-makers because its vitally important roles played in the international economics. While academics have concerned and developed theories of disequilibrium and equilibrium real exchange rate, the policy-makers concentrate more on exchange rate adjustment in order to examine its effects on the economy. Additionally, exchange rate risk is a key element related directly to the costs and profits for importers, exporters as well as foreign investors. Furthermore, it is argued that developing countries have tendency to devaluate their currency in order to gain the relative competition.

The paper aims to consider a link between Thailand Baht depreciation and Thailand's trade balance. According to Bahmani-Oskooee and Kantipong (2001), after Asian currency crisis, Thailand was one of the most suffered countries in comparison with other nations in the Asian region. Consequently, the country lost market shares of many export products and services to China and other ASEAN countries, and it suffered a severe deficit in its trade of balance. The strategy of devaluation would allow Thailand to increase her regional competitiveness, to recover her lost market shares, and to improve her trade balance. Therefore, Thailand is opted as a typical case to study such a link of effects of depreciation on trade balance.

This paper provides key advantages compared to previous studies. *First*, our analysis exploits panel data rather than individual data, which allows to obtain an individual country's behaviors by observing other countries' performance. *Second*, to control the fact that exchange rates are endogenous to trade balances mention in early research, the current study exploits the fully modified ordinary least squares (FMOLS) method and instrumental variable (IV) estimation to re-examine the link between currency devaluations and trade balances. *Third*, the disaggregated data of trade and exchange rate are utilized to cope with the aggregated bias problem (Rose & Yellen, 1989)

The paper is constructed as follow. The next part reviews theory and empirical evidence related to exchange rate and trade balance, whereas the following present research methodology in term of econometric technique and empirical model. Displayed in two last sections are research findings and conclusions.

2. Literature review

2.1. *Theoretical grounds*

The effect of a currency's devaluation bases on three approaches, including elasticity, income-absorption, and monetary. *Firstly*, the elasticity approach puts an emphasis on the elasticity of demand and supply both of domestic and of foreign country. The key issue of this method is Marshall-Lerner (ML) condition, providing that when the current account begins at an equilibrium position, the devaluation will increase trade flows in the case of the total of (i) price elasticity of domestic demands for imports and (ii) that of foreign demand for exports in absolute terms exceeds unity. After depreciation, it is observed that the balance of trade initially worsens before achieving an improvement. This is known as the so-called J-curve phenomenon. This phenomenon happens because of time lags in recognition, decision, delivery, replacement, and production (Junz & Rhomberg, 1973). The mathematical model showing effects of devaluation on the trade balance was be modelled byJohnson(1975) and Salvartore (2012 p.524). *Secondly*, the absorption approach is proposed by Alexander (1952) and further developed in Alexander (1959). This approach emphasizes how the devaluation affects expenditure behaviors of domestic nation, and thus affects trade balances. The trade balance is calculated by taking the difference between total aggregate demands and domestic absorption measured by consumption, investment, and government purchases. *Thirdly*, the monetary approach studies a broaden concept of balance of payment and considers it as an essentially monetary phenomenon on the view of international economics (Salvatore, 2012 p.509). It is supposed that devaluation may lead to a temporary increase in balance of payment rather than a permanent improvement, but in the long run, balance of payment returns to its initial level.

2.2. *Empirical Reviews*

2.2.1. *Determinants of a Trade Balance*

Furstenberg (1983) had an attempt to examine such domestic factors that significantly influenced the US current account and to suggest policies associated with the national saving and internal investment rates. Miles (1979) established direct relationship between exchange rate and trade balance, in addition to income, monetary supply, and the ratio of government consumption to output. The author investigated the experience of 14 nations using annual data over 1956-1972 periods and concluded that exchange rate devaluations did not improve trade balance of most cases but they increased balance of payments through the capital account. Although Himarios (1985) based on Miles' framework, the author provided critiques of Miles' findings, asserting that *(i)* the findings have problems of unit measurement, *(ii)* the effects of foreign variables and the real terms on trade balance may be differential from that of domestic and nominal ones, and *(iii)* the longer lagged structure of exchange rate plays a significant role. Himarios (1985, 1989) illustrated that devaluations had been a helpful tool for adjusting trade balance.

2.2.2. *Devaluation and Trade Balance*

The empirical studies of investigating the relationship between devaluation and the trade balance are mainly using aggregated and bilateral trade data. On account of aggregated trade data, Bahmani-Oskooee (1985), Himarior (1985, 1989) and Miles (1979) are representative authors using this type of data. However, Bahmani-Oskooee and Alse (1994) pointed out that the first differenced data in Miles (1979) research was stationary. Committedly, the data used in previous studies (Bahmani-Oskooee 1985; Himarios 1985, 1989) was not stationary. With the appliance of cointegration technique by Engle-Granger (1987) and developed by Johansen and Juselius (1990), Bahmani-Oskooee and Alse (1994) indicated that devaluation provided mixed results and found the J-curve phenomenon for some cases. Bahmani-Oskooee (1998) revealed that the devaluation could stimulate the trade balance of most surveyed nations, and found the evidence of the Marshall-Lerner (ML) condition for the case of Korea, South Africa, and Greece. Boyd et al (2001) and Lowinger (2002) provided a support for the J-curve phenomenon and the Marshall-Lerner (ML) condition. Singh (2002) concluded that real exchange rate was statistically related to the balance of trade in India.

According to Bahmani-Oskooee and Brooks (1999), using the effective exchange rate as an aggregate proxy for exchange rate is highly likely to face a serious problem that a nation's currency might appreciate with some currencies, but depreciate with other currencies. Additionally, taking weighted averaging estimate of the exchange rate would smooth out the fluctuation of real effective exchange rate, leading to an unsustainable connection between the effective exchange rate and total trade balance. In order to cope with the problem of effective exchange rate, a large body of studies have employed the disaggregate data or bilateral exchange rate. The list comprises Arora et al (2003), Bahmani-Oskooee & Brooks (1999), Bahmani-Oskooee & Harvery (2010), Bahmani-Oskooee et al (2006), Bahmani-Oskooee et al (2005), Bahmani-Oskooee & Wang (2007), Halicioglu (2008), Rose and Yellen (1989), Thorbecke (2006).

The results of earlier research may suffer the bias and ineffectiveness due to the problems of simultaneity and endogeneity among each variable. Rose and Yellen (1989) indicated that the trade balance model, containing output and exchange rate, may raise the problem of potential simultaneity bias and thus, instrumental variable (IV) method is more appropriate than ordinary least square (OLS). Yol and Baharumshah (2007) indicated that it is highly likely to be a direct and indirect causal relationship between trade balances and such macroeconomic as output, exchange rate, and money supply and some other indicators. To cope with the problem of endogenity, some studies use the IV method (Brissimis & Leventankis 1989; Rose and Yellen 1989, Rose 1990), whereas other utilize the fully modified ordinary least squares (FMOLS) approach (Yol and Baharumshah 2007, Chiu et al 2010). According to Gujarati & Porter (2009), panel data estimations allow taking such heterogeneity explicitly into account by controlling individual variances and provides more informative and less collinearity among the variables, more degree of freedom, and more efficiency.

As far as Thailand is concerned, the link between Thailand's trade balance and bilateral exchange rates has been investigated. For example, Bahmani-Oskooee and Kantipong (2001) revealed that there was at least existence of J-curve phenomenon for two cases of Japan and America out of five major trading partners. In contrast, Baharumshah (2001) indicated that there was no J-curve phenomenon in the short run and the real exchange rate devaluation would affect the trade balance after eight or nine quarters. Onafowara (2003) showed that while the J-curve exists for Thailand's bilateral trade balance with the US in the short run, Thailand's bilateral trade balance with Japan is more consistent with S-curve than J-curve. On one hand, Bahmani-Oskooee and Harvery (2010) pointed out that the real exchange rate changes have no effects on Malaysia's bilateral trade balance to Thailand. On the other hand, Chiu et al (2010) presented that the devaluation of the US dollar would improve her trade balance to Thailand.

3. Research methodology

3.1. *Econometric techniques*

3.1.1. *Panel Unit Root Test*

To avoid spurious regressions associated with time series data, the panel data is examined whether it is stationary or not with the use of Breitung's (2001) panel-based unit root test. It is argued that this test's performance is more powerful than unit root tests employed in individual time series data. Unlike panel-based unit root tests provided by Im et al (2003) and Maddala and Wu (1999), the approach of Breitung (2001) allows individual process to have a common unit root, which is similar to that of Levin et al. (2002). A common unit root assumes that the tests have a common autoregressive (AR) structure for all the series. The prime function form of Breitung (2001) test could be expressed in regressions:

$$\Delta y_{it} = \alpha_i + \beta y_{it-1} + \sum_{j=1}^{p_i} \theta_{ij}\, \Delta y_{i,t-j} + \varepsilon_{it}\ ; i = 1,2,\dots,n; t = 1,2,\dots,T \qquad (1)$$

where Δ represents the first difference variable, i=1,2,…, n individuals in the panel, and t=1,2,…,T time periods. The error term, ε_{it}, is independently distributed normal for all *i* and *t*, and have heterogeneous variances across individuals.

Under Breitung (2001) panel-based unit root test, the null hypothesis is that all panels contain a unit root, meaning that H_0: β=0. The alternative hypothesis is that not all of the individual series have a unit root; that is H_A: β < 0.

3.1.2. *Panel Cointegration Test*

3.1.2.1. Kao's Cointegration Test

Kao (1999) constructed the residual-based cointegration test on the basis of DF and ADF test. The estimation model is as follows:

$$y_{it} = \alpha_i + \beta_i y_{it} + e_{it};\ i = 1,\dots,N; t = 1,\dots,T \qquad \text{where error term } e_{it} \text{ is I(1).}$$

The DF test could be applied to the residuals with a function $\widehat{e_{it}} = p\,\widehat{e_{it-1}} + v_{it}$,
The ADF test uses an extension of above equation with an added lag changes in the regression to correct serial correlation. $\widehat{e_{it}} = p\,\widehat{e_{it-1}} + \sum_{j=1}^{k} \varphi_j\, \Delta\hat{e}_{it-j} + v_{itp}$

The null hypothesis of no co-integration is tested with p=1, and the alternative hypothesis is co-integrated with p<1. The function of the t-statistic calculation is presented in Kao (1999) (pp 8-9).

3.1.2.2. Pedroni Cointegration Test

The general estimation for Pedroni cointegration test is expressed as follow

$$y_{it} = \alpha_i + \sum_{m=1}^{M} \beta_{mi}\, x_{m\,i\,t} + \varepsilon_{it}\ ; i = 1,2,\dots,N; t = 1,2,\dots,T$$

where M, N, and T respectively represent the number of independent variables, the number of individuals, and the time periods. The parameter α_i denotes the unit-specific fixed effects. Pedroni (1999, 2001, 2004) proposed seven test statistics[1] for cointegration, which could be classified into two categories. These test statistics are calculated as follows.

Panel □-statistic:

$$\left(\sum_{i=1}^{N}\sum_{t=1}^{T}\hat{L}_{11i}^{-2}\ \hat{\varepsilon}_{i,t-1}^{2}\right)^{-1}$$

Panel rho statistic:

$$\left(\sum_{i=1}^{N}\sum_{t=1}^{T}\hat{L}_{11i}^{-2}\ \hat{\varepsilon}_{i,t-1}^{2}\right)^{-1}\sum_{i=1}^{N}\sum_{t=1}^{T}\hat{L}_{11i}^{-2}\ (\hat{\varepsilon}_{i,t-1}^{2}\ \Delta\hat{\varepsilon}_{it}-\hat{\lambda}_{i})$$

Panel PP statistic:

$$\left(\tilde{\sigma}_{NT}^{2}\ \sum_{i=1}^{N}\sum_{t=1}^{T}\hat{L}_{11i}^{-2}\ \hat{\varepsilon}_{i,t-1}^{2}\right)^{\frac{-1}{2}}\sum_{i=1}^{N}\sum_{t=1}^{T}\hat{L}_{11i}^{-2}\ (\hat{\varepsilon}_{i,t-1}^{2}\ \Delta\hat{\varepsilon}_{it}-\hat{\lambda}_{i})$$

Panel ADF statistic:

$$\left(\tilde{s}_{NT}^{*2}\ \sum_{i=1}^{N}\sum_{t=1}^{T}\hat{L}_{11i}^{-2}\ \hat{\varepsilon}_{i,t-1}^{*2}\right)^{\frac{-1}{2}}\sum_{i=1}^{N}\sum_{t=1}^{T}\hat{L}_{11i}^{-2}\ \hat{\varepsilon}_{i,t-1}^{*2}\ \Delta\hat{\varepsilon}_{i,t-1}^{*}$$

Group rho statistic:

$$\sum_{i=1}^{N}\left(\sum_{t=1}^{T}\ \hat{\varepsilon}_{i,t-1}^{2}\right)^{-1}\sum_{t=1}^{T}\ (\hat{\varepsilon}_{i,t-1}^{2}\Delta\hat{\varepsilon}_{it}-\hat{\lambda}_{i})$$

Group PP statistic:

$$\sum_{i=1}^{N}\left(\sum_{t=1}^{T}\hat{\sigma}_{i}^{2}\ \hat{\varepsilon}_{i,t-1}^{2}\right)^{\frac{-1}{2}}\sum_{t=1}^{T}\ (\hat{\varepsilon}_{i,t-1}^{2}\Delta\hat{\varepsilon}_{it}-\hat{\lambda}_{i})$$

Group ADF statistic:

$$\sum_{i=1}^{N}\left(\sum_{t=1}^{T}\hat{s}_{i}^{*2}\ \hat{\varepsilon}_{i,t-1}^{*2}\right)^{\frac{-1}{2}}\sum_{t=1}^{T}\hat{\varepsilon}_{i,t-1}^{*}\Delta\ \hat{\varepsilon}_{it}^{*}$$

The null hypothesis of seven tests is that there is no cointegration amongst variables. If the null hypothesis is rejected, a conclusion of the existence of long-run relationship amongst

[1] Of these seven statistics, four are based on the within-dimension approach and three referred to group-mean panel or between-dimension approach.

variables could be draw. In contrast, the null hypothesis cannot be rejected: there is no long run relationship amongst variables.

3.1.3. *Fully Modified OLS Approach*

This paper applies the fully modified ordinary least square (FMOLS) technique proposed initially by Phillips and Hansen (1990) and extended by Pedroni (2000). The following co-integrated system of equations is considered as follows.

$$y_{it} = \alpha_i + \beta y_{it} + \mu_{it} \,; i = 1, \dots, N \,; t = 1, \dots, T \qquad \text{and } x_{it} = x_{it-1} + \varepsilon_{it}$$

where the variables y_{it} and x_{it} are non-stationary and the vector error terms

The group-mean FMOLS estimator for the coefficient β is given by:

$$\hat{\beta}^*_{NT} = \frac{1}{N}\sum_{i=1}^{N}\left(\sum_{t=1}^{T}(x_{it} - \bar{x}_i)^2\right)^{-1}\left(\sum_{t=1}^{T}(x_{it} - \bar{x}_i)\, y^*_{it} - T\hat{\gamma}_i\right)$$

where $y^*_{it} = (y_{it} - \bar{y}_i) - \frac{\hat{L}_{21i}}{\hat{L}_{22i}}\Delta x_{it}$ and $\hat{\gamma}_i = \hat{\Gamma}_{21i} + \hat{\Omega}^0_{21i} - \frac{\hat{L}_{21i}}{\hat{L}_{22i}}\left(\hat{\Gamma}_{22i} + \hat{\Omega}^0_{22i}\right)$

$$L_{11i} = (\Omega_{11i} - \Omega^2_{21i}/\Omega_{22i})^{1/2} \,; L_{12i} = 0; \; L_{21i} = \frac{\Omega_{21i}}{\Omega_{22i}^{\frac{1}{2}}}; \; L_{22i} = \Omega_{22i}^{\frac{1}{2}}$$

The t-statistic for $\hat{\beta}^*_{NT}$ is defined as follows:

$$\bar{t}_{\hat{\beta}^*_{NT}} = \frac{1}{\sqrt{N}}\sum_{i=1}^{N}\hat{L}^{-1}_{11i}\left(\sum_{t=1}^{T}(x_{it} - \bar{x}_i)^2\right)^{-1/2}\left(\sum_{t=1}^{T}(x_{it} - \bar{x}_i)\, y^*_{it} - T\hat{\gamma}_i\right)$$

As N-> ∞ and T-> ∞, the t-statistic converges to the standard normal distribution.

3.2. *Empirical Models*

3.2.1. *Determinants of Thailand's Trade Balance*

The trade models are formed as follows:

$$TB_{it} = \Delta\frac{lnX_{it}}{lnM_{it}} = \beta_1\Delta lnRER_{it} + \beta_2\Delta\, ln\frac{GDP_{Thai}}{GDP_{it}} + \beta_3\Delta\, ln\left(\frac{(\frac{M2}{GDP})_{Thai}}{(\frac{M2}{GDP})_{it}}\right) + \beta_4\Delta\ln\left(\frac{(\frac{GOV}{GDP})_{Thai}}{(\frac{GOV}{GDP})_{it}}\right) + \beta_5\Delta ln\left(\frac{IR_{Thai}}{IR_{it}}\right) + +\varepsilon_{it}$$

where TB_{it} represents the trade balance between Thailand and her country partner i at the year t. The dependent variable, *bilateral trade balance*, is expressed as the ratio of the value of total exports to the value of total imports. This calculation is more favorable because of following reasons. *Firstly*, the trade balance could be expressed in term of logarithm and its negative value owing to trade deficit (Arora et al, 2003; Brada et al., 1997; Chiu et al, 2010). *Secondly*, the measurement could allow trade balance to intepret both real and nominal terms (Bahmani-Oskoee & Brooks, 1999). *Thirdly*, the ratio is not sensitive to the unit of value (Bahmani-Oskoee & Alse, 1994).

The independent variables appear in the right hand-side of the estimation equation. *Real bilateral real exchange rate* (RER_{it}) is defined as the nominal bilateral exchange rate adjusted by ratio of the consumer price index of country *i* to that of Thailand. *Relative income* is the ratio of Thailand GDP to GDP of a trading partner i (GDP_{Thai}/GDP_i). *Relative money supply* is the ratio of Thailand money supply to GDP in proportion to ratio of money supply to GDP of country i ($(M2/GDP)_{Thai}/(M2/GDP)_i$). *Relative interest rate* is the ratio of Thailand interest rate to interest rate of country i (IR_{Thai}/IR_i). *Fiscal variable* is the ratio of Thailand government expenditure to GDP in proportion to ratio of government expenditure to GDP of country i ($(GOV/GDP)_{Thai}/(GOV/GDP)_i$). All dependent and independent variables are first differentiated in order to be interpreted in terms of the growth rate (Bahmani-Oskooee, 1993; Miles, 1979). Rose and Jellen (1989) argued that the use of variables in terms of logs of level could be inappropriate owing to misleading statistic test with the presence of non-stationary variables. Thus, it is necessary to take variables first differenced, making them stationary and avoiding spurious estimation.

The coefficient of exchange rate variable is expected to be positive in order that the depreciation could offer a stimulus on trade balance. The sign of coefficients of the relative income is negative, providing that a reduction of relative growth rate leads to an improvement of trade balance ($\beta_1 > 0$). Additionally, an expectation is that the relative growth of money supply is negatively related to Thailand's trade balance. The effects of interest rate on consumption are unclear because of the switch between income and substitution effects, thus its impacts on trade performance are ambiguous. Coefficients of the government spending variable are expected to be negative.

The model for investigating the connection between bilateral real exchange rate and balance of trade includes four variables: (i) *bilateral trade balance* (TB_{it}), (ii) *bilateral real exchange rates* (RER_{it}), (iii) *domestic Thailand income* (GDP_t^{Thai}) and (iv) *foreign income* (GDP_{it}). The data is presented in term of natural log and in the real term. A panel framework in relation to CPI-based real exchange rate is described as follows:

$$ln\, TB_{it} = \alpha_i + \beta_1\, RER_{it} + \beta_2\, ln\, GDP_{it} + \beta_3\, ln\, GDP_{t\_Thai} + \varepsilon_{it}$$

4. Findings

4.1. *Determinants of Thailand's Trade Balance*

In this section, the OLS method and instrument variable (IV) method are used to consider the connection between Thailand trade balance and its determinants. The IV regression is applied as the endogeneity problem[2] from potential simultaneity bias, measurement errors would be likely to make OLS inconsistent and bias. Following the studies Willson (2001), Rose and

[2] The endogenity problem is taken into consideration in various studies (Brissimis & Leventakis, 1989, Chiu et al, 2010; Yol & Baharumshah, 2007; Rose & Yellen, 1989; Rose, 1991; Willson, 2001).

Yellen (1989), and Rose (1991), instrument variables for exchange rate comprise money supply, interest rate, and foreign exchange reserve in terms of foreign and domestic data.

With the similar framework, Miles (1979) and Himarios (1989) found different results for individual countries, proving that different countries may react in various ways in terms of trade balance and its determinants. Chiu et al (2010) strongly believes that nations with different per capital income may experience a diversity of their capability in export supply and import demand. Moreover, those factors like geographic distance, trade barriers, political and economic relationships are highly likely to influence to trade structure of Thailand to her trading partners. Hence, in this study, the entire data will be divided into seven sub-samples[3] to investigate whether the *geographic structure* and *income level* affect the relationship between Thailand's trade balance and its determinants.

Table 1 presents results using both OLS and IV regression for the fundamentals of Thailand's trade balance. Generally, two methods of regression provide consistent results with the exception for *bilateral real exchange rate*. In contrast, this coefficient in the IV regression carries a negative value, but statistical insignificance, providing that the exchange rate might not be an element of Thailand's trade. The coefficients of *the relative growth rate of income* are negative and statistically significant in both OLS and IV regressions. Such coefficients of the *growth rate of money supply* and *interest rate* are insignificant in both estimations.

Table 1: Results of OLS and IV estimations for determinants of Thai trade balance

3 The countries belonging to sub-samples ar displayed in Appendix A of the paper.

Table 2 presents estimation results for seven sub-groups divided by incomes and regions. The empirical results indicate that coefficients of *exchange rate* variable are statistical at least at 10% significance and carry correct signs for groups with low and middle income and in Asia, Oceania, and Europe. The largest coefficient of exchange rate (2.223) is for the case of upper middle-income group, meaning that reaction of trade balance to *exchange rate* face the most sensitive to this group. All coefficients of income variable holds negatively expected signs, but these coefficients are statistically significant for the case of high income and Africa and Western Asia. The coefficients of monetary variable (*the relative growth rate of money supply over GDP)* are statistical at 5% significance with negatively expected signs in the case of lower middle income and low income, Africa and Western Asia, and Asia and Oceania. This implies that a reduction of relative growth rate of Thailand's money supply over GDP would improve her trade balance to partners in these groups.

4.2. *Devaluation and Thailand's Trade Balance*

Table 3 indicates t-statistic of the Breitung (2001) panel-based unit root test both at the level and at the first difference. This results indicate that the *bilateral real exchange rates* are mixture of I(0) and I(1). On the contrary, the null hypothesis of a unit root cannot be rejected for the GDP and Thai's GDP variables at levels, but this hypothesis strongly reject at first difference at 1% significance, showing that two variables are integrated of I(1).

Table 4 present two types of cointergration tests by Pedroni (1999, 2001, &2004) and Kao (1999). Most t statistics from the Kao (1999) test indicate that the null hypothesis could be strongly rejected at 1% significant with an exception of high-income group. Meanwhile, seven statistics of Pedroni (1999, 2001, &2004) provide weaker evidence of long run relationship because of some insignificant statistics. All the *panel ADF* and *group ADF* statistics are statistically significant. As stated by Pedroni (1999), such statistics are superior to others statistics so that the results of long run relationship would be reliable. Thus, there is an existence of long run relationship amongst trade balance, bilateral real exchange rate, Thailand's GDP and foreign GDP.

On the panel estimation from Table 5, most coefficients of *bilateral real exchange rate* are positive except for Africa and Oceania group. For the case of 1980-2013 periods, the coefficient of exchange rate implies that when the Thailand's currency depreciates 1% on average, her trade performance would grow approximately 0.6% in the long term. Moreover, the coefficient of *foreign income* is positively significant. The figure is 1.23, providing that when the total income of all surveyed countries increases 1%, the Thailand's trade would rise approximately 1.23%. In contrast, the coefficient of Thailand's income is negatively significant, showing that when Thailand income rises, her trade balance would be worsened because of her higher imports. The number of 0.61 means that an increase of 1% in Thailand's income would lead to a decrease of approximately 0.61% in her trade balance.

As far as three income groups are concerned, empirical results show that the depreciation of Thailand currency offers positive influences on her trade balance with countries having high and upper middle income. The lower middle and low income might not be suffered from the Thailand's depreciation. Moreover, the coefficients of foreign income are positively significant for the case of high income, lower middle- and low-income group. This means that when foreign income increases, countries in such groups have higher tendency to imports Thailand's products and services, thus improving Thailand's trade balance. The coefficients of domestic income for three groups above are negatively significant, providing that when Thailand's income rises, Thailand would be suffered a distortion in her trade balance when Thailand income rises owing to her higher demand for importing goods and services.

In relation to regional groups, America group has a largest elasticity of real exchange rate and reverse sides to expectation for coefficients of domestic and foreign income. This implies that a Thailand's depreciation considerably improve Thailand's trade balance with America rather than other regional groups. The coefficient of foreign income is statistically negative, implying that when the real income rises in American countries, the demand for Thailand's goods and services reduce. On the contrary, the coefficient of Thailand's income is statistically positive, showing that an increase in Thailand income results in an improvement

in her trade balance due to a growth in producing import substitutes from such region, as stated in international trade theory. An explanation for the most striking feature of America group may be transportation costs with the furthest distance as compared to that of Thailand and other regions. Besides, the coefficients of real exchange rate, foreign income, and domestic income for Africa and Western Asia, Asia and Oceania, and Europe carry correct sides according to expectation, but few of them are not statistically significant.

As stated by Marquez (1990), sole reliance on multilateral elasticities conceals valuable information for both policy applications and empirical analysis of international trade. The individual estimations of FMOLS will also be conducted to further understand this relationship. The individual results are displayed in Table 6. The coefficients of *bilateral real exchange rates* are statistically significant in 30 out of 62 cases (countries), and 20 of them holds correctly-expected signs. This implies that a depreciation of Thailand Baht would stimulate her bilateral trade performance with over 20 countries. The coefficients of *foreign income* are statistically significant for 37 cases over the total of 62 countries. The number of cases carrying positively expected signs is 26, meaning that an increase in foreign income of these 26 countries leads to an improvement in Thailand trade balance in the long run. The similar patterns have been witnessed for coefficients of *domestic income*. The estimated coefficients being statistically significant and holding correctly expected signs are 36 and 26, respectively.

5. Conclusions and Implications for Vietnam

The study is conducted to examine the effects of a currency's devaluation on trade balance for the case of Thailand. This objective could be achieved by the two procedures. The first procedure is to analyze how changes on exchange rate policy, fiscal policy, and monetary policy affect Thailand's trade balance. In this task, effects of devaluation on trade balance are examined on various scenarios: (i) the entire sample of 62 countries who are trading partners with Thailand; (ii) different geography (between regions and regions of countries); (iii) different income levels. The second procedure is to examine the long run relationship between a devaluation of Thailand's currency and trade balance in term of panel and individual country.

Empirical findings indicate that the exchange rate policy and relative growth rate of incomes play a central role in explaining Thailand's trade balance, and the fiscal and monetary policies are beneficial in some cases. Moreover, the panel FMOLS estimations illustrate that a devaluation of Thailand Baht could provide positive effects on trade balance in the long run, especially for (i) the group of countries with high income, (ii) the group of countries with upper middle income, (iii) countries in America, and (iv) countries in Europe. The individual FMOLS regressions between Thailand and each of her 62 trading partners indicate that the devaluation of Thailand's currency would stimulate Thailand's trade performance with over 20 trading partners, but hurt its performance with the other 10 countries and inconclusive conclusion for the others.

Thailand and Vietnam are very similar in many aspects including both social and economic characteristics. This study is not conducted for Vietnam because of the data limitation. Given similarities between Thailand and Vietnam, we are of the view that implications from the findings of this empirical study can be drawn for the Government ogf Vietnam and also for the Government of Thailand. *First*, the government should focus on the money supply rather than on interest rate. As empirical findings from this study indicate money supply may provide a more significant effect to trade balance in comparison with interest rate. This finding also indicates that while an overall money supply is determined by the central bank (which then implies a basis interest rate), individual interest rates may be left with commercial banks to determine within a reasonable band. *Second*, a policy on currency devaluation should be strictly considered and adopted for the purpose of improving a national trade balance (and possibly encouraging economic growth) occasionally. However, it is cautious that this policy should be constantly reviewed to ensure that prevailing market condition still supports for an existence of such a devaluation policy.

Appendix A:

Data sources

This study has used annually panel-unbalanced data over the periods from 1980 to 2013 between Thailand and 62 her trading partners with a total of 1950 observations. The data are collected from different sources such as the Economics magazine, IMF, World Bank, and Bank of Thailand. The data for bilateral exchange rate and bilateral trade between Thailand and her trading partners are collected from IMF and Bank of Thailand. The rest of data including CPI, GDP, money supply over GDP, ratio of government spending to GDP, lending interest rate, and international reserve both of Thailand and of foreign countries are taken from World Bank.

Appendix B:

Countries associated with income and region groups

Europe	Austria, Belgium Bulgaria, Cyprus, Czech Republic, Denmark, Finland, France, Germany, Greece, Hungary, Ireland, Italy, Malta, Netherlands, Norway, Poland, Portugal, Romania, Russia
America	Brazil, Canada, Colombia, ChileMexico, PanamaPeru, United States
Afica and Western Asia	Benin, Coted' Ivoire, Egypt, Iran, Israel, Kuwait, Nigeria, Oman, Saudi Arabia, South Africa
Asia and Oceania	Australia, Bangladesh, Brunei,Cambodia, China, Hong Kong, India, Indonesia, Japan, South Korea, Lao PDR, Malaysia, Nepal, New Zealand, Pakistan, Philippines, Singapore, SriLanka, Vietnam
High income	Australia, Austria, Belgium,Brunei, Canada, Cyprus, Czech Republic, Chile, Denmark, Finland, France, Germany, Greece, Hong Kong, Ireland, Israel, Italy, Japan, South Korea, Kuwait
Upper middle income	Brazil, Bulgaria, Colombia, China, Hungary, Iran, Malaysia, Mexico, Panama, Peru, Romania, South Africa, Turkey
Lower middle and low income	Bangladesh, Benin, Cambodia, Coted' Ivoire, Egypt, India, Indonesia, Lao PDR, Nepal, Nigeria, Pakistan, Philippines, SriLanka, Vietnam

Adpating a Measure of Socially Responsible Consumption in France to the Vietnamese Context – A Study in Hochiminh City

lvtai@hcmut.edu.vn

The major aim of this study is to employ the measure of socially responsible consumption (SRC) developed by Francois-Lecompte and Roberts (2006) to empirically explore the level of Vietnamese consumers' awareness of SRC. Consumers in Hochiminh city are approached to distribute the questionnaires in stores, supermarkets, shopping malls, traditional markets, … The research findings show some salient points. Firstly, the order of SRC factors in Vietnamese consumers' perspectives is different from that in France. Secondly, 17 over 20 variables to measure SRC factors can be used to conduct SRC study in Vietnam. However, it is necessary to conduct a qualitative study to develop a measure more appropriately to Vietnamese consumers.

1. Introduction

With the development of the economy in countries, especially in emerging economy like Vietnam, growths of many aspects are also increasing dramatically. Among these aspects, consumption is one having significant growth. However, any development also has its own backside with many problems and concerns, which, if not paid enough attention, will lead to many negative consequences. In Vietnam, accompanying with rapid economic development, levels of consumption has been increasing dramatically. According to The Saigon Times, two third of GDP in Vietnam are recently contributed by individual consumption (Phuc 2014). Moreover, individual consumption is considered as the main factor not only to degrade the environment, but also to encourage companies to behave in a responsible manner (Mohr, Webb et al. 2001; Singh 2009).

There are studies conducted on socially responsible consumption in some advanced economies like France, U.S., UK and some emerging ones like India, China, Morocco (Roberts 1995; Francois-Lecompte and Roberts 2006; Chen and Kong 2009; Singh 2009; Lebzar, Sidmou et al. 2012). The point highlighted in these studies is that SRC cannot be forced by the government, but there is need for consumers to be self-realization and self-regulation to minimize any bad or negative influence on the society and the environment (Singh 2009).

However, in Vietnam, the frequent mentioned terms are smart consumption and green purchasing which are used to describe how to smartly spend money on consumption and to consider impacts on the environment. Therefore, the purpose of this study is (1) to empirically explore the level of socially responsible concerns among Vietnamese consumers; (2) to analyze differences of Vietnamese consumers' concerns of SRC across demographic factors; and (3) to discuss implications for marketers and policy makers regarding to improve SRC in Vietnamese consumers.

2. Research background

2.1. *Consumption and socially responsible consumption (SRC)*

Consumption is a marketing concept; however, it has attracted as well the attention of many researchers in other fields like economy, politics science, sociology and philosophy (Díaz-méndez 2010). It is considered as the way consumers perform to satisfy their needs and they try to make it as a never-ending process (Marinas 2001, 2007; cited in Díaz-méndez 2010). In other words, consumption is described as the way in which individuals live by using different types of products and services from different producers/providers (Singh 2009; Díaz-méndez 2010). From their capabilities and understanding, consumers will combine these types of products and services in different ways. However, these combinations can lead to different consequences as they are impacted by four factors, namely: price, other goods' price, consumer's economic capacity, and his/her likings (Díaz-méndez 2010)

In their study, Lebzar, Sidmou et al. (2012) summarized different way to define *consumption* and identified its components, which are included of : the emotional dimension (consumption is a "source of emotion and experience of pleasure"), the functional dimension (consumption utilities meet goals and practices), the aesthetic dimension (consumption is sought for "the beauty and expression"), the epistemic dimension (consumption allows consumers to "satisfy the curiosity, the desire knowledge") and finally, the social dimension (consumption allows consumers to structure their identify and position themselves in relation to a group).

However, consumption is also defined in another way. “Consumption means to consume, waste, squander or destroy”; or, it is concerned as an aspect of social representations of the economy (Francois-Lecompte and Roberts 2006; Gonzalez, Korchia et al. 2009). These considerations of consumption did drive researchers to thinking and doing research on SRC (Gonzalez, Korchia et al. 2009). There are many SRC definitions; however, the very first one documented by Webster in 1975 is with two main issues (Francois-Lecompte and Roberts 2006; Özçaglar-Toulouse 2009). Firstly, consumers concern about public consequences due to his/her consumption. Secondly, they want to make some changes in society by their purchasing power.

Mohr, Webb et al. (2001) identify socially responsible consumers by actions of avoiding buying products/services from companies that harm society and actively seeking out ones from companies that help society. Similarly, Díaz-méndez (2010) highlighted that SRC is a buying decision based on product’s origin, manufacturing process, labour working conditions, environmental impact, and manufacturer’s social responsibility.

Among SRC definitions, the one developed by Roberts (1995), which is employed and cited in many other empirical studies (Roberts 1995; Francois-Lecompte and Roberts 2006; Gonzalez, Korchia et al. 2009; Lebzar, Sidmou et al. 2012), can be considered as the most-used SRC definition. In his study, Roberts (1995) defines SRC as consumer behaviors taking into account the impact on the environment of private consumption decisions or using purchasing power to express current social concerns.

2.2. *Factors influencing customers in SRC*

The factors which have their influences on consumers in their SRC can be divided into two groups, drivers and obstacles. In the literature, some studies explored these factors.

In their study, Mohr, Webb et al. (2001) point out a contradiction of a common assumption that SRC is based only on consumers’ self-interest. Their findings suggest some important issues relating to drivers for consumers to consume responsibly. Firstly, the more knowledge about social responsibility customers have; the more positive consumption they behave. Moreover, such knowledge also creates a positive relationship between customers’ beliefs and behaviors in SRC. Lastly, customers likely practice SRC when they recognize their purchasing power, which can impact companies’ behaviors. From these findings, it can be seen that drivers to promote consumers consuming responsible are rooted out from the way companies behave and from their purchasing power.

Regarding obstacles preventing socially responsible consumption, in his study, Carmen (2008) identified three groups which created a considerable gap between attitudes ad actual behaviors of customers. These three obstacles are: motivational, cognitive and behavioral obstacles.

Motivational obstacles can be considered as willingness to make political statements or actions in the marketplace depend on self-identity and perceived efficacy (Carmen 2008). The first obstacle is from consumers' perspectives of self-perception of citizenship and of corporate social responsibility (CSR). The main point mentioned is that, although good people, not all consumers are good citizens who concern about others' welfares; and they have different conceptualized understanding of CSR. The second obstacle is from their understanding of their purchasing power and from sources information they have. Carmen (2008) analyzed that "… if consumers believe that their purchase decision may make a difference, they are more likely to buy responsibly…" and this is used to express their expectation of the society (Brinkmann 2004).

Cognitive obstacles are described as opportunities to get information and ability to process, store and recall information about brands (Carmen 2008). This kind of obstacle refers to the information consumers have about corporate impact on social welfare (Carmen 2008; Öberseder, Schlegelmilch et al. 2011). It also refers to the availability of this information to customers (Mohr, Webb et al. 2001; Carmen 2008).

Behavioral obstacles is likely opportunity and ability to find a fair brand to purchase (Carmen 2008). Actually, customers can not be responsible in consuming if they cannot find good producers/manufacturers (Shaw and Clarke, 1999 cited in Carmen 2008). The other behavioral obstacle is cost spending for responsibly consuming, including higher price, travelling a certain distance to find good manufacturers, and so on.

2.3. *Measures of socially responsible consumption*

Even though the concept SRC is mentioned and studied from 1975, the measures of SRC have not been properly developed. Many scales are borrowed from sociology, therefore, they do not have items related to consumer behavior and not well suited in marketing and management context (Francois-Lecompte and Roberts 2006). Moreover, Francois-Lecompte and Robert (2006) also point out that SRC is only put in the context of environmental context.

In their study, Mohr, Webb et al. (2001) conducted a qualitative study to develop items to measure SRC. Their research findings suggested 5 items. However, it needs to be tested quantitatively and developed sub-items for SRC studies. Among studies conducted in developing countries, a study conducted in China by Chen and Kong (2009) developed and used a scale of 7 items to measure SRC. However, the process of developing these items is not described clearly to illustrate their reliability.

In their study conducted in France, Francois-Lecompte and Robert (2006) developed a scale of 5 factors to measure SRC, including firm's behavior with 5 factors, cause-related products with 4 items, small businesses with 4 items, geographic origin with 4 items, and consumption volume with 3 items. This 20 item-scale is developed by qualitative study with methods to collect data like in-depth interview, focus group. Then, this measurement is confirmed by a quantitative study. That is the reason this study employs the scale developed by Francois-Lecompte and Robert (2006) to base on.

3. Methodology

The main purpose of this study is to empirically explore the level of socially responsible concerns among Vietnamese consumers. Therefore, the main method used to collect data is through questionnaire to conduct a survey among consumers. The employed questionnaire is adapted from Francois-Lecompte and Robert (2006). In this questionnaire, there are five factors with 20 items, namely: firm's behaviors (consumption acts related to irresponsible corporate behaviors) - (BF), cause-related products (preferences for cause-related products, including purchase) - (CRP), small businesses (desires to help small businesses) - (SB), geographic origin (the purchasing local products) - (GO) and consumption volume (reducing one's consumption to what is only necessary for not bad impact on the environment - (CV).

The factors and items from the study of Francois-Lecompte and Roberts (2006) are adjusted for the appropriateness to the research and consumption context in Vietnam. To construct the questionnaire, a group of 6 people in different gender, age, occupation, and income has been gathered to discuss about the meaning of SRC. At first, it is free discussion about the meaning of SRC, to warm up and learning what people think about SRC. Then, the scale of Francois-Lecompte and Roberts (2006) is raised to discuss and clarify what should be included and adjusted to be accepted with the case of Vietnam. After consensus on using these 19 variables (omitting 1 variable regarding to politic matter), a pilot survey is conducted with small sample (20 respondents) to adjust the questions for more clear and understandable with Vietnam customers. The questionnaire is then finalized and used to survey with large sample to get data for analysis. After adjustment, there are 5 factors and 19 items which are presented as follow:

Factor 1: Firm's behaviors (FB)

1. I pay attention not to buy products from companies that are narrowly illegal.
2. I try not to buy products from companies that employ children
3. I try not to buy products from companies that don't respect their employees
4. I try not to buy products from companies that strongly harm the environment

In Vietnam, there is only one political party, therefore, the origin item "I try not to buy products from companies or shoppers that are narrowly linked to political parties that I condemn" in the study of Francois-Lecompte and Roberts (2006) has been removed from the questionnaire.

Factor 2: Cause-related products (CRP)

5. I buy some products of which a part of the price is transferred to a humanitarian cause.
6. I buy some products of which part of the price goes to developing the country.
7. I buy products of which part of the price is given to a good cause.
8. I buy fair trade products

Factor 3: Small businesses (SB)

9. I avoid doing all my shopping in big businesses (large retailers).
10. I buy in small businesses (bakeries, butcher's trade, book shoppers) as often as possible (small shopkeepers).

11. I help the storekeepers of my quarter to live through my purchases.
12. I go to small markets to support fruits and vegetables small producers.

Factor 4: Geographic origin (GO)

13. When I have the choice between a Vietnamese product and an exported product, I choose the local one.
14. I buy preferably Vietnamese products (like cosmetics…).
15. I buy fruits and vegetables made in Vietnam.
16. I buy products made in my country – Vietnam.

Factor 5: Consumption volume (CV)

17. I try to reduce my consumption to what I really need.
18. In a general manner, I try to reduce my consumption.
19. I try not to buy objects that I can do by myself.

The convenient sampling is chosen, and the participants in this study are consumers who are over 18. Totally, 180 respondents are approached to answer the questionnaire at supermarkets, convenient stores, markets, book stores, shopping malls. The data is cleaned and processed by using exploratory factor analysis (EFA technique) in SPSS software. The Principle component method with Promax rotation method are used to adapt with the method used in the study of Francois-Lecompte (2006). Before applying the EFA method, the reliability of the scales has been tested by using Cronbach's alpha criteria, it should be at least 0.6 to be accepted (Nunnanly và Burnstein, 1994). Then, EFA technique is applied with data exploration and variable reduction steps. The EFA process is accepted with the threshold of KMO measure higher than 0.5 and significant at 5%, Eigen values must be larger than 1, Factor loadings of each variable should be at least 0.5, it is no any cross-loading above 0.35 into more than one factors (Hair et al., 2006). Besides, the difference between groups of customer distinguish by demographic variables are considered by ANOVA analysis

4. Data analysis and findings

The percentage of men and woman in valid sample are 51 and 49, respectively. Most of respondents are in the age of 24-31 with 63 percent, the others are 28 percent for the age of 18-23 and 9 percent for over 32. The ranges of age also suit the occupation status, including: office staff, managers and engineers, students, workers and housekeepers at 44, 14, 28 and 7 percent, respectively. The ranges of respondents' incomes are relevant to the occupation with 49 percent of them earning from 5-10 millions VND; more than 37 percent getting less than 5 million VND; and about 14 percent receiving salary higher than 10 million VND.

Most of variables are dispersed in the Likert 5 scales with mean and mode is at 3 (neutral) or 4 (agree) (*See Table 1*). That means the customer's perceptions on SRC described by these variables seem not high, especially for variables measuring firm's behaviors and small business groups. It could be understood that the information of Vietnam enterprises is not transparent and their communication with customers is not so good. Therefore consumers have not thought much on the responsibility to help small businesses as well as corporations that have practiced social responsibility. Furthermore, due to low income, consumers tend to

Table 1: Descriptive Statistics for measurement scales of SRC

	Valid	Minimum	Maximum	Mean	Median	Mode	Variance
FB1	172	1	5	3.069767	3	3	0.860601
FB2	172	1	5	3.302326	3	3	0.913913
FB3	172	1	5	3.116279	3	3	0.945464
FB4	172	1	5	3.046512	3	3	0.839929
CRP1	172	1	5	3.860465	4	4	1.103223
CRP2	172	2	5	3.906977	4	4	0.599483
CRP3	172	1	5	3.744186	4	3	0.75289
CRP4	172	2	5	3.744186	4	3	0.706106
SB1	172	1	5	3.55814	4	3	0.575547
SB2	172	1	5	2.790698	3	3	1.008568
SB3	172	2	5	3.488372	3	3	0.43846
SB4	172	1	5	3.511628	3	3	0.578811
GO1	172	1	5	3.767442	4	4	0.740922
GO2	172	1	5	3.837209	4	4	0.792058
GO3	172	2	5	3.767442	4	4	0.647355
GO4	172	1	5	3.72093	4	4	0.76377
CV1	172	2	5	3.418605	4	4	0.759418
CV2	172	1	5	3.372093	3	3	0.983544
CV3	172	1	5	3.488372	4	4	0.906297

consume low-price-products or think about the products that bring most benefits to them, rather than share with firm's difficulties. These might contribute to form their consumption attitude. The variables of GO seem to take the highest concern since the scare of some products from China which may affect negatively their health and the campaign of boycott Chinese products have been emerging in recent years. Variables in CRP group also express concerns from customers if they know that a part of products price will be used for humanitarian charity or developing the country, especially after the call from the government '*For Hoang Sa and Truong Sa*' to contribute to Hoang Sa and Truong Sa or the campaign of using Vietnam products '*Vietnamese consumes Vietnamese products*'.

Testing the reliability of the scales, all 5 primary factors receive the Cronbach's Alpha from 0.792 (for SB) to 0.948 (for GO), satisfy the condition mentioned above. Therefore, all of these variables will be used in the EFA step.

Taking EFA for 19 variables, it is also divided into five factors as proposed model with KMO and Eigen values satisfy the condition mentioned above and factor leading for each variable higher than 0.5. However, there are cross-loading at two variables SB3 (*I help the storekeepers of my quarter to live through my purchases*) and CRP1 (*I buy some products of which a part of the price is transferred to a humanitarian cause*). Therefore, they are dropped out one by one from the next EFA steps. This process also satisfies KMO criteria and factor loadings requirements. This action also help increasing the total variance explained from

78.7% to 81.6%. The final components matrix and the result of testing reliability of the new factors are represented in the table 2.

Table 2 shows that the factor loading of all variables get value between 0.602 and 0.946. In that, variables from factor GO have values above 0.84 showing strong correlation between variables. As a result, Cronbach's alpha is on top at 0.948. This factor explains 30.4% for the variance being the most important factor to measure the meaning of SRC. The highest one among 5 factors using to measure SRC suggest for the case of Vietnam. With four variables of FB, although still having high factor loading and Cronbach's alpha is high (0.869), this factor contributes less than 20% in explaining for the variance when combines with the other factors and take the second position in the list of factors to measure SRC. CV and SB support factors take the ranks of 3 and 4 in the list and contribute about 12% each factor in explaining for the variance. The CRP factor come in end of the list with 7.6% of variance explained. This order is almost different with that in the study of Francois-Lecompte and Roberts (2006), i.e. CRP factor at first, FB-2nd, SB-3rd, GO-4th and CV-the last.

Table 2: EFR and reliability testing result

	Component					Cronbach's alpha	total variance explained
	1	2	3	4	5		
GO2 - I buy preferably Vietnamese products (like cosmetics…).	.936						
GO1 - When I have the choice between a Vietnamese product and an exported product, I choose the local one.	.934					0.948	30.4
GO3 - I buy fruits and vegetables made in Vietnam.	.856						
GO4 - I buy products made in my country – Vietnam	.843						
FB1- I pay attention not to buy products from companies that are narrowly illegal		.887					
FB3- I try not to buy products from companies that don't respect their employees		.870				0869	49.6
FB2- I try not to buy products from companies that employ children		.864					
FB4- I try not to buy products from companies that strongly harm the environment		.752					
CV2 - In a general manner, I try to reduce my consumption			.881				
CV1 - I try to reduce my consumption to what I really need.			.858			0.853	62.1
CV3 - I try not to buy objects that I can do by myself			.822				
SB1 - I avoid doing all my shopping in big businesses (large retailers).				.946			
SB4 - I go to small markets to support fruits and vegetables small producers				.894		0.797	74.0
SB2 - I buy in small businesses (bakeries, butcher's trade, book shoppers) as often as possible (small shopkeepers)				.602			
CRP4 - I buy fair trade products					.857		
CRP3 - I buy products of which part of the price is given to a good cause					.753	0.806	81.6
CRP2 - I buy some products of which part of the price goes to developing the country					.697		

Extraction Method: Principal Component Analysis.
Rotation Method: Promax with Kaiser Normalization.

Customer attitude from different demographic groups

Base on the variables remain after EFA, the score of each factor will be computed by taking the average score of the belong variables, and then used to test whether there is different on attitude between demographic groups for each factor of SRC by using ANOVA

With gender variable, only two factors – FB and GO – receive different attitudes between men and women significantly at 5%, women evaluate these factors more highly than men.

There is no significant difference between groups of age, statistically. The younger even give lower scores than the older; however, the groups of 24-31 and above 32 seem not so different.

In respect of the occupation variable, SB is the only factor supporting. Meanwhile, the other four factors are significantly different between occupational groups. Among these groups, engineers showing the lowest score in all these four factors (less than 2.5 – between disagree and neutral) are followed by the groups of students, housekeepers, staffs, and managers in orderly.

For income variable, average scores of low income and high income groups are slightly lower than that of the middle income group. This is due to the fact that almost people from low income group are student who are still receiving support from their family, still young and have not much experience as well as choice in consuming products. For the high income people, they tend to consume by convenience. However, the difference is not high and the confident level is not achieved at 95% for testing.

5. Discussion

This study is adapted from the study of Francois Lecomple and Roberts (2006) to test whether it could be used the measurement scale of SRC in France case for Vietnam context. The analysis has shown that the suggested scales ensuring the reliability and convergence in measuring the factors of SRC. Only 3 variables is not suitable with the context of Vietnam should be dropped out. In the study of Francois-Lecompte and Roberts (2006), 20 variables are divided into 5 factors. Similarly, in the present study, 17 variables are also divided into these 5 factors.

In comparison, mean score between demographic groups of customer, gender and occupation groups get statistical significant at 5%. This is a hint for company having suitable marketing campaign and the government has reasonable policy to improve it.

This research could be considered as a pioneer research in this field at Vietnam. It is taken place under circumstance of Vietnam customers scared of using low cost but harmful some products from China; and they are also getting angry with series of scandals about environment being degraded/ destroyed by unfaithful and irresponsible producers. They are more concerned on social responsibility when making consumption decision. Therefore, when conducting the present study, the researchers also received much of concern from customers. However, there are some variables in the questionnaire not easy for them to answer due to lacking of information, apparently. That might be the reason leading some of consumers to not think about it when making buying decision.

As mentioned above, even though SRC raised since 1970s, it is understood differently in different areas and cultures. Therefore, when applying this SRC measure to research in Vietnam, the suggested measure seems still strange and not receives high concern of Vietnam customer. Respondents still think that they are responsible consumer but the score they get from the survey has shown that they are not concern much on their responsibility. That's because the income of Vietnamese is still low, two thirds of their income is used for consumption. Therefore, the scale about supporting SB or CRP seem not being welcome.

Furthermore, Vietnam is a developing country with the incomplete legal system, and lacking of market information. This point creates more difficulties for consumers in realizing socially responsible firms to perform their socially responsible consumption. This has shown that, the measure of Francois-Lecompte and Roberts (2006) is not properly appropriate for Vietnamese context. It is needed to develop another measure more appropriately, which consumers can have enough information or easily understand to evaluate factors.

6. Implication and limitation

Even though some factors in the measure of Francois-Lecompte and Roberts (2006) are still strange with Vietnamese customers, it is also useful to improve their thinking and awareness of SRC. On the one hand, this contributes to increase their social responsible awareness when performing consuming behavior in the future. On the other hand, businesses may improve their performance to adapt with new requirements from customer.

The demographic origin factor receives highest concern as well as being the most important factor to measure SRC. As mentioned above, this could be the consequence of thread and dangerous of some products from China as well as the campaign of government with slogan of "*Vietnamese consume Vietnamese products*". People understand and react well with this factor. The government should focus on this to increase the SRC of customer and Vietnam companies should benefit this chance to develop and improve their business. In particular, they should concentrate on women, managers, and staffs who show that they are ready to encourage Vietnamese firms. Moreover, companies should grant same concern to firm's behavior, the second factor in the list of factors after EFA even the score of variables in this factor is not as high as that of demographic origin factor. Meanwhile the government should improve the information system to deliver more information about firms to the customers to help them making a better decision on consumption and having a chance to improve their SRC.

For the small business support factor, the score is not high and there are no significant different between demographic groups of customers. Beside the reason of low income as mentioned above, small businesses have still not created prestige in doing business and customers do not trust in them due to low quality or expensive products. This also an alert for them in changing their performance and improve themselves to pull customer.

With the responsibility on CRP factor, although getting slightly high score from customer, the convergence of this factor is not high, correlation between variable is loosen in some cases and it ranks in the last position in EFA. Thus, variables should be considered to adjust for more suitable with Vietnam case.

However, this research also suffers some limitations. Firstly, due to limit knowledge and information, the employed scale may not adapt well with Vietnamese consumers' perspectives; and something they understand as SRC are not included in the questionnaire and vice a versa. That is the reason, in some cases, respondents tried completing the questionnaire without properly understanding. This limitation is also mentioned in the study of Roberts (1995). Therefore, it is necessary to conduct a qualitative study to explore constructs to measure SRC in Vietnamese context. Secondly, the survey is conducted in Ho Chi Minh City only. Consequently, the findings cannot be generalized for Vietnamese market. Further studies can be conducted and collect data in many other areas in Vietnam to have a better understanding of Vietnamese customers' awareness of SRC.

This paper investigates whether firms dynamically alter their corporate decisions on investment, financing, and dividend payment, and compares speeds of adjustments among those corporate decisions. Using U.S. listed firms from 1965 to 2012, we find that those ratios are mean-reverting, indicating that firms adjust their levels of investment, leverage and dividend toward optimal levels. We further find that investment and leverage are adjusted faster than dividend payment. This result confirms that firms tend to stabilize their dividend to prevent changing the investors’ prospective. We reexamine Leary and Roberts’s (2014) results in term of joint determination of investment, financing and dividend policies. The firms with high market concentration have the higher speed of adjustment of debt financing. The firms with greater fixed production costs (i.e. capital-intensive firms) have less flexibility to adjust their investments and debt financing. The small firms correct deviations in debt financing more quickly than big firms. This finding tends to support the flexibility to the environmental change for small firms rather than the adjustment cost reduction for big firms.

Keywords: Corporate investment; Leverage; Dividend; Speed of adjustment

1. Introduction

The investment, dividend, and debt financing are major decisions of a firm. The literature of corporate finance views that firms strive to maintain optimal levels of the three policies. Most past theoretical papers presume the existence of optimal investment and try to find some variables to explain the target level (e.g., Abel and Eberly, 1996; Chenery, 1952; DeMarzo and Fishman, 2007; Fine and Freund, 1990; Gordon, 1963; Koyck, 1954). Richardson (2006) uses U.S. data to construct the optimal investment level for each firm. For dividend payout, Fama (1974), Benartzi et al. (1997), and Fama and French (2002) confirm the Lintner model, which suggests the firms have target payout level. Rozeff (1982), Lee et al. (2011), and Chen et al. (2013) suggest that the growth rate helps to determine the optimal dividend payout. Regarding the debt financing policy, Bradley et al. (1984), Leary and Roberts (2005), Flannery and Rangan (2006), Kayhan and Titman (2007), and Frank and Goyal (2009) find the evidence to support the optimal capital structure. The survey paper of Graham and Harvey (2001) indicates that about 80% of the CFOs responded to have a target range or a strict target for their debt-equity ratio[1].

The abovementioned papers studying optimal levels associated with corporate decisions imply that firms have incentive to adjust their levels toward the target levels to maximize firms' value. The past studies such as Shyam-Sunder and Myers (1999), Fama and French (2002), Flannery and Rangan (2006), and Byoun (2008) use the speed of adjustment to examine whether firms change their debt ratio toward the target levels. Moreover, Jalilvand, and Harris (1984), Drobetz and Wanzenried (2006), Faulkender et al. (2008), Cook and Tang (2010), and Ö ztekin and Flannery (2012) investigate the determinants of the speed of adjustment of debt ratio among firms. However, based on the optimal investment and dividend literature, few studies investigate the corresponding speed of adjustment from these two decisions.

In this paper, we estimate and compare the speed of adjustment of these three policies. If the optimal level exists, we would see mean-reverting situation, namely the adjustment coefficients of these three corporate finance variables are predicted to be negative. Given the presence of adjustment costs, the speed of adjustment should be less than one. The speed of adjustment, as such, means the speed that firms adjust their levels to the target levels. The faster speed of adjustment for corporate decision implies the more important for the firm to make this decision. The investment decision for the firm is related to the future outputs, productivity, and profitability. The speed of adjustment for financing decisions implies the degree of urgency for the outside funds. The dividend payout decision may be used to signal the future profitability of the firm to the outside investors[2]. Thus, comparing the speeds of adjustment among these three corporate decisions helps us to understand which one is more urgent for the firm to adjust to the optimal level.

We further investigate the determinants to influence the speed of adjustment toward the targets. Leary and Roberts (2014) argue that the manager considers the financial policies and

[1] In addition, Jalilvand and Harris (1984), Hovakimian et al. (2001), and Cook and Tang (2010) document that the firm's financing decision is characterized as partial adjustment to long run targets

[2] Bhattacharya (1979), Miller and Rock (1985), and Ambarish et al. (1987) argue that firms can use the dividend payout as a costly signal to convey their true values.

characteristics of its peer firms to decide its financial decisions. Accordingly, this externality effect may increase or decrease the speed of adjustment of the financial policies. Past studies suggest that firms in less competitive market (i.e. oligopolistic firms) tend to adjust their investment, payout, and debt financing more than firms in more competitive markets (Akdoğu and MacKay, 2008; Brander and Lewis, 1986; Grullon and Michaely, 2007; Massa et al., 2007). In addition, firms with greater fixed production costs have less flexibility to change the input resources, thus capital-intensive firms tend to spend more time to correct investment levels than labor-intensive firms. Further, the size of firm seems to be a relevant factor on the financial adjustment. Big firms usually have lower adjustment costs and thereby adjust faster than small firms because of the effect in economics of scale (e.g., Banerjee et al., 2004; Jalilvand and Harris, 1984; Skinner, 2008). However, small firms may decrease response time to environmental change because of the greater interaction among departments (Neilsen, 1974). Thus, we could directly examine the effect of market competition, capital-labor intensity, and firm size on the adjustment of firm's decision by considering the speed of adjustment toward the optimal levels.

Our sample consists of U.S. listed dividend-paying firms from 1965 to 2012[3]. We estimate the models by using individual firm's time-series data, which allow speeds of adjustment to vary with firms. Using firm-by-firm estimations, we then present the mean of the parameter estimates of our results to capture an average behavior of the firms. In addition, to prevent the autocorrelation and the unobserved individual-specific time-invariant effects we also estimate these three target adjustment models by generalized method of moments (GMM) estimation of dynamic panel regression as robust check. Papers argue that the investment decision is related to financing decision and dividend decision (Dhrymes and Kurz, 1967; Fama, 1974; McCabe, 1979; McDonald et al., 1975; Peterson and Benesh, 1983; Pruitt and Gitman, 1991; Switzer, 1984). Thus, we also apply two-stage least squares (2SLS) to estimate the simultaneous-equations model that consider the interaction of the three policies.

As expected, we find that those adjustment coefficients are mean-reverting, indicating that firms adjust their levels of investment, dividend, and leverage toward optimal levels. We further find that investment and leverage are adjusted faster than dividend payment. The economic implications are shown as follows. Generally, the dividend payment is relatively long term and tends to be a permanent decision. Garrett and Priestley (2000) find that firms tend to smooth the dividend payouts to prevent changing the investors' prospective. To avoid signaling bad information about firms' prospective, Brav et al. (2005) also show that managers have no incentive to cut dividend. By contrast, investment decisions are usually short-term and related to future outputs. Firms have to react quickly to the good investment opportunity in order to make profits. When the internal funds of firms are not sufficient, firms will raise cash from capital markets. Thus, the adjustment speed of debt financing may be quick to match up the fast adjustment of the investment and is faster than the adjustment of dividend payout.

Regarding the determinants of speed of adjustment, we find that the firms with a higher

---

[3] Smirlock and Marshall (1983) and Fama and French (2002) also only consider the firms paying dividend.

market concentration tend to adjust to the debt financing faster, which is consistent with Brander and Lewis (1986). In addition, we find that capital-intensive firms correct deviation in investment and debt financing more quickly than labor-intensive firms. This result is consistent with the economic implication that firms with greater fixed production costs (i.e. capital-intensive firms) have less flexibility to adjust their investments. In addition, debt could be used to finance the investment needs for firms, thus a low speed of adjustment in investment would cause a low adjustment of debt financing. Finally, we find that small firms adjust faster in debt financing than do big firms. Our finding tends to support the flexibility to the environmental change for small firms rather than the adjustment cost reduction for big firms.

Our research offers three contributions to the literature. First, this paper is the first one to examine the speed of adjustment of investment, dividend, and debt financing policies in a simultaneous system while most past studies focus on the speed of adjustment for debt financing. Although Jalilvand and Harris (1984) and Fama and French (2002) investigate dividend and debt policies at the same time, they do not consider the possible influence of investment and do not discuss causes of adjustment speeds. Second, we compare the speed of adjustment of investment, dividend, and debt financing to understand which decision is more important for firms. Our result implies that firms care about the future productivity and sufficiency of funds more than the signal of dividend to outside investors. Third, by directly examining the speed of adjustment from the optimal adjustment model, we find that the market concentration, capital-labor intensity and firm size influence the speed of adjustment. While results of past studies (e.g., Brander and Lewis, 1986; Jalilvand and Harris, 1984; Skinner, 2008) imply these possible determinants for adjustment, they do not directly calculate and compare the speeds of adjustment.

The paper proceeds as follows. Section 2 presents the literature reviews about these three corporate decisions and our four hypotheses. Section 3 describes the empirical models and methodologies. Section 4 describes the data and shows the empirical results of speed of adjustment. Section 5 examines the determinants for the speed of adjustment. Conclusions are presented in Section 6.

2. Literature review and hypotheses

Most papers suppose that firms should have optimal investment level and try to find some variables to explain the target level. Chenery (1952) and Koyck (1954) use the flexible accelerator model of investment to capture the process that capital adjusts toward its target level. In this flexible accelerator model, capital is adjusted by a constant proportion of the deviation of its target from actual capital, and the target capital level is proportional to its output. Theoretical models such as Gordon (1963), Fine and Freund (1990), Abel and Eberly (1996), and DeMarzo and Fishman (2007) solve for the optimal investment of a firm under different conditions, indicating that optimal investment is a well-accepted concept. In addition to these theoretical papers, Richardson (2006) calculates the appropriate investment from the outlays for maintenance on assets in place and for future investment of positive NPV projects, which represents the optimal investment level for firms.

Since Lintner (1956) provides a partial adjustment model, the optimal dividend level is well investigated in finance papers. The Lintner model describes the tendencies that dividends adjust toward the target payouts, where the target dividend is proportional to profit. Based on the Lintner model, Fama (1974) applies simultaneous equations models of dividend and investment decisions and does not find an association between the dividend and investment decisions of firms. Fama and French (2002) confirm that dividends are mean-reverting and estimate the adjustment speed of dividend payout. The empirical results and theoretical models of Rozeff (1982), Lee et al. (2011), and Chen et al. (2013) show that there is an optimal dividend payout and a firm will reduce its dividend payout when the growth rate increases. Regarding the relationship among these three financial decisions, Lambrecht and Myers (2012) develop a dynamic Linter model of payout by maximizing the managers' rents, subject to the firm's budget constraint. In this theoretical model, they suggest that payout adjusts smoothly and propose the signaling information of the dividend payout through the manager view of the firm's prospects. Regarding the debt financing policy, a large body of literature agrees that leverage exhibits mean reversion and firms adjust their leverage toward the target levels. Bradley et al. (1984) find strong industry influences on firm leverage ratio and support the optimal capital structure. The survey paper of Graham and Harvey (2001) find that firms follow the trade-off theory and about 80% of the CFOs responded to have the target debt ratio. By allowing firms' target ratios to change over time, Hovakimian et al. (2001) confirm that firms tend to move toward a target debt ratio. Leary and Roberts (2005) find that firms actively rebalance their leverage to stay within an optimal range. Flannery and Rangan (2006) find firms pursue target capital ratios and use the partial-adjustment model to estimate the speed of adjustment. Kayhan and Titman (2007) find that the capital structures of firms are adjusted to target debt ratios even though firms' histories strongly influence their capital structures. Frank and Goyal (2009) support the optimal capital structure and find six core factors such as assets and profits for capital structure decisions. Huang and Ritter (2009) show that both the market-timing model and the static trade-off model are important determinants for the optimal capital structure.

The speed of adjustment, which is the proportion that changes in this variable are explained by deviations of its current level from the target level, is extensively used to examine whether the firms have the optimal level. Shyam-Sunder and Myers (1999), Fama and French (2002), and Flannery and Rangan (2006) estimate the speed of adjustment to examine the optimal capital structure. Most of investment papers such as Greenberg (1964) and Coen (1968) use the investment adjustment parameter to investigate the optimal investment model. Thus, according to the optimal hypothesis of the corporate decisions, we propose the following hypothesis:

Hypothesis 1: *The financial levels including investment, leverage, and dividend payment would be adjusted to the optimal level when the speeds of adjustment are significant.*

The externality effects such as the economic environment may influence the adjustment cost and thus affect the speed of adjustment of corporate decisions. Both Drobetz and Wanzenried (2006) and Cook and Tang (2010) find that firms adjust their leverage toward target faster in good macroeconomic states relative to bad states. Öztekin and Flannery (2012) compare firms' capital structure adjustment across countries and find that legal and financial traditions significantly correlate with firm adjustment speeds. Faulkender et al. (2008) find a faster adjustment speed when adjustment costs are sunk relative to when these costs are incremental. Byoun (2008) finds that firms make the most significant adjustment toward the target when they have above-target debt (below-target debt) with a financial surplus (a financial deficit). Leary and Roberts (2014) find that the behavior and characteristics of peer firms play an important role in determining corporate capital structures and financial policies. In their paper, smaller, younger, less successful, and more financially constrained firms are especially highly influenced by their large, more successful peers.

Accordingly, the characteristics of firms may be relevant to the speed of adjustment for the corporate decisions. First, past studies suggest that firms in less competitive market (i.e. oligopolistic firms) tend to adjust their corporate decisions more than firms in more competitive markets. Akdoğu and MacKay (2008) consider the value of investing strategically and the value of waiting to invest and find that investment speed are highest in oligopolistic industries and lowest in monopolistic industries. Grullon and Michaely (2007) and Massa et al. (2007) find that firms in a higher market concentration tend to pay out more cash than firms in a less market concentration. Brander and Lewis (1986) argue that firms in a low competitive market (i.e. oligopoly firms) have more incentive to adjust their financial structure to react to the change of financial structure of their competitors in order to influence their market outputs. Therefore, we propose the following hypothesis:

Hypothesis 2: *Firms in less competitive market (i.e. oligopolistic firms) tend to adjust their investment, payout, and debt financing faster than firms in more competitive markets.*

In addition, the production cost may be an issue for firms to decide the financial decisions. MacKay and Phillips (2005) find that firms that deviate from the industry median capital–labor ratio use more financial leverage than firms near the industry median capital–labor ratio. Their finding implies that firms near the industry median capital–labor ratio have lower cash flow risk and thereby use less debt financing. Mills and Schumann (1985) argue that the flexibility of firms is related to the capital intensity of their production technology and find that the firms relying on greater capital technology have higher fixed production cost. Firms with greater fixed production costs have less flexibility to change the input resources, thus capital-intensive firms tend to spend more time to correct their investment or debt financing than labor-intensive firms. Thus, we propose the following hypothesis:

Hypothesis 3: *Capital-intensive firms may adjust the financial levels more slowly than labor-intensive firms because of less flexibility resulted from greater capital intensity.*

Further, the size of firm is usually a relevant determinant in the financial decision. Big firms tend to have lower adjustment costs because of the effect in economics of scale. Jalilvand and Harris (1984) and Banerjee et al. (2004) suggest that large firms adjust faster to the target capital structure than small firms because less information asymmetry and less bankruptcy in big firms result in lower adjustment costs. Skinner (2008) finds that large firms adopt a stable dividend policy (i.e. lower speed of adjustment) because these firms use the flexible repurchase to substitute the dividend payout. However, in terms of the structure of organization, small firms have flexibility to react the market change. Neilsen (1974) finds that small firms decrease response time to environmental change because the greater interaction among departments. Leary and Roberts (2014) consider the mimicking effect among the peer firms and find that smaller firms are highly sensitive to the leverage changes of their larger peers. According to the above discussions, we propose the following competing hypotheses:

Hypothesis 4a: *Big firms have faster adjustment than small firms when the cost of adjustment is the dominant effect in the financial decisions.*

Hypothesis 4b: *Small firms have faster adjustment than big firms when the flexibility of organization is the dominant effect in the financial decisions.*

3. Models and methodologies

3.1. *Model*

In the finance literature, the simple form of target adjustment model for one variable states that changes in this variable are explained by deviations of its current level from the target level[4]. Specifically, changes in the investment (ΔInv_{it}), dividend (ΔDiv_{it}), and n debt financing ($\Delta Debt_{it}$) of firm *i* from year *t-1* to year *t* are given by

$$\Delta Inv_{it} = \phi_i\left(Inv_{it}^* - Inv_{i,t-1}\right) + \epsilon_{it} \ , \tag{1}$$

$$\Delta Div_{it} = \rho_i\left(Div_{it}^* - Div_{i,t-1}\right) + \eta_{it} \ , \tag{2}$$

$$\Delta Debt_{it} = \tau_i\left(Debt_{it}^* - Debt_{i,t-1}\right) + \xi_{it} \ , \tag{3}$$

Where Inv_{it}^*, Div_{it}^*, $Debt_{it}^*$, are the target investment, dividend, debt levels and ϕ_i, , τ_i are the speeds of adjustment for the investment, dividend, and debt. Inv_{it} is net property, plant, and equipment divided by shares outstanding. Div_{it} is the dividends divided by shares outstanding. $Debt_{it}$ is the ratio of total book liabilities to total book assets.

We follow the past studies to estimate the target levels. Chenery (1952) and Koyck (1954) suggest that the target investment for firms *i* at the year *t* is proportional to output (Q_{it}). Lintner (1956) proposes the targer dividends for firm *i* at year *t* are assumed to be proportional to earnings

[4] These studies include Chenery (1952), Koyck (1954), Lintner (1956), Fama (1974), Shyam-Sunder and Myers (1999), Fama and French (2002), Drobetz and Wanzenried (2006), Flannery and Rangan (2006), Byoun (2008), Huang and Ritter (2009), and Cook and Tang (2010).

(P_{it}). Fama and French (2002) suggest that target leverage is influenced by the volatility of earnings and net cash flows and the expected profitability of assets in places[5]. Fama and French (2002) use the firm size, the natural logarithm of total book assets, In $(A_{i,t-1})$, as the proxy for the volatility of earnings and net cash flows. They also adopt the ratio of annual pre-interest pretax earnings to end-of-year total assets, $E_{i,t-1}/A_{i,t-1}$, to present the expected profitability of assets in place. Thus, the target levels are shown as follows:

$$Inv^{*}_{it} = \phi_{1i} + \phi_{2i}Q_{it}\,, \tag{4}$$

$$Div^{*}_{it} = \rho_{1i} + \rho_{2i}P_{it}\,, \tag{5}$$

$$Debt^{*}_{it} = \tau_{1i} + \tau_{2i}\ln(A_{i,t-1}) + \tau_{3i}E_{i,t-1}/A_{i,t-1}\,, \tag{6}$$

where ϕ_{1i}, ρ_{1i}, τ_{1i} are ixed effects of the firm i. Q_{it} is calculated by sales plus change in inventories and P_{it} is net income before extraordinary items plus depreciation minus preferred dividends.

Therefore, substituting (4), (5), (6) into (1), (2), (3) and rearranging the model, we obtain the following estimated models[6]:

$$\Delta Inv_{it} = \alpha_{1i} + \alpha_{2i}Inv_{i,t-1} + \alpha_{3i}Q_{it} + \epsilon_{it}\,, \tag{7}$$

$$\Delta Div_{it} = \beta_{1i} + \beta_{2i}Div_{i,t-1} + \beta_{3i}P_{it} + \eta_{it}\,, \tag{8}$$

$$\Delta Debt_{it} = \gamma_{1i} + \gamma_{2i}\,Debt_{i,t-1} + \gamma_{3i}\ln(A_{i,t-1}) + \gamma_{4i}E_{i,t-1}/A_{i,t-1} + \xi_{it}\,. \tag{9}$$

Due to the presence of adjustment costs, the adjustment of corporate decisions toward the target levels may not be immediately. Specifically, the hypothesis will be held when the coefficient of speed of adjustment, α_{2i}, β_{2i}, γ_{2i}, are significantly between 0 and -1.

3.2. *Methodology*

3.2.1. *Regressions for single equation models*

We use ordinary least squares (OLS) method to estimate the abovementioned models (7), (8), and (9). By using OLS method, we estimate our time-series data for each of the 1,107 firms in the total sample, which allows speeds of adjustment to vary by firms. After firm-by-firm estimations, we present the mean of the parameter estimates of our results to capture an average behavior of the firms.

3.2.2. *Generalized method of moments estimation of dynamic panel data models.*

[5] We also consider the influence of expected investment opportunities, expected R&D investment, and depreciation to estimate the target investment as Fama and French (2002), then we obtain the similar result

[6] The coefficients in (7), (8) and (9) are displayed as follows: $\alpha_{1i} = \emptyset_i\emptyset_{1i}$, $\alpha_{2i} = -\emptyset_{1i}$, $\alpha_{3i} = \emptyset_i\emptyset_{2i}$, $\beta_{1i} = \rho_i\rho_{1i}$, $\beta_{2i} = -\rho_i$, $\beta_{3i} = \rho_i\rho_{2i}$, $\gamma_{1i} = \tau_i\tau_{1i}$, $\gamma_{2i} = -\tau_i$, $\gamma_{3i} = \tau_i\tau_{2i}$, $\gamma_{4i} = \tau_i\tau_{3i}$,

In regression models (7) to (9), we test the speed of adjustment by imposing the Inv_{t-1}, Div_{t-1}, $Debt_{t-1}$, which are lagged of dependent variables. Since the dependent (for example, Inv_t) and independent variables (Inv_{t-1}) share the same random source, it is obviously that covariance of independent and residual is not zero, leading an endogeneity concern. Therefore, as suggested by Arellano and Bond (1991), we estimate the coefficient estimates of our panel regression– a form of dynamic panel– for each regression (investment, dividend and debt ratio) with generalized method of moments (GMM). We select lagged variables of *Inv*, *Div* and *Debt* as instrument variables where Arellano and Bond (1991) suggest they are a useful instrument, if properly lagged. Denote $y_{(j)}$ to be lagged variable of independent variable (i.e., *Inv*, *Div* and *Debt* in our paper), and j denotes number of lags. We have

$$Z = \begin{pmatrix} y_{(1)} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & y_{(1)} & y_{(2)} & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & y_{(1)} & y_{(2)} & y_{(3)} & 0 & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & & & & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & y_{(1)} & \cdots & y_{(T-2)} \end{pmatrix},$$

$$A_N = \left(\frac{1}{N}\sum_{i}^{N} Z'HZ\right)^{-1}, \text{ and}$$

$$H = \begin{pmatrix} 2 & -1 & 0 & \dots & 0 & 0 & 0 & 0 & 0 & 0 \\ -1 & 2 & -1 & 0 & \dots & 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 2 & -1 & 0 & \dots & 0 & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & & & & \vdots & & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \dots & 0 & 0 & -1 & 2 & -1 \\ 0 & 0 & 0 & 0 & \dots & 0 & 0 & 0 & -1 & 2 \end{pmatrix}.$$

We further define a vector of lagged difference as $\Delta y\_$ and Δy denotes vector of dependent variable, then the GMM estimator □ for α_2, β_2 and γ_2, in models (7) to (9) is

$$\phi = \left[\left(\sum_i \Delta y_-' Z\right) A_N \left(\sum_i Z'\Delta y_-\right)\right]^{-1} \left(\sum_i \Delta y_-' Z\right) A_N \left(\sum_i Z'\Delta y_-\right), \text{ and variance for the parameter:}$$

$$\sigma^2 \left[\left(\sum_i \Delta y_-' Z\right) A_N \left(\sum_i Z'\Delta y_-\right)\right]^{-1}.$$

3.2.3. *Regressions for system equation models*

Past studies argue some relations among investment, dividend and debt financing[7]. To prevent the possible endogenous problems among investment, dividend, and debt financing decisions, we also apply two-stage least squares (2SLS) method that includes the other two policy choices into each one equation. Specifically, each equation contains the remaining two endogenous variables as explanatory variables along with other exogenous variables. The other exogenous variables in each equation are controlled as the previous mentions. The structural equations are estimated as follows:

$$\Delta Inv_{it} = \alpha_{1i} + \alpha_{2i}\Delta Div_{it} + \alpha_{3i}\Delta Debt_{it} + \alpha_{4i}Inv_{i,-1} + \alpha_{5i}Q_{it} + \epsilon_{it} \quad , \tag{10}$$

$$\Delta Div_{it} = \beta_{1i} + \beta_{2i}\Delta Inv_{it} + \beta_{3i}\Delta Debt_{it} + \beta_{4i}Div_{i,-1} + \beta_{5i}P_{it} + \eta_{it} \quad , \tag{11}$$

$$\Delta Debt_{it} = \gamma_{1i} + \gamma_{2i}\Delta Inv + \gamma_{3i}\Delta Div_{it} + \gamma_{4i}Debt_{i,t-1} + \gamma_{5i}\ln(A_{i,t-1}) + \gamma_{6i}E_{i,-1}/A_{i,t-1} + \xi_{it} \quad . \tag{12}$$

To ensure these equations by 2SLS, we use the fitted values obtained from regressing the endogenous variables on all exogenous variables in the system as the instrumental variable estimates of the endogenous variables ΔInv_i, ΔDiv_{it} and $\Delta Debt_{it}$ in (10), (11), (12).

4. Data and empirical results

4.1. *Data*

The sample consists of all dividend-paying U.S. firms listed on NYSE, AMEX, OTC, and NASDAQ stock markets from 1965 to 2012. All of our accounting variables are annual and collected from Compustat Annual Industrial Files. Following previous research (e.g., Cook and Tang, 2010; Fama and Fench, 2002; Huang and Ritter, 2009), we exclude financial firms (SIC 6000-6999) and regulated utilities (SIC 4900-4999) from the sample. We also require firms to have positive total assets and a number of common shares outstanding.[8]To increase the testing power in the regression analysis, we also require firms to survive 20 years or longer.[9] These exclusions leave us with complete information for 35,300 firm-year observations, which consists of 1,107 firms.

Table 1 presents summary statistics on the investment, dividend, and debt financing for

[7] Higgins (1972), Fama (1974), Morgan and Saint-Pierre (1978), Smirlock and Marshall (1983), Lee et al. (2011) and Chen et al. (2013) investigate the relationship between investment decision and dividend decision. Fama and French (2002) consider the interaction between dividend and financing decisions. Dhrymes and Kurz (1967), McDonald et al. (1975), McCabe (1979), Peterson and Benesh (1983), Switzer (1984), and Pruitt and Gitman (1991) argue that the investment decision is related to financing decision and dividend decision.

[8] These variables are used to deflate other variables and the results become difficult to interpret when they have non-positive values.

[9] The different sample selection criteria for the firms with different survive years (7 and 15 years) also have the similar results in Appendix Table A1.

different time periods. All of these variables are winsorized at the 1st and 99th percentiles to avoid the influence of extreme observations. Compared with different time periods, the investment during 1980s is the highest. This result may be from the simulating policies (e.g., the reduction of capital gain tax and the reduction of interest rate), which are promoted by U.S. President Ronald Reagan during the 1980s. Dividend payout is more likely to be reduced after the 1990s. Such finding is consistent with Fama and French (2001), Grullon and Michaely (2002), and Brav et al. (2005), indicating that repurchase is more prevalent to adopt than dividend payout in the recent decades. The average book leverage is 0.489 and the book leverage tends to be higher in later years than in earlier years.

[Insert Table 1 about here]

4.2. *Empirical results*

4.2.1. *Ordinary least squares results*

Table 2 shows OLS regression results for single equation models. Panel A presents averages of individual firms' coefficient estimates of the investment, dividend, and debt financing regressions, respectively. In the investment equation, we find the coefficient of lagged investment is significantly negative, which is the speed of adjustment of investment, indicating that firm adjust its investment toward its target level. The coefficient of lagged investment of our paper implies that, on average, the firm closes 46.8% of the gap between its actual and its desired investment levels. The output positively and significantly affects the change of investment, which is consistent with Fama (1974).

[Insert Table 2 about here]

In the dividend model, the coefficient of lagged dividend is -0.402 significantly negative, implying that firms adjust the firms' dividends to the targeted levels. The speed of adjustment indicates that the firms close about 40% of the gap between current and desired dividend levels within one year. This finding is consistent with the past studies which also confirm the possible adjustment of dividend to optimal dividends[10].The coefficient of P_{it} is significantly positive, implying the firms with high net income tend to increase to pay dividends.

In the debt financing equation, the coefficient of lagged leverage is -0.363 significantly negative. The result is consistent with Jalilvand and Harris (1984), Flannery and Rangan (2006), and Huang and Ritter (2009), which implies firms also tend to adjust toward the target leverage levels. The coefficient of $\ln(A_{i,t-1})$ is significantly positive, indicating that large firms leverage more than small firms. This finding results from that large firms tend to have a greater reputation and less information asymmetry than small firms and thus large firms can finance at a lower cost

[10] These papers include Lintner (1956), Fama and Babiak (1968), Spies (1974), Jalilvand and Harris (1984), Fama and French (2002), and Brav et al. (2005).

than small firms. The positive relation between size and leverage is consistent with Fama and French (2002), Flannery and Rangan (2006), and Frank and Goyal (2009). The coefficient of $E_{i,-1}/A_{i,t-1}$ is significantly negative. This result implies that more profitable firms have higher internal funds from their earnings and thus have less incentive to obtain the outside funds by debt issuing. The negative relationship between profitability and leverage is consistent with the findings of Long and Malitz (1985), Rajan and Zingales (1995), Fama and French (2002), and Flannery and Rangan (2006).

The negative coefficients of lagged investment, lagged dividend, and lagged debt financing in Panel A of Table 2 imply that firms tend to adjust towards target levels. However, from these lagged coefficients, we cannot directly judge which decision is more important for firms. Thus, we further calculate the standardized coefficients of lagged investment, dividend, and debt financing in order to compare these three decisions. The standardized coefficient is calculated by multiplying the unstandardized coefficient by the ratio of the standard deviation of the independent variable (i.e. the lagged terms) to the standard deviation of the dependent variable[11]. Panel B of Table 2 shows the speed-of-adjustment coefficients after standardization. The absolute value of coefficients of lagged investment and lagged debt financing are larger than the absolute value of coefficient of lagged dividend. This result indicates that firms adjust toward the target investment and debt levels more quickly than the target dividend payment. In addition to the case with firm surviving 20 years or longer, we also examine speed of adjustments upon different sample selection criteria for the firms with different survive years (7 and 15 years). All these results are quantitatively similar. We present the results in Appendix Table A1.

4.2.2. *Dynamic generalized-method-of-moments results*

The investment, dividend, and debt in our sample are panel data and thus may have autocorrelation. For example, Skinner (2008) finds that firms' dividend payout decisions are substantially affected by their dividend history. Thus, as a robustness check, we estimate the speed of adjustment by panel regression; that is, for each corporate policy, we carry regression analysis by pooling all firm-year observations in one regression model. As the above mention, the GMM estimation of dynamic panel regression, which uses the first difference and lag dependent variables as instruments to calculate the asymptotic estimators, helps to solve the endogenous problem of individual-specific time-invariant effects.

The results of GMM estimation of dynamic panel regression for each corporate policy are shown in Table 3. Panel A of Table 3 shows the coefficients of lagged investment, lagged dividend and lagged debt financing are significantly negative, also indicating the mean-reverting for these three decisions. The influence of control variables in the GMM estimation also has thesimilar result as the OLS. Specifically, the firms with higher outputs need greater investment input; firms with higher net income are more likely to pay more dividends; large firm needs more debt financings; firms with higher internal funds have less incentive to issue debt financings.

[11] The standardized estimates of speed-of-adjustment coefficient are comparable because they all refer to one standard deviation change in their respective independent variables rather than a one unitchange.

Panel B of Table 3 shows the speed of adjustment by standardizing coefficients of lagged investment, lagged dividend, and lagged debt financing. By comparing these three speed of adjustment, we also find the similar result of OLS, namely, the adjustments toward the target investment and debt levels are more quick than the adjustment toward the target dividend payment. Thus, we find that our main conclusions are still valid in this GMM approach.

[Insert Table 3 about here]

4.2.3. *Two-stage least squares results*

Table 4 shows results of 2SLS of (10), (11), and (12). Panel A presents the means of individual firms' 2SLS coefficients across the 1,107 firms. The results of relations among these three financial decisions could be directly obtained in this method. First, the significantly positive coefficient of $\Delta Debt_{it}$ (in investment decision), and ΔInv_{it} (in debt financing decision) imply that firms with higher investment changes have higher debt financing changes and vice versa. Ross (1977) and Myers and Majluf (1984) suggest that debt is preferred to equity for managers to signal the optimistic investment opportunity to investors because the firms are expected to have higher future cash flows to repay the debt. Harris and Raviv (1990) argue that debt is a device to solve the asymmetric information for the investors because it helps to monitor managers and force the firm to liquidation. In addition, our finding that increases in debt financing enhance the funds available to outlays for investment is consistent with McCabe (1979), Peterson and Benesh (1983), John and Nachman (1985), and Froot et al. (1993). Thus, our optimal debt ratio may be the result of a trade-off between the value of information (from more debt) and the cost of monitor.

[Insert Table 4 about here]

Second, the significant coefficients of $\Delta \mathrm{Di}v_{it}$ and ΔInv_{it} imply that dividend outlays influence investment decisions and vice versa. This finding implies that the firms may use dividend payout to signal the growth opportunity and then these firms increase their investment. The firm with higher investment input may experience the higher earnings and thus could increase the dividend payout. Such finding, that dividend payout responds to investment, confirms the model prediction of Lambrecht and Myers (2012). The relationship between dividend payout and investment is also consistent with the signaling cash flow hypothesis of dividend payout in Yoon and Starks (1995).

Third, the changes of dividend on the change of debt financing are significantly negative, showing that the firms need less debt financing when they are capable of paying more dividend. This finding is consistent with the economics intuition that the firms with higher dividend payout usually have greater earnings (e.g., Lintner, 1956; Skinner, 2008) and thus have less incentive to issue debt financing. In addition, the increases in debt financing seem to enhance the funds available to outlays for dividend payout, implying that firms may transfer the wealth from bondholders to shareholders.

By comparing the results from these methods, we find all the coefficients of lagged investment, lagged dividend and lagged debt financing are negative significantly. This result supports our hypothesis 1, implying that these three policies tend to be adjusted to the optimal levels. All the exogenous variables have a similar impact as in the single equation models. In addition, all of the three equations in the 2SLS regressions have greater adjusted R-squares than that of OLS regressions. Thus, after considering the possible endogenous problems, we still obtain the similar result. Namely, firms tend to adjust toward the target investment, debt financing, and dividend levels. In Panel B of Table 4, we also show the speed-of-adjustment coefficients after standardization. By comparing the speed of adjustment of these three policies, we find that investment and debt financing decisions adjust more quickly than dividend payment. This finding is also consistent with the results of OLS and GMM.

Such a finding of speed of adjustment seems to have the following implication. The past studies (such as Brav et al., 2005; Garrett and Priestley, 2000) find that managers are reluctant to cut dividends because they want to prevent changing the investors' prospective. The dynamic Linter model suggested by Lambrecht and Myers (2012), which jointly incorporates the investment and debt into the payout policy, also suggest the payout adjusts smoothly than debt financing. In contrast to the dividend payout, investment is a relatively short-term decision. Usually, firms need to pursue good opportunities to earn profits and thus adjust investment quickly. In addition, firms need to raise fund from capital markets when the internal funds are insufficient for new investment projects. The investment infusion financed from debt may result in that debt financing is adjusted quickly to match the adjustment of the investment. Thus, the comparing results among speed of adjustment ofthese three decisions confirm the economic intuition and the past studies.

5. The determinants for the speed of adjustment

This section examines the effect of market concentration, capital-labor intensity, and firm size on the speed of adjustment. Any decision by firms is affected by their characteristics and the relationship with their competitors. First, we examine the relationship between the speed of adjustment and the industry effect. Fig. 1, Fig. 2, and Fig. 3 show the adjustment coefficients of investment, dividend, and debt financing, respectively, grouped by Fama-French 48 industry classifications. The negative speed of adjustment in all industries implies that firms still adjust toward the target investment, dividend, and debt levels even in different industries. In addition, Fig. 1 shows that firms in commodity sectors (such as tobacco products and food products) adjust their investment levels faster than ones in heavy industries (such as construction and steel works). This result is consistent with the economics intuition that firms in heavy industries tend to have higher capital and thus need more time to adjust toward their target investment level.

[Insert Figures 1, 2, and 3 about here]

Table 5 presents the speed of adjustment for corporate decisions sorted by Herfindahl–Hirschman Index (HHI). HHI is the sum of squared market shares in Fama-French 48 industries constructed from 4-digit Standard Industrial Classification (SIC) industry groupings. Firms with high HHI means firms are in a high concentration market or a low competitive market. Regarding the speed of adjustment for investment and dividend, we do not find any relationship with the market concentration. In addition, there is significantly positive relation between the speed of adjustment of capital structure and the market concentration, implying the higher speed of adjustment of debt financing for the oligopolistic firms. Thus, debt financing supports our hypothesis 2. Brander and Lewis (1986) suggest that compared with the monopolist or the perfectly competitive firms, oligopolistic firms tend to adjust financial structure to react the rival firms in influencing their output market. Our paper is consistent with Brander and Lewis (1986).

[Insert Table 5 about here]

Table 6 presents the speed of adjustment for corporate decisions sorted by capital-labor intensity. The capital-labor intensity is defined as net plant and equipment divided by number of employees. The speed of adjustment of investment decision is negatively related to the degree of capital-labor intensity. That is, capital-intensive firms adjust their investment more slowly than labor-intensive firms. This finding is consistent with the economic implication that capital-intensive firms with greater fixed production factors (i.e. capital) have less flexibility and thus need more time to adjust toward their target investment level. In addition, the speed of adjustment of capital structure is also negatively associated with capital-labor intensity. Debt could be used to finance the investment needs for firms, thus a low speed of adjustment in investment causes a low speed of adjustment of debt financing. Consequently, the adjustments of investment and debt financing support hypothesis 3.

[Insert Table 6 about here]

Table 7 presents the speed of adjustment for corporate decisions sorted by firm size. Firm size is defined as the natural logarithm of total assets (*lnA*). The speed of adjustment of investment is not significantly related to the degree of firm size. Also, the speed of adjustment of dividend is not related to the firm size. For debt financing, small firms adjust faster to the target leverage than large firms do. Big firms have an advantage in lower adjustment cost because of the economies of scale while small firms have an advantage in flexibility of adjustment because of greater interaction among departments (Fiegenbaum and Karnani, 1991; Neilsen, 1974). Our result that small firms adjust debt financings faster than big firms tends to support that small firms have the flexibility to react to the environmental change. This finding is consistent with Leary and Roberts (2014) that smaller firms are highly influenced by their large peers and small firms tend to adjust their financial structure to react to the peers' effects. The result in this table shows that the adjustments of debt financing support hypothesis 4b.

[Insert Table 7 about here]

6. Conclusion

This paper investigates whether firms dynamically alter their corporate decisions of investment, financing, and dividend payment. We estimate and compare the speed of adjustment of the three decisions. Using U.S. listed firms from 1965 to 2012, we find that those variables are mean-reverting, indicating that firms adjust their levels of investment, leverage, and dividend towards optimal levels.

By comparing the speed of adjustment of these three corporate decisions, we find that investment and leverage are altered faster than dividend payment. This result confirms the argument of past studies that firms tend not to change their dividend in order to prevent changing the investors' prospective. In addition, this finding also implies that firms usually adjust investment and debt financing quickly for pursuing good opportunities.

With respect to the determinants of speed of adjustment, we find that less competitive firms (i.e. oligopolistic firms) tend to adjust debt financing faster to react to the rival firms in the market. This result is consistent with Brander and Lewis (1986). In addition, capital-intensive firms adjust investment and debt financing more slowly than labor-intensive firms. Finally, we find that small firms adjust debt financing faster than big firms. These findings tend to support that the flexibility from firm with small size rather than the lower adjustment cost from firm with large size.

This table presents the summary statistics where we show the mean, median, first quartile, third quartile, and the standard deviation of each variable from 1965 to 2012. N is the number of firm-year observations. The sample consists of 35,300 firm-year observations from annual Compustat files, excluding financial and regulated firms. Inv denotes net property, plant, and equipment. Div denotes dividends. Both v and Div are measured on a per share basis. $Debt$ refers to book leverage, defined as the ratio of total liabilities to total assets. All variables are winsorized at the 1st and 99th percentiles to avoid the influence of extreme observations.

Table 2

Results of OLS regression.

Independent Variables \ Dependent Variables	ΔInv_{it}	ΔDiv_{it}	$\Delta Debt_{it}$
Panel A: Regression analyses of investment, dividend and debt financing			
Constant	0.406	0.054	0.133
	(3.95)	(8.23)	(17.86)
$Inv_{i,t-1}$	-0.468		
	(-66.98)		
$Div_{i,t-1}$		-0.402	
		(-55.06)	
$Debt_{i,t-1}$			-0.363
			(-50.61)
Q_{it}	0.164		
	(26.64)		
P_{it}		0.073	
		(34.27)	
$\ln(A_{i,t-1})$			0.009
			(8.08)
$E_{i,t-1}/A_{i,t-1}$			-0.130
			(-10.59)
Adjusted R-squares	0.46	0.35	0.16
Panel B: Standardized coefficients of lagged investment, dividend and debt financing			
$Inv_{i,t-1}$	-0.805		
	(-65.69)		
$Div_{i,t-1}$		-0.591	
		(-59.81)	
$Debt_{i,t-1}$			-0.594
			(-51.92)

This table presents the OLS regression results of investment, dividend, and debt financing, respectively:

$$\Delta Inv_{it} = \alpha_{1i} + \alpha_{2i} Inv_{i,t-1} + \alpha_{3i} Q_{it} + \epsilon_{it} \quad ,$$
$$\Delta Div_{it} = \beta_{1i} + \beta_{2i} Div_{i,t-1} + \beta_{3i} P_{it} + \eta_{it} \quad ,$$
$$\Delta Debt_{it} = \gamma_{1i} + \gamma_{2i}\, Debt_{i,t-1} + \gamma_{3i} \ln(A_{i,t-1}) + \gamma_{4i} E_{i,t-1}/A_{i,t-1} + \xi_{it} \quad .$$

In Panel A, the coefficients are shown in averages across the 1,107 firms. Regressions are based on non-missing observations and winsorization at the 1st and 99th percentiles. The three dependent variables are ΔInv_{it}, ΔDiv_{it}, and $\Delta Debt_{it}$, which are the change in net plant and equipment, the change in dividends, and the change in book leverage ratio, respectively. The independent variables in the investment regression are lagged investment ($Inv_{i,-1}$), and sales plus change in inventories (Q_{it}). The independent variables in the dividend regression are lagged dividends ($Div_{i,-1}$), and net income before extraordinary items plus depreciation minus preferred divi-dends (P_{it}). All the variables in both of investment and dividend equations are measured on a per share basis. The independent variables in the debt financing regression are lagged book leverage ($Debt_{i,-1}$), natural logarithm of lagged total assets ($\ln(A_{i,t-1})$), and the lag of earnings before interest and taxes divided by total assets($E_{i,t-1}/A_{i,t-1}$). Panel B shows the average standardized coefficients of speed-of-adjustment across the firms, that is, the coefficients of lagged investment, dividend, and debt financing. The standardized coefficient is calculated by multiplying the unstandardized coefficient by the ratio of the standard deviation of the independent variable (i.e. the lagged terms) to the standard deviation of dependent variable. Numbers in the parentheses are t-statistics.

Table 3

Results of GMM estimation of dynamic panel regression

Independent Variables \ Dependent Variables	ΔInv_{it}	ΔDiv_{it}	$\Delta Debt_{it}$
Panel A: Regression analyses of investment, dividend and debt financing			
Constant	-0.096 (-2.41)	-0.000 (-0.22)	-0.001 (-1.00)
$Inv_{i,t-1}$	-0.431 (-23.62)		
$Div_{i,t-1}$		-0.581 (-45.52)	
$Debt_{i,t-1}$			-0.651 (-18.42)
Q_{it}	0.142 (20.51)		
P_{it}		0.093 (23.15)	
$\ln(A_{i.t-1})$			0.032 (2.60)
$E_{i,t-1}/A_{i,t-1}$			-0.269 (-6.29)
Panel B: Standardized coefficients of lagged investment, dividend and debt financing			
$Inv_{i,t-1}$	-1.793		
$Div_{i,t-1}$		-1.501	
$Debt_{i,t-1}$			-1.862

This table presents the results of Generalized-Method-of-Moments (GMM) of dynamic panel regression of investment, dividend, and debt financing, respectively, by pooling all firm year observations:

$$\Delta Inv_{it} = \alpha_{1i} + \alpha_{2i} Inv_{i,t-1} + \alpha_{3i} Q_{it} + \epsilon_{it} \quad ,$$

$$\Delta Div_{it} = \beta_{1i} + \beta_{2i} \mathrm{Div}_{i,t-1} + \beta_{3i} P_{it} + \eta_{it} \quad ,$$

$$\Delta Debt_{it} = \gamma_{1i} + \gamma_{2i}\, Debt_{i,t\text{-}1} + \gamma_{3i} \ln(A_{i,t-1}) + \gamma_{4i} E_{i,t-1}/A_{i,t-1} + \xi_{it} \quad .$$

The GMM estimations are based on non-missing observations and winsorization at the 1st and 99th percentiles. The three dependent variables are ΔInv_{it}, ΔDiv_{it}, and $\Delta Debt_{it}$, which are the change in net plant and equipment, the change in dividends, and the change in book leverage ratio, respectively. The other variables are the same as in Table 2. Numbers in the parentheses are t-statistics.

Table 4 Results of 2SLS regression.

Independent Variables \ Dependent Variables	ΔInv_{it}	ΔDiv_{it}	$\Delta Debt_{it}$
Panel A: Regression analyses of investment, dividend and debt financing			
Constant	0.449 (4.76)	0.026 (1.60)	0.126 (15.10)
$Inv_{i,t-1}$	-0.346 (-38.10)		
$Div_{i,t-1}$		-0.290 (-34.16)	
$Debt_{i,t-1}$			-0.350 (-42.08)
ΔInv_{it}		0.035 (8.73)	0.016 (5.88)
ΔDiv_{it}	5.715 (9.64)		-0.087 (-7.36)
$\Delta Debt_{it}$	9.890 (10.07)	0.423 (5.43)	
Q_{it}	0.113 (19.15)		
P_{it}		0.049 (20.48)	
$\ln(A_{i.t-1})$			0.009 (6.93)
$E_{i,t-1}/A_{i,t-1}$			-0.117 (-7.68)
Adjusted R-squares	0.52	0.47	0.20
Panel B: Standardized coefficients of lagged investment, dividend and debt financing			
$Inv_{i,t-1}$	-0.591 (-38.88)		
$Div_{i,t-1}$		-0.411 (-40.32)	
$Debt_{i,t-1}$			-0.577 (-40.23)

This table presents the 2SLS regression results of a simultaneous equation system model for investment, dividend, and debt financing:

$$\Delta Inv_{it} = \alpha_{1i} + \alpha_{2i}\Delta Div_{it} + \alpha_{3i}\Delta Debt_{it} + \alpha_{4i} Inv_{i,-1} + \alpha_{5i} Q_{it} + \epsilon_{it} \quad ,$$
$$\Delta Div_{it} = \beta_{1i} + \beta_{2i}\Delta Inv_{it} + \beta_{3i}\Delta Debt_{it} + \beta_{4i} Div_{i,-1} + \beta_{5i} P_{it} + \eta_{it} \quad ,$$
$$\Delta \mathrm{Debt}_{it} = \gamma_{1i} + \gamma_{2i}\Delta Inv_{it} + \gamma_{3i}\Delta \mathrm{Div}_{it} + \gamma_{4i}\mathrm{Debt}_{i,-1} + \gamma_{5i}\ln(A_{i,t-1}) + \gamma_{6i} E_{i,t-1}/A_{i,t-1} + \xi_{it} \quad .$$

Panel A shows the coefficients in averages across the 1,107 firms. Regressions are based on non-missing observations and winsorization at the 1st and 99th percentiles. The three endogenous variables are ΔInv_{it}, $\Delta \mathrm{D}iv_{it}$, and $\Delta \mathrm{D}ebt_{it}$, which are the change in net plant and equipment, the change in dividends, and the change in book leverage ratio, respectively. The other variables are the same as in Table 2. Panel B shows the average standardized coefficients of speed-of-adjustment across the firms, that is, the coefficients of lagged investment, dividend, and debt financing. The standardized coefficient is calculated by multiplying the unstandardized coefficient by the ratio of the standard deviation of the independent variable (i.e. the lagged terms) to the standard deviation of dependent variable. Numbers in the parentheses are t-statistics.

Table 5

Speeds of adjustment sorted by market concentration.

HHI	N	$Inv_{i,t-1}$	$Div_{i,t-1}$	$Debt_{i,t-1}$
$0 \leq$ HHI < 0.02	216	-0.479 (-32.75)	-0.380 (-23.70)	-0.357 (-23.11)
$0.02 \leq$ HHI < 0.028	236	-0.433 (-26.32)	-0.400 (-23.11)	-0.340 (-20.55)
$0.028 \leq$ HHI < 0.04	212	-0.482 (-29.88)	-0.389 (-25.13)	-0.345 (-21.83)
$0.04 \leq$ HHI < 0.055	210	-0.473 (-30.50)	-0.426 (-25.56)	-0.368 (-24.80)
$0.055 \leq$ HHI	233	-0.474 (-31.64)	-0.414 (-26.25)	-0.401 (-23.97)
ANOVA ProbF		0.142	0.286	0.045

This table presents the coefficients of speed-of-adjustment, that is, the coefficients of lagged investment, dividend, and debt financing in the three OLS regression models, sorted by Herfindahl–Hirschman Index (HHI). HHI= $\sum_{i=1}^{N} S_i^2$, where Si is the market share of firm in the belonging Fama and French 48 industry. Market share (Si) is calculated as sales of firm i divided by the sum of total sales in the industry. Numbers in the parentheses are t-statistics. HHI is the sum of squared market shares in Fama-French 48 industries constructed from 4-digit Standard Industrial Classification (SIC) industry groupings.

Table 6

Speeds of adjustment sorted by capital-labor ratio.

Capital-labor Intensity	N	$Inv_{i,t-1}$	$Div_{i,t-1}$	$Debt_{i,t-1}$
$0 \leq K/L < 13$	212	-0.483 (-30.45)	-0.427 (-23.83)	-0.426 (-25.29)
$13 \leq K/L < 22$	230	-0.500 (-36.71)	-0.377 (-24.93)	-0.357 (-20.95)
$22 \leq K/L < 35$	221	-0.498 (-30.51)	-0.396 (-23.63)	-0.351 (-21.70)
$35 \leq K/L < 80$	207	-0.460 (-28.10)	-0.395 (-23.52)	-0.338 (-22.50)
$80 \leq K/L$	212	-0.402 (-25.54)	-0.405 (-25.35)	-0.339 (-22.68)
ANOVA ProbF		<.0001	0.308	0.0005

This table presents the coefficients of speed-of-adjustment, that is, the coefficients of lagged investment, dividend, and debt financing in the three OLS regression models, sorted by capital-labor ratio (K/L). K/L = net plant and equipment / Number of employees. *N* is the number of firm-year observations. Numbers in the parentheses are t-statistics.

Table 7

Speeds of adjustment sorted by firm size.

Size	N	$Inv_{i,t-1}$	$Div_{i,t-1}$	$Debt_{i,t-1}$
$0 \leq lnA < 4.5$	240	-0.444 (-28.32)	-0.392 (-22.84)	-0.387 (-25.54)
$4.5 \leq lnA < 6$	235	-0.478 (-31.69)	-0.406 (-25.46)	-0.376 (-23.29)
$6 \leq lnA < 7$	231	-0.488 (-31.45)	-0.417 (-26.22)	-0.391 (-23.58)
$7 \leq lnA < 8$	182	-0.490 (-29.85)	-0.383 (-22.15)	-0.339 (-18.21)
$8 \leq lnA$	219	-0.442 (-29.30)	-0.407 (-27.04)	-0.310 (-23.70)
ANOVA ProbF		0.058	0.6235	<.0001

This table presents the coefficients of speed-of-adjustment, that is, the coefficients of lagged investment, dividend, and debt financing in the three OLS regression models, sorted by firm size. The proxy for firm size is the natural logarithm of total assets (lnA). N is the number of firm-year observations. Numbers in the parentheses are t-statistics.

Appendix Table A1

OLS Results of different sample selection criteria.

In this study, we reconfirm the pervasively documented diversification discount in the 2000-2013 sampling period. First, we decompose firms according to their diversification status and subsequent changes in diversification, and then explore the determinants and consequences of the changes in firm diversification. We find a unilateral relationship between diversification and firm value: an increase (decrease) in firm diversification is followed by a decrease (an increase) in firm value, but not the reverse. The factors that dictate changes in a firm's diversification are profitability and capital expenditure. On average, diversified firms are associated with 12.2% lower excess value than their focused counterparts. Moreover, firms that increase their degree of diversification are associated with 10.3% lower excess value than their unchanged counterparts. Finally, we find that a low coinsurance effect and managerial entrenchment are the two main factors that explain the diversification discount.

Keywords: diversification discount, coinsurance, entrenchment

1. Introduction

Firm diversification has been widely studied both theoretically and empirically for more than three decades. The main issue of debate is whether diversification increases or decreases firm value. Proponents of the former argument mainly refer to the potential benefits, such as greater operating efficiency, less incentive to forsake positive net-present-value projects, greater debt capacity, and lower taxes (e.g., Fluck and Lynch, 1999; Bradley et al., 1998; Kaplan and Weisbach, 1992; Porter, 1987; Ravenscraft, 1987, among others). Arguments supporting the latter indicate that diversification gives managers discretionary resources to undertake value-decreasing investments, and to cross-subsidize poor segments that drain resources from better-performing segments and create potential conflicts of interest between central and divisional managers(e.g., Comment and Jarrell, 1995; Liebeskind and Opler, 1995; Lang and Stulz, 1994; Servaes, 1996; Berger and Ofek, 1995; Denis et al., 2002).Recent studies seem to partially alleviate the negativity of diversification and propose that it may be beneficial, or at least not value destroying (Villalonga, 2004; Whited, 2001; Campa and Kedia, 2002; Mansi and Reeb, 2002). These studies attribute the diversification discount to the acquisition of poorly performing units (Graham et al., 2002) or to miscalculations of Tobin's Q (Whited, 2001).Nevertheless, Santalo and Becerra (2008) indicate that the effect of diversification on performance is not homogeneous across industries: diversified firms perform better in industries with a small number of non-diversified competitors or when specialized firms have a small combined market share, but worse when specialized firms increase in number and compete strongly.

The first part of this study revisits the controversial issue of whether diversification is value incremental or detrimental. Using data on U.S. listed firms in the 2000-2013 period, we find that diversification is indeed value detrimental, regardless of whether firm value is measured by Tobin's Q or the excess value proposed by Berger and Ofek (1995). Because diversification and firm value may be endogenously determined, we identify firms' diversification status and inter-temporal changes in diversification status, and then explore the determinants and consequences of these changes. The decomposition in firms' diversification status and changes in diversification may partially ameliorate the endogeneity issue associated with diversification and firm value. For example, if diversification and firm value are reciprocally affected, we would expect to find that a firm's value affects its subsequent diversification (change) status, which will in turn affect the firm's value in the next period.

Using logistic regression, we find that assets, profitability, capital expenditure, and leverage are the possible determinants of firms' changes in diversification status. However, the effects on diversified and focused firms are somewhat different. After showing a decrease in profitability, diversified firms tend to refocus their domain of businesses in the following period. They also tend to choose a refocused strategy after an increase in financial leverage. Focused firms are prone to increase the degree of diversification after experiencing an increase in profitability and are more likely to focus their domain of business after an increase in capital expenditure. We note that firm value is not in the array of possible determinants. We further investigate the effect of a change in diversification on a firm's follow-on value. The result indicates that an increase (decrease) in diversification is followed by a decrease (increase) in value. In a nutshell, our empirical results indicate that a change in a firm's diversification affects its value. However, a change in value does not affect a firm's change in diversification. The relationship between diversification and firm value is robust to alternative methods of identifying firms' diversification status and measures of firm value.

After identifying the detrimental effect associated with diversification, we further explore the possible factors influencing the diversification discount. The first factor is relative value added, proposed by Rajan, Servaes, and Zingales (2000), who indicate that the efficiency of redeploying assets or resources within a conglomerate could affect the value of diversification. Specifically, they argue that funds that are transferred among divisions with similar levels of resources and opportunities are efficient, while those that are transferred among divisions with diversified resources and opportunities are inefficient. The relative value added measure is used to gauge investment efficiency within diversified firms compared with that of single-segment firms. Unfortunately, we fail to find supporting evidence that the relative efficiency of redeploying assets affects the diversification discount.

The second factor of interest is the coinsurance effect proposed by Lewllen (1971) and Hann, Ogneva, andOzbas (2013). If coinsurance reduces default risk (Lewellen, 1971) and enables a diversified firm to avoid the countercyclical deadweight costs of financial distress (Elton, Gruber, Agrawal, and Mann, 2001; Almeida and Philippon, 2007), then coinsurance should lead to a reduction in a diversified firm's systematic risk and hence the cost of capital. Hann et al. (2013) use the correlation of cash flows among segments within a diversified firm as the surrogate of the coinsurance effect and find that diversified firms on average have a lower cost of capital than comparable portfolios of standalone firms. Moreover, diversified firms with less correlated segment cash flows have a lower cost of capital. Our empirical result indicates that the correlation between cash flows within a diversified firm is negatively correlated with its value. This supports the coinsurance effect, indicating that one reason diversified firms are associated with value detriment is that their lines of business are too homogeneous to reduce risks that could be mutually offset.

The third factor of interest is managerial entrenchment. Jiraporn, Kim, Davidson, and Singh (2006) illustrate that firms in which shareholder rights are more suppressed by restrictive corporate governance suffer a deeper diversification discount. Specifically, one additional governance provision results in a 1.1–1.4% decline in firm value. Hoechle, Schmid, Walter, and Yermack (2012) find that the diversification discount narrows by 16 to 21% when they add governance variables as regression controls. Bebchuk et al. (2004) construct an "Entrenchment Index" to measure managerial entrenchment based on 6 of the 24 governance provisions in Gompers et al. (2003). The six provisions included in the Entrenchment Index are staggered boards, limits to shareholder bylaw amendments, supermajority requirements for mergers, supermajority requirements for charter amendments, poison pills, and golden parachutes. They contend that this index can better explain firm value and stock returns than the 24-provision governance index. We also calculate the entrenchment index and find that it is negatively correlated with the value of diversified firms.

A synopsis of our findings is that we find a unilateral negative effect of diversification on firm value, which is mainly due to a low coinsurance effect and managerial entrenchment.

This paper makes two potential contributions. First, we decompose firms' diversification status. With this base, we trace the determinants and consequences of firms' changes in diversification. The decomposition at least partially ameliorates the endogeneity concern between firm value and diversification because we find no reciprocal or inter-temporal relationship. Second, we identify low coinsurance and high managerial entrenchment as the main causes of the diversification discount.

The remainder of this paper is organized as follows. Section 2 reviews the related literature. Section 3 depicts the sample and variable. Section 4 reports the empirical findings and Section 5 concludes.

2. Literature Review and Hypotheses Development

2.1. *Diversification and Firm Value*

Studies indicate that diversified firms tend to underperform and have lower values than their focused counterparts (Berger and Ofek, 1995; Lang and Stulz, 1994; Servaes, 1996). Hoechle et al. (2012) find that the diversification discount persists even when controlling for endogeneity. The negative effect of diversification on firm value seems to be robust in studies using different periods and countries[1]. An intuitive explanation is that diversification itself destroys value.

However, not all theories predict that diversification is detrimental to firm value. The benefits associated with diversification include tax benefits and a reduction in the probability of financial distress (Lewellen, 1971), and in information asymmetry (Hadlock et al., 1999). Another advantage of diversification, which is supported by empirical studies using samples from the 1960s (e.g., Hubbard and Palia, 1999; Fulghieri and Hodrick, 1997; Stein, 1997; Wulf, 2000), is related to the efficiency of the internal capital market.

We propose a possible resolution for these seemingly contradictory arguments. The crux probably lies in the tradeoff between the agency problem and the comparative efficiency of the internal capital market. Diversification is negatively associated with firm value when the agency problem outweighs the comparative efficiency of the internal capital market, and vice versa. It could also be that the comparative efficiency of the internal capital market has dwindled with the passage of time because external capital markets have become much more developed in the past decade. Therefore, cases of diversification that took place at a later point in time are more likely to have been value-destroying than value-enhancing. Given that most of the cases of diversification we investigate took place after the 1990s, the first hypothesis is proposed as follows.

Hypothesis 1: Diversification is negatively correlated with firm value.

---

[1] Servaes (1996) finds a discount for conglomerates during the 1960s. Lins and Servaes (1999) document a significant discount in Japan and the UK, although none exists for Germany. However, the evidence from emerging economies is mixed: Lins and Servaes (1998) report a diversification discount in a sample of firms from seven emerging markets, while Khanna and Palepu (1999), Fauver, Houston and Naranjo (1998) find little evidence of a diversification discount in emerging markets.

However, firm value and diversification could either be endogenously related or simultaneously affected by firm characteristics. For example, Campa and Kedia (2002) indicate that firm characteristics that cause firms to diversify also cause them to be discounted. Himmelberg, Hubbard, and Palia (1998), Agrawal and Knoeber (1996), and Holthausen and Larcker (1993) control for the endogeneity of managerial ownership in evaluating the relationship between managerial ownership and performance. These papers follow the insight of Demsetz and Lehn (1985) by presenting models indicating that managerial ownership, as optimally determined by firms, is structured in such a way as to maximize firm value when the firm's contracting environment is heterogeneous. Campa and Kedia (2002) and Villalonga (2004) alternatively use instrumental variables, Heckman's two stage approach, and propensity scoring matching to control the endogeneity issue. They conclude that diversification is not detrimental to value; rather, it is associated with a positive spillover effect. In contrast, Lamont and Polk (2002) find that diversification remains detrimental after controlling for the endogeneity issue. Santalo et al. (2008) question the legitimacy of using instrumental variables by indicating that some of the instruments are questionable if industry heterogeneity is taken into account.

In this study, we characterize firms' diversification status into focused and diversified firms, and further categorize changes in status into refocused, no change, and more diversified. This decomposition allows us to mitigate the endogeneity issue. For example, if firm value and diversification are simultaneously determined by certain firm characteristics, the decomposition should be able to isolate the effects of firm characteristics when they are included in the empirical models. Moreover, if firm value and diversification are reciprocally affected, we would expect them to be inter-temporally related. However, our empirical findings do not support this argument. Finally, we relate changes in diversification to changes in firm value. The endogeneity issue is less severe for variables that are differentially treated.

2.2. *Factors Affecting the Value of Diversified Firms*

Previous studies (Lamont, 1997; Shin and Stulz, 1998) show that resource allocation in diversified firms differs from that in focused firms. Therefore, there seems to be a connection between resources allocation and the value of diversified firms. Berger and Ofek (1995) find that the investment in segments with a low Q is the main cause of the diversification discount. Other studies also indicate that the misallocation of resources results, on average, in diversified firms trading at a discount relative to a portfolio of single-segment firms in the same industries (Lang and Stulz, 1994; Berger and Ofek, 1995; Servaes, 1996; Lins and Servaes, 1999).

The allocation among segments of a diversified firm involves at least three theories. The first is the efficient internal capital market, which suggests that diversified firms form an internal capital market in which internally generated cash flows can be pooled and allocated to their best use (e.g., Matsusaka and Nanda, 1997; Stein, 1997; Weston, 1970; Williamson, 1975). The second is the agency cost model, which indicates that top management in diversified firms has greater opportunities to undertake negative net present value (NPV) projects (Stulz, 1990; Matsusaka and Nanda, 1997). Therefore, the decision to diversify could be viewed as an attempt by the CEO to entrench herself (Shleiferand Vishny, 1989). The third is the influence of cost models. As indicated by Meyer, Milgrom, and Roberts (1992), managers of bleak-future divisions have an incentive to influence the top management of the firm to channel resources in their direction.

Rajan, Servaes, and Zingales (2000) model the distortions that arise from internal power struggles and predict that funds are allocated efficiently if divisions have similar resources and opportunities, and are inefficiently allocated if divisions have varied resources and opportunities. We follow the relative value added measure proposed by Rajan et al. (2000), and postulate that it is positively correlated with the value of diversified firms.

Hypothesis 2: Diversified firms with better asset-redeployment efficiency, as manifested in a higher relative value added, are associated with a smaller diversification discount.

Hann, Ogneva, and Ozbas (2013) indicate that the imperfect correlation of cash flows among a firm's business units creates a coinsurance effect that can reduce systematic risk through the avoidance of countercyclical deadweight costs. The deadweight costs faced by firms include costly financial distress, adverse selection and transaction costs of external financing that result in investment distortions, forgone business opportunities due to defections by important stakeholders such as suppliers, customers, or employees, and so on. As these deadweight costs may be mitigated by the coinsurance effect, diversified firms with a high coinsurance effect have a lower default risk (Lewellen, 1971) that would otherwise have been incurred by standalone firms. The reduction in systematic risk gives diversified firms a lower cost of capital.

Hypothesis 3: Diversified firms with a higher coinsurance effect, as manifested in low correlations of cash flows among business units, are associated with a smaller diversification discount.

Managers who have access to free cash rights tend to spend it unwisely to reduce shareholder value (Jensen, 1986). One possible way for managers to waste free cash flow is to expand the firm through acquisitions in unrelated business segments that may not supply adequate returns to shareholders. However, this detrimental diversification can be constrained if shareholder rights are strong. Hoechleet al.(2012) suggest that better corporate governance is associated with less value destruction (or more value creation) when diversifying mergers occur. In this paper, we follow Gompers et al. (2003) and Bebchuck et al. (2009)in using the number of antitakeover provisions as the measure of shareholder rights. The Entrenchment Index, according to Bebchuck et al. (2009), measures how many of the six antitakeover provisions are implemented. The more antitakeover provisions, the higher the index, and the weaker the shareholder rights. Our fourth hypothesis is formulated as follows.

Hypothesis 4: Diversified firms with weaker shareholder rights, as manifested in a high Entrenchment Index, are associated with a larger diversification discount.

3. Sample and Variables

3.1. *Sample*

Our sample of U.S. listed firms in the 2000-2013 period was collected from the Compustat database. Following Berger and Ofek (1995), the following criteria were imposed on the sample selection: (1) all firms with at least one segment in the financial industry(SIC codes between 6000 and 6999) were excluded from the sample; (2) all firm-years with sales lower than $20 million were excluded to avoid distortion in valuation multiples; (3) the sum of segment sales had to be within 1% of the firm's total sales to ensure the integrity of the segment data; and (4) all of the firm segments with missing data for assets, sales, and equity value were excluded. The final sample of 32,643 firm-year observations is summarized in Table 1. The distribution shows that focused firms (23,944 firm-year observations) outnumber diversified firms (8,699 firm-year observations). The proportion of focused firms is in the range of 69-75%, and that of diversified firms is in the range of 25-31%.

3.2. *Valuation*

We use two methods to gauge firm value: Tobin's Q (Lang and Stulz, 1994) and excess value (Berger and Ofek, 1995). The measurement of Tobin's Q, referring to Chung and Pruitt (1994), is defined as

$$\text{Tobin's Q} = \frac{(MV(CS)+BV(PS)+BV(LTD)+BV(INV)+BV(CL)-BV(CA)}{BV(TA)}, \tag{1}$$

where MV(X) and BV(X) indicate the market and book values of the argument X, respectively. CS is common stock, PS is preferred stock, LTD is long-term debt, INV is inventory, CL is capital leases, CA is current assets, and TA is total assets.

The sales-based (assets-based) excess value is defined as

$$\text{Excess Value} = \ln\left(\frac{V}{I(V)}\right), \tag{2}$$

where V is a firm's value, I(V), is the intrinsic value calculated as

$$\mathrm{I(V)} = \sum_{i=1}^{n} Asset_i\ (or\ Sales_i) \times \left(\frac{Total\ Capital}{Asset\ (or\ Sales)}\right)_k, \tag{3}$$

where $(\text{Total capital/Assets (or Sales)})_k$ is the multiple of total capital to assets (or sales) for the median single-segment firm in segment i's industry.

3.3. *Diversification*

We use three variables to measure the degree of firm diversification. The first, referring to Berger and Ofek (1995), is a dichotomous variable that is assigned a value of 1 (diversified firms) for firms with multiple segments and 0 (focused firms) otherwise. The second is the number of segments. The third is the Herfindahl index (Comment and Jarrell, 1995; Berger and Ofek, 1995; Denis et al., 2002), valued with respect to sales or revenues (sales-based Herfindahl index and revenue-based Herfindahl index). The sale-based Herfindahl index is calculated as follows:

$$\text{Sales} - \text{based Herfindahl index} = \sum_{i=1}^{n}(Sales_i/\sum_{i=1}^{n} Sales_i)^2 \text{ ,} \tag{4}$$

where $Sales_i$ denotes the sales in segment i. The index values range between 0 and 1, and higher values indicate greater focus.

3.4. *Factors Affecting the Valuation of Diversification*

We include three possible factors affecting the valuation of diversification: the relative value added within internal assets deployment, the coinsurance effect, and corporate governance.

3.4.1. *Relative Value Added*

Rajan, Servaes, and Zingales (2000) propose a model that indicates that funds transferred among divisions with similar levels of resources and opportunities are efficient, while funds transferred among divisions with diversified resources and opportunities are inefficient. Relative value added (RVA), with reference to Rajan, Servaesm, and Zingales (2000), is calculated as follows:

$$\text{RVA} = \frac{1}{BA}\sum_{j=1}^{n} BA_j\left(q_j - \bar{q}\right)\left[\frac{I_j}{BA_j} - \frac{I_j^{ss}}{BA_j^{s}} - \sum_{j=1}^{n} w_j\left(\frac{I_j}{BA_j} - \frac{I_j^{ss}}{BA_j^{s}}\right)\right] \text{ ,} \tag{5}$$

where n denotes the number of segments;I_j/BA_j is the capital expenditure of segment jin proportion to the book value of assets of segment j; (I_j^{ss}/BA_j^{ss}) is the asset-weighted average capital expenditure to assets ratio for the single-segment firms in the corresponding industry;w_j is the ratio of segment assets to firm assets;q_j is the end-of-year, assets-weighted average Tobin's q of single-segment firms that operate in the three-digit industry of segment j; and $\bar{q}$ is the firm's asset-weighted average of q segments.

3.4.2. *Coinsurance Effect*

Past studies indicate that coinsurance reduces the default risk (Lewellen, 1971) and enables a diversified firm to avoid the countercyclical deadweight costs of financial distress (Elton, Gruber, Agrawal, and Mann, 2001; Almeida and Philippon, 2007). Hann, Ogneva, and Ozbas(2013) find that diversified firms have on average a lower cost of capital than comparable portfolios of standalone firms. In addition, diversified firms with less correlated segment cash flows have a lower cost of capital, which is consistent with a coinsurance effect. Following Hann et al. (2013), the coinsurance effect is defined by the correlation among cash flows, an inverse measure of coinsurance.

$$\text{Correlation among cash flows} = \sum_{p=1}^{n}\sum_{q=1}^{n} w_{ip(j)}\, w_{iq(k)}\, Corr_{[t-10,t-1]}\,(j,k) \text{ ,} \tag{6}$$

where $w_{ip(j)}$is the sales share of segment p of firm i operating in industry j (similarly for business segment q of firm i operating in industry k), and $Corr_{[t-10,t-1]}\ (j,k)$is the estimated correlation of idiosyncratic industry cash flows or investments between industries j and k over the 10-year period before year t.

3.4.3. *Entrenchment Index*

The Entrenchment Index proposed by Bebchuck et al. (2009) measures the number of anti-takeover provisions implemented by a firm. The six provisions are staggered board, limits to shareholder bylaw amendments, poison pills, golden parachutes, supermajority requirements for mergers, and charter amendments. The higher the index, in the range between 0 and 6, the poorer the firm's governance.

3.5. *Summary Statistics*

Table 2 reports the summary statistics and tests of differences between diversified and focused firms. The classification of diversified versus focused firms is based on lines of business. The result in Panel A indicates that diversified firms are associated with lower valuation measures than their focused counterparts, regardless of whether the valuation is measured by Tobin's Q, sales-based, or asset-based excess value. This reconfirms the findings of other studies on the diversification discount (e.g., Comment and Jarrell, 1995; Liebeskind and Opler, 1995; Lang and Stulz, 1994; Servaes, 1996; Berger and Ofek, 1995; Denis et al., 2002).

In Panel B, we contrast the variables measuring firm characteristics. Diversified firms have larger assets and a lower leverage than focused firms. This could easily be understood as implying that diversified firms covering a wide range of businesses are associated with larger assets, and that diversification allows firms to offset partial nonsystematic risks and therefore have a higher leverage in their capital structure. However, we find that diversified firms are associated with a higher profitability (as manifested in EBIT/sales and ROA) and a lower capital expenditure than focused firms. This probably illustrates the positive side of diversification: diversified firms are cautious in making investments and have better performance measures. In Panel C, the Herfindahl–Hirschman Index of diversified firms (mean of 0.644 and median of 0.618) is significantly lower than that of focused firms (mean and median of 1).

In Panel D we calculate the relative value added, the coinsurance effect, and the entrenchment index, which past studies identify as possible factors affecting the valuation of diversification. The relative value added is used to gauge the investment effectiveness among segments of diversified firms compared with signal segment firms. The mean RVA of diversified firms is 0.205, which is significantly higher than that of focused firms. However, the difference is due to some outliers that result in a right-skewed mean. The median value of diversified firms is insignificantly different from that of focused firms. The second measure is the coinsurance effect gauged by the correlation among cash flows. The result indicates that the mean correlation among cash flows is lower for diversified firms (0.572) than focused firms (1), implying that diversified firms benefit from the coinsurance effect among cash flows, such that diversified firms may have lower odds of encountering financial distress. In contrast, we find that, on average, diversified firms have a higher entrenchment index (2.738) than focused firms (2.508), implying that diversified firms are associated with poor corporate governance.

<<Insert Table 2 Here>>

3.6. *Change in Diversification and Firm Value*

The purpose of this study is to investigate the effect of diversification on firm value. However, the two issues are possibly endogenously determined. To partially tackle this issue, we explore inter-temporal changes in diversification and examine how past performance affects inter-temporal changes in diversification, and how such changes affect future value. In Table 3, we tabulate the possible changes in diversification across two consecutive periods. The diversified firms identified in t-1 can become refocused when the number of segments decreases in t ($SN_t - SN_{t-1} < 0$), unchanged when the number of segments remains the same ($SN_t - SN_{t-1} = 0$), and more diversified when the number of segments increases ($SN_t - SN_{t-1} > 0$). The status of focused firms can only change to unchanged ($SN_t - SN_{t-1} < 0$) or diversified ($SN_t - SN_{t-1} > 0$). The third row indicates the possible changes in diversification status for all firms.

<<Insert Table 3 Here>>

We explore the value and change in value for the possible types of diversification changes identified in Table 3. The values of interest include Tobin's Q and excess value in t-1 (Tobin's Q_{t-1}, EV_{t-1}), the averages of these values through t+1 and t+3 (Tobin's Q_{after}, EV_{after}), and the changes in them before and after a change in diversification (ΔTobin's Q and ΔEV). Specifically, the change in Tobin's Q (excess value) is calculated as the average of Tobin's Q (excess value) through t+1 and t+3 minus Tobin's Q (excess value) in t-1.

Panel A reveals the possible changes for diversified firms in t-1. Among these firms, those that choose to refocus are on average associated with an increase of 0.06 in Tobin's Q and an increase of 0.045 in excess value (ΔTobin's Q and ΔEV). The numbers are significantly higher than the corresponding measures of -0.228 and -0.167 for firms that choose to become more diversified. Moreover, firms choosing to refocus are on average associated with an increase of 0.089 in Tobin's Q and 0.047 in excess value. The numbers are significantly higher than the corresponding measures of -0.049 and -0.041 for firms with an unchanged diversification status. Furthermore, comparing more diversified and unchanged firms, we find that firms with a higher Tobin's Q (2.182) or excess value (-0.054) at t-1 tend to increase their level of diversification (Tobin's Q_{t-1}, EV_{t-1}).

In Panel B we investigate focused firms at t-1. The result indicates that firms that choose to increase their diversification are associated with a lower post-change mean Tobin's Q (Tobin's $Q_{after,}$ 2.151) than that of their unchanged counterparts (2.383). A summary of the findings so far illustrates an interesting pattern: that increasing (decreasing) diversification is value detrimental (enhancing), and that firms with good performance measures are more likely to increase their level of diversification.

<<Insert Table 4 Here>>

4. Empirical Results

4.1. *Effect of Diversification on Firm Value*

In Table 5, we conduct a regression analysis of firm value (alternatively gauged by Tobin's Q, sales-based, and assets-based excess value) on diversification. Diversification is also alternatively gauged by a diversification dummy in model 1 and the number of segments in model 2. We also include HHI to capture the clustering effect of industry, size, profitability, and leverage in the current and previous periods. The control variables are included with reference to Berger and Ofek (1995) and Campa and Kedia (2002).

The result indicates that diversification is negatively correlated with firm performance, measured either by Tobin's Q, sales-based, or assets-based excess value. Moreover, we find that HHI is positively correlated with sales-based and assets-based excess value, implying that the adoption of a focused strategy is value enhancing.

<<Insert Table 5 Here>>

4.2. *Determinants of Change in Diversification*

Although diversification has been proven to be value detrimental, the endogeneity issue between performance and diversification has not been successfully addressed. In this section, we explore the possible determinants that cause firms to change their diversification status. Table 6 presents the results of logistic regressions exploring the determinants of changes in diversification, given that a firm's diversification status has been identified. The possible classifications of firm diversification in t-1 and change in diversification in t are presented in Table 3. The result indicates that for firms classified as diversified in t-1, the EBIT to sales ratio is positively correlated with the odds of a firm's diversification status remaining unchanged. For focused firms, the EBIT to sales ratio is positively correlated with the odds of a firm choosing to become more diversified. This is consistent with the previous finding that high-performing firms are more likely to increase their level of diversification. Moreover, we find that for focused firms, the capital expenditure in proportion to total sales is negatively correlated with the odds of increasing diversification. This implies that focused firms that increase their capital expenditure prefer to spend the money on their focused segments rather than on alternative lines of business. Furthermore, for diversified firms we find that leverage is negatively correlated with the odds of enhancing diversification, meaning that highly leveraged and diversified firms try to reduce their level of diversification to mitigate risks.

<<Insert Table 6 Here>>

4.3. *Change in Diversification and Future Firm Value*

Table 6 indicates that firm value in t-1 does not affect a firm's change in diversification, whereas profitability and capital expenditure do. In Table 7, we further explore the effect of a change in diversification on future firm value. The most critical independent variable is the change dummy, which reflects a firm's diversification status in t-1 and its change in diversification status in t. For example, the change dummy of -0.48 in the first column indicates that firms that are identified as diversified in t-1 and that increase their diversification in t are associated with a reduction of 0.48 in Tobin's Q. The reduction is gauged by the difference between the average Tobin's Q from t+1 to t+3 and Tobin's Q in t-1. The increase in diversification for diversified firms is also associated with a reduction of 0.232 in excess value (column 2). The negative sign of the change dummy indicates that an increase in diversification status is detrimental to firm value. Moreover, we find that the drop in firm value is more significant when firm value is measured by excess value than by Tobin's Q. Specifically, the change dummy is significant across three models when firm value is gauged by excess value (model 2, 4, and 6), but in only one model when gauged by Tobin's Q (model 1).

<<Insert Table 7 Here>>

4.4. *Factors Affecting the Value of Diversified Firms*

The results so far suggest that firm value does not affect firm diversification, while increasing diversification negatively affects firm value. In this section, we explore the possible factors that result in the diversification discount. These factors include the relative value added (RAV), the coinsurance effect measured by the correlation of cash flows among segments within a diversified firm, and corporate governance measured by the entrenchment index. The results reported in Table 8 include these three factors in the regression on the value of diversified firms. The correlation of cash flows among segments within a diversified firm is negatively correlated with the value of diversified firms when the value is measured either by Tobin's Q or excess value. The higher the correlation of cash flows among segments within a diversified firm, the lower the coinsurance effect. Therefore, one possible explanation of the diversification discount is that diversified firms superficially cover a wide range of segments that indeed have highly correlated cash flows. Moreover, we find that the entrenchment index is negatively correlated with Tobin's Q, significant at the 1% level. This is another factor that results in a diversification discount when managers are engaged in launching anti-takeover provisions to secure their managerial positions. The negative relationship between the E-index and the diversification discount is also sustainable for the full sample. In contrast, the relative value added, which is used to measure managers' efficiency in asset deployment, is not significant. In a nutshell, the main causes of the diversification discount are a low coinsurance effect and high managerial entrenchment. In contrast, whether managers are capable of redeploying a firm's assets to their best use is less of a concern.

<<Insert Table 8 Here>>

5. Concluding Remarks

In this study, we decompose firms' diversification status and change in diversification status into identifiable categories. The decomposition helps us to disentangle the endogeneity issue between firm value and diversification. We find that firm value is not a critical factor affecting a firm's change in diversification. However, a firm's change in diversification affects its future value. Specifically, an increase in diversification results in a decrease in future value. We further explore the possible factors that affect this diversification discount. The main factors are a low coinsurance effect and strong managerial entrenchment. Whether managers are capable of redeploying assets or sources to their best use within a conglomerate is less of an issue.

Table 2: Test of Differences in Variables

Firms are classified into diversified and focused firms based on the number of lines of business. The criterion for selection is that there are at least five focused firms in the same 4-digit (2-digit) SIC code. This table reports the tests of differences in the variable means between diversified and focused firms. The variables of interest are valuation (Tobin's Q, and sales-based and assets-based excess value, from Berger and Ofek (1995), in Panel A), firm characteristics (total assets, profitability (EBIT/SALES), capital expenditure in proportion to sales (CAPX/SALES), debt ratio (Debt ratio), and return on assets (ROA) in Panel B), diversification (assets-based Herfindahl–Hirschman Index (HHI) in Panel C), and possible determinants of the value of diversified firms (relative value added (RVA), correlation among cash flows, and the Entrenchment Index in Panel D). The variables are defined as follows. Tobin's Q, following Chung and Pruitt (1994), is defined as Q = ((MV(CS)+BV(PS)+BV(LTD)+BV(INV)+BV(CL)-BV(CA))/(BV(TA)),where MV(X) and BV(X) indicate the market and book variables of argument X, respectively. CS is common stock, PS is preferred stock, LTD is long-term debt, INV is inventory, CL is capital leases, CA is current assets, and TA is total assets. The sales-based (assets-based) excess value is defined as ln(V/I(V)), where V is a firm's value, I(V) is the intrinsic value calculated as Imputed Value = $\sum_{\mathrm{i}=1}^{\mathrm{n}} \mathrm{Asset_i}\ (\mathrm{or\ Sales_i}) \times \left(\frac{\mathrm{Total\ Capital}}{\mathrm{Asset\ (or\ Sales)}}\right)_{\mathrm{k}}$, where (Total capital/Assets (or Sales))k is the multiple of total capital to assets (or sales) for the median single-segment firm in segment i's industry. Following Rajan, Servaes, and Zingales (2000), the RVA is calculated as follows: $\frac{1}{BA}\sum_{j=1}^{n} BA_j(q_j-\bar{q})\left[\frac{I_j}{BA_j}-\frac{I_j^{ss}}{BA_j^{s}}-\sum_{j=1}^{n} w_j\left(\frac{I_j}{BA_j}-\frac{I_j^{ss}}{BA_j^{s}}\right)\right]$, where n denotes the number of segments;I_j/BA_j is the capital expenditure of segment j (item #4 of the COMPUSTAT segment file) in proportion to the book value of assets of segment j; (I_j^{ss}/BA_j^{ss}) is the asset-weighted average capital expenditure to assets ratio for the single-segment firms in the corresponding industry;w_j is the ratio of segment assets to firm assets;q_j is the end-of-year asset-weighted average Tobin's q of single-segment firms that operate in the three-digit industry of segment j; and $\bar{q}$ is the asset-weighted average of segment q's for the firm. The correlation among cash flows, an inverse measure of coinsurance, is computed as $\sum_{p=1}^{n}\sum_{q=1}^{n} w_{ip(j)}\, w_{iq(k)}\, Corr_{[t-10,t-1]}\,(j,k)$, where $w_{ip(j)}$is the sales share of segment

p of firm i operating in industry j (similarly for business segment q of firm i operating in industry k), and $Corr_{[t-10,t-1]}\ (j,k)$is the estimated correlation of idiosyncratic industry cash flows or investments between industries j and k over the 10-year period before year t. Following Bebchuck et al. (2009), the entrenchment effect is the sum of the number of anti-takeover provisions, including a staggered board, limits to shareholder bylaw amendments, poison pills, golden parachutes, and supermajority requirements for mergers and charter amendments. The entrenchment index is in the range between 6 and 0.

Table 3: Change in Diversification

This table summarizes the possible inter-temporal change for firms characterized as diversified and focused. SN denotes the number of segments.

Change at t / Status at t-1	SN_t-SN_{t-1}<0	SN_t-SN_{t-1}=0	SN_t-SN_{t-1}>0
Diversified	Refocused	Unchanged	More diversified
Focused	--	Unchanged	Diversified

Table 4: Change in Value due to Change in Diversification

This table reports the changes in value before and after the change in diversification for firms characterized as diversified, focused, or both in t-1. The value in t-1 is alternatively gauged by Tobin's Q in t-1（Tobin's Q_{t-1}）and excess value in t-1（EV_{t-1}）. Tobin's Q_{after} (EV_{after}) denotes the average Tobin's Q (excess value) in t+1 through t+3. ΔTobin's Q is the change in Tobin's Q (Tobin's Q_{after}- Tobin's Q_{t-1}) and ΔEV is the change in excess value (EV_{after}- EV_{t-1}).

Table 5: The Impact of Diversification on Firm Value

This table reports the regression of firm value (alternatively gauged by Tobin's Q, sales-based excess value, and assets-based excess value) on diversification and other control variables. Diversification is alternatively measured by D (diversification) (being assigned the value 1 for diversified firms and 0) and number of segments. All other variables are defined in Table 2. In each cell, the regression coefficient and p-value are reported in the upper and lower case, respectively. ***, **, and * denote the significance level of 1%, 5%, and 10%, respectively.

Table 6: The Determinants of Changes in Diversification

This table reports the logistic regression exploring the determinants of change in diversification. The status of diversification in t-1 is classified as diversified and focused. The dependent variable is a dummy indicating changes in status of diversification and is defined in the second row of each column. In each cell, the regression coefficient and p-value are reported in the upper and lower case, respectively. ***, **, and * denote the significance level of 1%, 5%, and 10%, respectively.

Table 7: Changes in Diversification and Firm Value

This table reports the regression of change in firm value on change in diversification. Change in firm value is alternatively gauged by change in Tobin's Q (the average of Tobin's Q from t+1 through t+3 minus the Tobin's Q in t-1) and change in excess value (the average excess value from t+1 through t+3 minus the excess value in t-1). Change dummy is alternatively defined in the second row. In each cell, the regression coefficient and p-value are reported in the upper and lower case, respectively. ***, **, and * denote the significance level of 1%, 5%, and 10%, respectively.

This study explores whether IFRS provides more relevant information than GAAP to investors for evaluating systematic risks. By investigating American Depository Receipts' (ADRs) responses to the elimination of Form 20-F reconciliation, we find an insignificant difference in risk relevance between IFRS and U.S. GAAP. In addition, the findings show that dual reporting under IFRS and U.S. GAAP conveys incremental, risk-relevant accounting information to external users as compared to reporting only under IFRS. In the extensive analysis, the findings show that dual disclosure helps eliminate information asymmetry, which is conducive to lower firm-specific risks and more value relevance. Collectively, the findings suggest that dual reporting under IFRS and U.S. GAAP is necessary although accounting information under IFRS is sufficiently comparable to U.S. GAAP. However, several caveats are mentioned.

Keywords: risk relevance, systematic risk, market beta, accounting beta, IFRS

1. Introduction

Systematic risk is risk that impairs the functioning of a financial system to the point where economic growth and welfare suffer materially. During crises, for example, both the financial markets and individual assets are hit by catastrophic events whose ex-ante probabilities were previously considered negligible. As a result, determining a method for understanding the build-up of systematic risk and containing crises when they do happen becomes extremely important. Although previous studies document a positive relation between systematic risk in the form of market beta and accounting risk in the form of accounting beta,[1] little attention has been paid to whether accounting systems generate incremental risk information under different sets of accounting principles.

A growing number of countries have moved to direct adoption of or convergence with International Financial Reporting Standards (hereafter, IFRS). For example, the European Union (hereafter EU) required all listed companies in its member states to prepare their consolidated financial statements in accordance with IFRS after 2005[2]. The Chinese government allowed Chinese accounting standards to converge with IFRS by 2007. Nonetheless, to date some countries still hesitate to adopt or converge with IFRS for political reasons or due to concerns about IFRS financial reporting quality (Reilly, 2011; Ball, 2012).

In 2007, the Securities and Exchange Commission (hereafter, the SEC) took a step to allow non-U.S. companies coming from IFRS member states and cross-listing on U.S. exchanges (hereafter, IFRS firms) to prepare financial statements without reconciliation to the Generally Accepted Accounting Principles in the United States (hereafter, U.S. GAAP) (SEC 2007). This decision is based upon the belief that eliminating reconciliation improves the comparability and quality of accounting information, which in turn benefits users (SEC 2008; Barth, Landsman, Lang, and Williams 2012).

Among the users of accounting information, financial analysts play a key role in the capital markets (Beaver 1998). They intensively study companies' financial statements and rate risks and also provide guidance to businesses and individuals making investment decisions. In addition their concerns about financial reporting quality, they want to know more relevant information about systematic risk, given that unsystematic risks can be minimized through diversification. Thus, determining whether principle-based or rule- based accounting standards faithfully reflect more information about a firm's exposure to systematic risk is an extremely crucial issue. Therefore, the purpose of this study is to investigate which of these two systems (IFRS or U.S. GAAP) provides more risk-relevant accounting information to financial reporting users.

Based on a sample of non-U.S. companies traded as American Depository Receipts (hereafter, ADRs) from 1991 to 2012, we do not find a significant difference in risk relevance between IFRS and U.S. GAAP. This implies that the risk relevance under IFRS is comparable to that under U.S. GAAP. When we subdivide the ADRs into several groups

---

[1] E.g., Ball and Brown (1969), Beaver, Kettler, and Scholes (1970), Mensah (1992), and Khan and Bradbury (2014).

[2] European Union (2002), Regulation (EC) 1606/2002 of the European Parliament and of the Council on the Application of International Accounting Standards, Brussels, Official Journal of the European Communities.

according to whether they eliminate the Form 20-F reconciliation, we find that dual reporting under IFRS and U.S. GAAP conveys incremental risk-relevant accounting information to external users as compared to single reporting under IFRS. In the extensive analysis, we find that ADRs choosing dual reporting under IFRS and U.S. GAAP have lower idiosyncratic risks and value relevance following their decisions. This implies that dual reporting helps eliminate information asymmetry, which is conducive to lower firm- specific risks and more value relevance. The findings also show that single reporting under IFRS fails to offer incremental, value-relevant accounting information. Collectively, the findings suggest that dual reporting under IFRS and U.S. GAAP provides better information to users, although accounting numbers under IFRS are sufficiently comparable to U.S. GAAP. The main findings remain robust when we use different earning measures following Baran, Lakonishok, and Ofer (1980).

Our study contributes to the literature in the following aspects. First, although many empirical studies compare accounting quality and value relevance under principle-based accounting with those under ruled-based accounting,[3] no studies compare the risk relevance under these two types of accounting standards. We fill this gap. Second, our findings show that dual reporting under IFRS and U.S. GAAP is important for non-U.S. companies cross-listing in the U.S. capital markets, although accounting numbers under IFRS are sufficiently comparable to U.S. GAAP. Finally, we add to traditional capital asset pricing theory by showing that incremental risk-relevance is conducive to value relevant accounting information.

The remainder of the paper is organized as follows: The next section reviews related research and develops predictions. Section three explains the methodology and sample selection. The empirical results are presented and discussed in section four, while additional tests are provided in section five. The final section offers conclusions.

2. Literature review and predictions

Risks and Accounting Information

In the capital market, financial reporting users face systematic and idiosyncratic risks. The former is relatively more important than the latter because users may not be able to reduce systematic risk through diversification. For example, investors cannot deal adequately with fluctuations in all stocks during a recession unless they stay away from all risky investments, but they can diversify idiosyncratic risk through portfolio strategies when a targeted company has a high possibility of financial distress.

Many studies probe related areas and empirically find a relation between accounting information and market risks. Ball and Brown (1969) is the pioneer research that investigates the relationship between accounting data and systemic risk. They show that accounting income numbers are sensitive to systematic risk. Beaver et al. (1970) examine the association

---

[3] E.g., Francis, LaFond, Olsson, and Schipper (2004), Daske, Hail, Leuz, and Verdi (2008), Hail, Leuz, and Wysocki (2010a, and 2010b), Kabir, Laswad, and Islam (2010), Li, (2010), Liu, Yao, Hu, and Liu (2011), Barth et al. (2012), and Ahmed, Neel, and Wang (2013).

between market-determined and accounting-determined risk measures. They find that market risk is positively correlated with accounting risk, growth, dividend policy, and earnings variability, and is negatively correlated with liquidity and firm size. Many studies extend this stream of literature to explore the association between systematic risk and various accounting variables.[4] For instance, Lev (1974) finds operating leverage to be positively associated with systematic risk because the higher a company's capital expenditures, the higher its operating leverage. Beaver and Manegold (1975) investigate whether accounting information on profitability is associated with systematic risk. Their results show a high correlation between accounting information and profitability and systematic risk. Brimble and Hodgson (2007) provide evidence that accounting variables are significantly associated with systematic risk over time. Nevertheless, the association is shown to be influenced according to industry and size. Khan and Bradbury (2014) find comprehensive income to be associated with systematic risk, which is similar to the relationship between net income and systematic risk.

Value Relevance of IFRS

The trend toward convergence of local GAAP and IFRS has inspired researchers in the global accounting research community[5]. Some studies investigate the effects of shifting from local GAAP to IFRS, but the empirical results are inconsistent. Hung and Subramanyam (2007) investigate German companies adopting International Accounting Standards (hereafter, IAS) from 1998 through 2002 and find significant accounting differences between IAS and German GAAP. They find that total assets, book value of equity, and variations in book value and net income are higher under IAS than under German GAAP.

Jeanjean and Stolowy (2008) focus on three IFRS first-time adopter countries: Australia, France, and the United Kingdom (hereafter, UK). They find that the pervasiveness of earnings management does not decline after the introduction of IFRS; it even increases in France. Using European listed companies, Morais and Curto (2009) find that implementation of IFRS results in more value-relevant accounting information than local GAAP. Iatridis (2010) finds IFRS adoption enhances the quality of accounting information for UK firms, evidenced by decreases in earnings management, timely recognition of losses, and increases in the value relevance of accounting information. Devalle, Onali, and Magarini (2010) find accounting information is more relevant following the introduction of IFRS in Germany, France, and the UK, but the influence on book value of equity decreases in most of the countries except for the UK. Kabir et al. (2010) examine the earnings quality of accounting information for firms in New Zealand and find that earnings quality decreases with the adoption of IFRS. Liu et al. (2011) explore the effects of mandatory implementation of IFRS in China and provide evidence of a reduction in earnings management and higher value relevance in accounting information. Chua, Cheong, and Gould (2012) find that Australian

[5] See Auer (1996); Barth, Clinch, and Shibano (1999); Harris and Muller (1999); Bartov, Goldberg, and Kim (2005); Van Tendeloo and Vanstraelen (2005); Daske (2006); Hung and Subramanyam (2007); Barth, Landsman, and Lang (2008); Kabir et al. (2010); Li (2010); Liu et al. (2011); Ahmed et al. (2013).

companies have better accounting quality following the mandatory adoption of IFRS.

Several empirical studies compare IFRS with U.S. GAAP by using German samples. Studies suggest insignificant differences in reporting quality (Leuz and Verrecchia 2000; Leuz 2003), earnings management (Van Tendeloo and Vanstraelen 2005), and value relevance (Bartov et al. 2005; Hung and Subramanyam 2007) between IFRS and U.S. GAAP.

By contrast, the findings in studies using U.S. cross-listed firms are relatively mixed. Harris and Muller (1999) investigate whether foreign firms should be allowed to list in the United States using IAS. They find that the U.S. GAAP earnings-reconciliation adjustment is value-relevant. They also find IAS amounts to be more related to price-per-share than U.S. GAAP amounts and U.S. GAAP amounts to be more related to stock returns than IAS amounts. Henry, Lin, and Yang (2009) evaluate the impact of IFRS on U.S. GAAP and IFRS using reconciliation disclosures of EU cross-listed companies from 2004 to 2006. They find that the differences in earnings and in shareholders' equity between U.S. GAAP and IFRS declined from 2004 to 2006, but reconciliation amounts vary with industries and with the legal origins of the companies' home countries.

More recently, Barth et al. (2012) examine the comparability of accounting information between IFRS and U.S. GAAP using a sample of non-U.S. companies cross- listing in the U.S. capital market. They find that IFRS is more comparable with U.S. GAAP as compared to other local GAAPs. The comparability between IFRS and U.S. GAAP is stronger for firms that adopt IFRS mandatorily, common law firms, and firms in countries with high enforcement. Despite the finding that IFRS is comparable to U.S. GAAP, Barth et al. (2012) indicate that IFRS exhibits lower value relevance than U.S. GAAP.

Similarly, Eng, Sun, and Vichitsarawong (2014) examine whether accounting amounts reported under IFRS by ADRs are comparable with those reported under U.S. GAAP from 2006 to 2009. They find no significant change in value relevance and accounting quality after 2007, the year in which SEC permitted elimination of Form 20-F reconciliation. Based on their findings, they suggest that reconciliation to U.S. GAAP is unnecessary when financial statements are prepared in accordance with IFRS. In their research design, however, Eng et al. (2014) did not check the exact year in which the ADRs changed their methods. Some ADRs switched to different forms of disclosure in later years which could lead to insignificant differences in value relevance and accounting quality before and after 2007.

Collectively, these studies support the substantial fair-value orientation of IFRS. However, there is a lack of research comparing the risk relevance under IFRS with U.S. GAAP. This study fills that gap.

Predictions

External users analyze financial accounting numbers for two purposes. First, they want to identify mispriced securities so that they might attempt to "beat the market" and earn abnormal returns. Second, they want to predict the systemic riskiness of stock returns (market beta), so that they might adjust their portfolio risk. Hence, a good accounting system should provide useful information by which users can predict systematic risk and reduce portfolio adjustment costs in attempting to achieve a target level of portfolio risk (Elgers

1980).

Although IFRS is considered closer to the fair value and the underlying economic phenomena that are real determinants of beta, a controversial issue is whether its principle-based approach applies to mature capital markets. Rules-based accounting is basically a list of detailed rules that must be followed when preparing financial statements intended to increase accuracy and reduce ambiguity. The complexity of such rules, however, can cause unnecessary complexity in the preparation of financial statements. Principles-based accounting provides a simple set of conceptual guidelines. Although some rules are unavoidable, the guidelines are not meant to be used for every situation. The drawback with principles-based guidelines is that a lack of guidelines can lead to inconsistent information that reduces comparability. Lease accounting under U.S. GAAP and IFRS best illustrates the differences between rules-based and principles-based accounting. Under U.S. GAAP, a lease is considered a capital lease if it meets any of the specified criteria. In contrast, under IFRS, a lease is classified as a finance lease if it transfers substantially all the risks and rewards incidental to ownership of an asset. Although the IASB also provides several indicators that are similar to the criteria under U.S. GAAP, it does not provide any specified percentage. Instead the IASB uses terms such as "substantially all" and"major part," which require a great deal of professional judgment. Hence, earnings are expected to be inherently volatile under IFRS. Ostensibly, IFRS simplifies the complex rules, yet it may in turn reduce the users' level of understanding of accounting numbers, especially in a developed capital market where complex transactions are prevalent. Thus, the risk relevance of IFRS might be lower than or insignificant in relation to that of U.S. GAAP. The risk relevance of IFRS, nevertheless, might be higher than that of U.S. GAAP if simplified accounting treatments and supplemental disclosures under IFRS collectively convey superior accounting information in regard to the prediction of systematic risk as compared to U.S. GAAP.

3. Methodology and Sample selection

ResearchDesign

We base our analyses on a sample of ADRs for three reasons. First, a single-country analysis mitigates potential effects caused by differences in legal, regulatory, political, and economic environments among countries[6]. Second, we believe that market discipline and rigid regulations on ADRs in the United States mitigate potential endogeneity rooted in the case of voluntary application[7]. Third, the SEC has allowed ADRs to prepare financial statements in accordance with IFRS without GAAP reconciliation since 2007[8], which grants us a valuable opportunity to investigate the risk relevance of accounting information.

We identify a firm that has both "-ADR" in the firm name and an ADR ratio

---

[6] E.g. Alford, Jones, Leftwich, and Zmijewski (1993), Sloan (2001); Chaudhuri and Maitra (2008), Hail et al. (2010a), and Barth et al. (2012).

[7] E.g. Holthausen and Leftwich (1983), Core (2001), Lim, Matolcsy, and Chow (2007), Francis, Nanda, and Olsson (2008), and Hostak, Lys, Yang, and Carr (2013).

[8] Securities Act Release No. 8879, "Acceptance from Foreign Private Issuers of Financial Statements Prepared in Accordance with International Financial Reporting Standards Without Reconciliation to U.S. GAAP."

(Compustat item: ADRR) in the *COMPUSTAT* database, identifying it as an ADR firm. We then match the ADRs with U.S. companies that in the year 2007 or later changed their disclosure policies, have the closest market capitalizations, belong to the same quintile of total assets and cash flows from operation at the beginning of the year, and are in the same industry (on the basis of the two-digit SIC code).

Following the *COMPUSTAT* classification system, we divide the ADRs into three groups[9]: ADRs adopting domestic standards (*DS*), ADRs adopting domestic standards generally in accordance with U.S. GAAP (*DU*), and ADRs adopting domestic standards generally in accordance with or fully compliant with IFRS (*DI*). In the following sections, we define the ADRs in the *DI* group as IFRS firms.

We mainly pay attention to the risk-relevant information available for IFRS firms. We further subdivide the IFRS firms into three sub-groups based on their reporting choices: (1) IFRS firms that provide both IFRS and U.S. GAAP information (hereafter $\text{IFRS}^{\text{Both}}$), (2) IFRS firms that merely provide IFRS information (hereafter $\text{IFRS}^{\text{Only}}$), and (3) IFRS firms that became U.S. companies and used U.S. GAAP when the U.S. ownership exceeds 50 percent of issued share capital, or the firms reincorporate in the United States (hereafter IFRS^{US}).

To do this, we manually check the ADR firms' Form 20-F and 6-K filings via the SEC's EDGAR system, including the basis of accounting used to prepare the financial statements, the disclosure choices of accounting standards before and after eliminating the reconciliations requirements, and the first change year if the ADR makes a different disclosure choice.

We then compare the relationship between accounting beta and market beta of IFRS firms with that of their counterparts before and after the IFRS firms prepared financial statements without reconciliation to U.S. GAAP. In addition, we conduct regression analyses and additional checks. The following sections introduce the market beta, accounting beta, and regression model used in our research.

Estimation of Accounting Beta and Market Beta

In the research, we employ accounting and market betas to quantify the systematic volatility in earnings and the systematic risk, respectively. Empirical studies find that the systematic volatility in earnings, as captured by accounting beta, is an important explanatory variable of market beta, a measure of a security's systematic risk under the Capital Asset Pricing Model (CAPM) (Beaver et al. 1970; Bowman 1979; Baran et al. 1980; Bowman 1980; Bowen, Burgstahler and Daley 1986; Mensah 1992).

Folloing Mensah (1992), we use the following time-series regression model to iteratively estimate the accouting beta (α_1)

$$X_{it} = \alpha_0 + \alpha_1 X_{mt} + \varepsilon_{it}, \qquad (1)$$

where X_{it} refers to the change in earnings per share for firm *i* in fiscal year *t*, divided by the

[9] According to the COMPUSTAT database, *DI* firms were made available from December 31, 2004, forward; prior to that date, *DS* will appear. Therefore, we identify *DI* firms before 2005 based on the 2005 classification

earnings per share for firm i in fiscal year t-1. X_{mt} refers to the change in arithmetic average of the sample earnings per share for firm i in fiscal year t, divided by the arithmetic average of the sample earnings per share for firm i in fiscal year t-1.

The market beta (β_1) is iteratively estimated from the following time-series regression:

$$R_{it} = \beta_0 + \beta_1 R_{mt} + \varepsilon_{it}\ , \tag{2}$$

where R_{it} refers to the annualized monthly stock returns for firm i in fiscal year t. R_{mt} refers to the *ex post* annualized monthly stock returns of the market portfolio in fiscal year t. A firm's monthly returns are compounded starting from the beginning of the third month after the end of the prior fiscal year to ensure that the financial information has been released.

Regression Models

In addition to a correlation analysis, our primary analysis is a multivariate test that controls for potential differences across the sample groups. The estimated market betas are regressed on the estimated accounting betas, an indicator variable that represents the period following the elimination of Form 20-F reconciliations or the change in disclosure policies and several important variables that are related to the market beta.

We first shed light on the risk relevance of accounting before and after the IFRS firms choose to report only IFRS information. Thus, we separately apply equation (3) to firms according to different types of disclosure after the elimination of reconciliation. Second, we investigate the relative risk relevance between the IFRS and U.S. GAAP. As a result, we use Equation (4) to compare IFRS^{Only} with the matched U.S. companies.

$$\begin{aligned} MBeta_{it} = {} & \gamma_0 + \gamma_1 ABeta_{it} + \gamma_2 ELIMINATE + \gamma_3 ABeta_{it} \times ELIMINATE \\ & + \gamma_4 SIZE_{it} + \gamma_5 DOL_{it} + \gamma_6 DFL_{it} + \gamma_7 IBR_{it} + \gamma_8 \Delta GDP + \gamma_9 CIVIL \\ & + \varepsilon_{it} \end{aligned} \tag{3}$$

$$\begin{aligned} MBeta_{it} = {} & \gamma_0 + \gamma_1 ABeta_{it} + \gamma_2 ONLYIFRS + \gamma_3 ABeta_{it} \times ONLYIFRS \\ & + \gamma_4 SIZE_{it} + \gamma_5 DOL_{it} + \gamma_6 DFL_{it} + \gamma_7 IBR_{it} + \gamma_8 \Delta GDP + \gamma_9 CIVIL \\ & + \varepsilon_{it} \end{aligned} \tag{4}$$

where $MBeta_{it}$ is the market beta of the ith firm in year t, estimated from Equation (2). $ABetait$ is the accounting beta of the ith firm in year t, estimated from Equation (1). *ELIMINATE* is a dummy variable that equals 1 if the year is after 2007 or the year in which the firms changed their disclosure policies, and 0 otherwise. *ONLYIFRS* is a dummy variable that equals 1 if an IFRS firm switched to reporting only IFRS information after the elimination of Form 20-F reconciliation, and 0 otherwise. $SIZEit$ is the logarithm of total assets of the ith firm in year t. $DOLit$ is the firm's degree of operating leverage, measured by the ratio of percentage change in earnings before interest and taxes to the percentage change in sales in year t. DFL_{it} is the firm's degree of financial leverage, measured by the ratio of percentage change in earnings per share to percentage change in earnings before interest and taxes in year t. IBR_{it} is the firm's intrinsic business risks, measured following Mensah

(1992)[10].*ΔGDP* is the annual percentage change in gross domestic product in year *t*. *CIVIL* is a dummy variable that equals 1 if the firm is in a civil law country, and 0 otherwise.

In Equation (3), *ABeta* captures the correlation between accounting risk and market risk. *ELIMINATE* captures the shift in the intercept for the period when IFRS firms change their disclosure policies on Form 20-F. We expect the coefficient on *ABeta* × *ELIMINATE* in Equation (3) to be positive if the companies provide incremental risk-relevant accounting information after eliminating Form 20-F reconciliation.

In Equation (4), *ONLYIFRS* measures the shift in the intercept for IFRS firms as compared to that of other firms. *ABeta* × *ONLYIFRS* captures the marginal effect of IFRS on the slope of the variable *ABeta*. If IFRS provides more risk-relevant information than U.S. GAAP, we expect the coefficient on *ABeta* × *ONLYIFRS* in Equation (4) to be positive.

Following previous studies, we include a set of important variables that control for firm size (Ben-Zion and Shalit 1975), the degree of operating leverage (Hill and Stone 1980; Mandelker and Rhee 1984; Rhee 1986; Mensah 1992), the degree of financial leverage (Ben-Zion and Shalit 1975; Hill and Stone 1980; Mandelker and Rhee 1984; Rhee 1986; Mensah 1992), intrinsic business risks (Mandelker and Rhee 1984; Rhee 1986; Mensah 1992), differences in legal systems (Soderstrom and Sun 2007; Barth et al. 2012)[11], and macroeconomic effects (Vassalou and Xing 2004).

Sample Selection

We retrieve the financial and stock returns data from the *COMPUSTAT* and *CRSP* databases during the sample period from 1991 to 2012. We manually collect the ADR disclosure policies in Form-20F and 6-K filings via the SEC's EDGAR system. Data regarding the gross domestic product are retrieved from the U.S. Bureau of Economic Analysis.

We impose several restrictions: (1) we remove financial service firms (SIC codes between 6000 and 6999); (2) We require ADRs to have annual data at least two years before and one year after 2007; (3) We require IFRS firm to have annual data at least two years before and one year after 2007, as well as the year in which they changed their disclosure policies on Form 20-F during the period of post-elimination of reconciliation; (4) We require ADRs to have Form 20-F or 6-K filings available in the EDGAR system; (5) We require ADRs to have non-missing values of financial and stock returns data for the regression analyses; (6) We trim the top and bottom 1% and 99% of earnings before interest and taxes, as well as stock returns, to mitigate the potential effects of outliers.

---

[10] To estimate *IBR*, we estimate the compound growth rates of sales (g_s) and earnings (g_x) by separately regressing the natural log of sales and the natural log of earnings before interest and taxes on the time period for each firm, expressed in the following equations. *IBR* is then derived as (g_s/g_x) * *Abeta*.

$$InS_{it} = v_0 + g_{si}T + \square_t,$$

$$InX_{it} = \omega_0 + g_{xi}T + \square_t,$$

where InS_{it} refers to the natural log of sales revenue for firm *i* in fiscal year *t*. InX_{it} refers to the natural log of earnings before interest and taxes for firm *i* in fiscal year *t*. *T* refers to the number of years after going public.

[11] The ADRs are classified into three legal systems according to the Central Intelligence Agency (CIA): (1) common law, (2) civil law, and (3) mixed legal system. See the CIA website at https://www.cia.gov/library/publications/the-world-factbook/fields/2100.html.

Table 1 summarizes the sample-selection procedure and the accounting standard choices of IFRS firms. As reported in Panel A of Table 1, the preliminary merged sample contains 10,702 firm-years with valid financial and stock return data, corresponding to 989 distinct ADRs. We delete 2,680 observations with extreme values and those with missing values as well as financial institutions, corresponding to 142 distinct ADRs. We remove 512 ADRs that do not meet the requirement on years or with SEC filings available, corresponding to 2,939 firm-years. We then remove 895 firm-years (61 firms) due to an inability to find matches. The final sample consists of 4,188 observations corresponding to 274 distinct ADRs.

Panel B of Table 1 reports the sample distribution of IFRS firm reporting choices. There are 189 IFRS firms corresponding to 3,155 firm-years. Among these IFRS firms, 73 firms (1,168 firm-years) choose to disclose both IFRS and U.S. GAAP information, 127 firms (1,957 firm-years) choose to disclose only IFRS information, and 2 firms (30 firm-years) switch to being a U.S. company and thus follow U.S. GAAP[12]. In Panel B, most of the IFRS firms disclose only IFRS information after the SEC allowed the elimination of Form 20-F reconciliation. This could be due to two reasons. First, managers of these IFRS firms believe that investors in the U.S. capital markets consider IFRS information more useful. In their Form 20-F, some firms state that they provide only IFRS information is because U.S. investors are familiar with IFRS. Second, the trade-off between costs and benefits could drive the decision to report only IFRS information. Providing only IFRS without reconciliation to U.S. GAAP may substantially reduce related charges on reconciliations.

[Insert Table 1 here]

Table 2 reports the distribution of ADRs across industries and time. Panel A shows that our sample spans 40 different two-digit SIC codes. Chemicals and Allied Products (12.9%), Electronic and Other Electric Equipment (9.6%), and Communications (13.5%) are well represented in the sample.

Panel B reports the distribution of the number of ADRs during the sample period. There was a fast-growing trend of ADRs since 1992. The growth rate slowed and became negative after 2008. Such a declining trend could be due to two reasons. First are the SEC's new ADR requirements in September 2008.[13] They include the following: (1) ADRs that prepare financial statements under U.S. GAAP should prepare segment data in accordance with U.S. GAAP; (2) ADRs must disclose information about their corporate governance practices that are different from U.S. firms, a change in certifying accountant, American Depositary Receipts fees and payments, and so on. These requirements increase costs associated with preparing financial statements for ADRs. Second, the declining trend may result from our requirement that sample firms have observations at least two years before and one year after the first year the IFRS firms change their disclosure policies

[12] When an IFRS firm's U.S. ownership exceeds 50% of issued share capital or the firm reincorporates in the United States, it loses its foreign private-issue status and must prepare a 10-K as its annual financial statement in accordance with U.S. GAAP.

[13] SEC Release Nos. 33-8959; 34-58620 "Foreign Issuer "Reporting Enhancements." (September 23, 2008).

[Insert Table 2 here]

Table 3 presents the descriptive statistics for the test and the control samples in 2007 and in the year the ADRs change their disclosure policies on Form 20-F. The mean log of market capitalization is 8.678 for ADRs and 8.467 for the matched U.S. companies, respectively. The mean log of total assets is 8.636 for ADRs and 8.375 for the matched U.S. companies, respectively. Both the mean differences in the total assets and in the market capitalization between the ADRs and their counterparts are statistically insignificant, indicating that our sample-selection procedure is effective in matching test and control firms on firm size. The insignificant difference in the mean market-to-book ratio suggests that the ADRs have growth opportunity similar to the matched U.S. companies. The ADRs have lower debt ratios than the matched U.S. companies (-0.033; t=-1.72). Both the accounting and the market betas of the ADRs are approximated to those of the matched U.S. companies. Overall, the results in Table 3 grant us confidence in the matching procedure.

[Insert Table 3 here]

4. Empirical Results

Correlation between Accounting Beta and Market Beta

Table 4 presents the analysis of the correlations between the accounting and market betas for the sample firms according to different types of disclosures on the Form 20-F reconciliations. All the correlations have a positive sign, indicating a positive relationship between accounting and market risk measures.

Columns (1) and (6) of Table 4 report the correlations between the accounting and market betas for the ADRs and for the matched U.S. companies, respectively. The correlation coefficient for the ADRs is 0.121 (p-value<0.01) in the pre-elimination period. The correlation coefficient increases to 0.125 (p-value<0.01) after the SEC allows the elimination of Form 20-F reconciliation. The correlation coefficient for the matched U.S. companies increases from 0.038 (p-value<0.01) to 0.082 (p-value<0.01) in the post- elimination period as well.

Columns (2), (3), (4) and (5) of Table 4 report the correlations between the accounting and market betas for the IFRS firms according to their choices of disclosure after the elimination of reconciliation, respectively. Column (2) shows the results for $IFRS^{Both}$.The correlation coefficient in Column (2) is 0.142 in the pre-change period, which increases to 0.166 in the post-change period. This suggests that IFRS firms switching to dual reporting under IFRS and U.S. GAAP exhibit higher levels of risk-relevant information after the change.

Column (3) shows results for $IFRS^{Only}$. As reported in Column (3), the correlation coefficient slightly shifts from 0.153 to 0.152 in the post-change period. This suggests that risk relevance decreased when IFRS firms choose to report only IFRS information on Form 20-F.

Column (4) shows results for $IFRS^{US}$. The correlation coefficient in Column (4) shifts from 0.500 to 0.877 in the post-change period. Column (5) shows the results for other ADRs that reconcile non-IFRS local GAAP to U.S. GAAP. The correlation coefficient in Column (5) is 0.072 in the pre-elimination period and reduces to 0.054 in the post- elimination period.

Overall, the correlation analysis in Table 4 outlines the IFRS firms' reporting choices around the elimination of the Form 20-F reconciliation, as well as the shifts in the correlations between accounting information and systematic risk.

[Insert Table 4 here]

Regression Analyses

In this section, we conduct a multivariate analysis that controls for potential differences across the sample groups. Table 5 reports the regression results. Column (1) reports the regression results for all ADRs. The coefficient on $ABeta \times ELIMINATE$ in Column (1) is 0.019 and is statistically significant at the 10% level, which indicates that eliminating Form 20-F reconciliation has a positive effect on risk relevance. Relatively, the insignificant coefficient on $ABeta \times ELIMINATE$ in Column (6) suggests that eliminating Form 20-F reconciliation has little influence on the matched U.S. companies.

Columns (2), (3), (4), and (5) of Table 4 further report the regression results according to the IFRS firms' reporting choices related to Form 20-F. Among these columns, we mainly shed light on Column (3). We expect a positive sign on $ABeta \times ELIMINATE$ in Column (3) if $IFRS^{Only}$ convey incremental risk-relevant accounting information.

The coefficient on $ABeta \times ELIMINATE$ in Column (2) is significantly positive (0.035; p-value=0.04), which indicates that the IFRS firms' decision to report accounting numbers under both IFRS and U.S. GAAP is associated with higher levels of risk relevance. For $IFRS^{Only}$, the coefficient on $ABeta \times ELIMINATE$ in Column (3) is significantly negative (-0.031; p-value=0.04). This indicates that the risk relevance was lower when IFRS firms switch to providing financial-reporting users with accounting information under IFRS. The insignificant coefficient on $ABeta \times ELIMINATE$ in Column (4) indicates that there is no significant change in risk relevance when IFRS firms switch to being U.S. companies and filing Form 10-K in accordance with U.S. GAAP. For other non-IFRS ADRs, the insignificant coefficient on $ABeta \times ELIMINATE$ in Column (5) indicates no significant change in risk relevance after eliminating the Form 20-F reconciliation.

Consistent with prior studies (Beaver et al. 1970; Beaver and Manegold 1975), the negative coefficients on *SIZE* in most of the Columns indicate that larger firms are less risky than smaller firms. The coefficients on *DFL* and *IBR* in some of the Columns are significantly positive, indicating that a firm's financial leverage and intrinsic business risks are positively related to market risk. The results of the relation between market beta and legal system are mixed. The coefficient on *CIVIL* in Column (3) is positive and significant at the 10% level, which suggests that IFRS firms in civil law countries that provide only IFRS information have higher market betas than other IFRS firms with similar decisions. The coefficient on *CIVIL* in Column (5) is significantly negative, suggesting that non-IFRS ADRs coming from civil law countries have lower market betas than other non-IFRS ADRs.

Collectively, the regression analysis indicates that IFRS firms switching to reporting under IFRS information do not provide incremental risk-relevant accounting information. By contrast, IFRS firms that switch to dual reporting under IFRS and U.S. GAAP provide more risk-relevant accounting information.

[Insert Table 5 here]

We further compare the risk relevance of IFRS with that of U.S. GAAP. Therefore, we run Equation (4) with two sets of samples. One set contains $IFRS^{Only}$ and $IFRS^{US}$. The other set contains $IFRS^{Only}$ and the matched U.S. companies.

Columns (1) and (2) of Table 6 show the regression results for the first set of samples before and after the decisions related to IFRS firm disclosure choices, respectively. The coefficient on $ABeta \times ONNLYIFRS$ in Column (1) is statistically insignificant, which suggests that the relation between accounting risk and market risk for the $IFRS^{Only}$ is not different from $IFRS^{US}$ before their decisions. Following their decisions, the risk-relevance difference between $IFRS^{Only}$ and $IFRS^{US}$ in Column (2) is statistically insignificant, too.

Columns (3) and (4) of Table 6 report the regression results for the second set of samples before and after the decisions related to IFRS firm disclosure choices. The coefficient on $ABeta \times ONNLYIFRS$ in Column (3) is significantly positive (0.032; p-value<0.01), which indicates that $IFRS^{Only}$ has higher risk relevance than U.S. companies required to reconcile IFRS to U.S. GAAP. After the $IFRS^{Only}$ choose single reporting under IFRS, the risk-relevance difference became statistically insignificant. This is evidenced by the insignificant coefficient on $ABeta \times ONNLYIFRS$ in Column (4). Overall, the regression results in Table 6 suggest that the risk relevance under the IFRS is not different from that under U.S. GAAP.

[Insert Table 6 here]

5. Extensions

Risk-Relevant Accounting Information and Idiosyncratic Risk

In previous analyses, we observe that the impact of Form 20-F reconciliation elimination on the relation between systematic risk and accounting risk varies with IFRS firm reporting decisions. We find that IFRS firms have higher risk relevance after they chose dual reporting under IFRS and U.S. GAAP as compared to those choosing single reporting. In their study, Hughes, Liu, and Liu (2007) document that greater information asymmetry related to systematic factors is associated with higher uncertainty and costs of capital. Rajgopala and Venkatachalam (2011) find higher earnings quality to be associated with lower idiosyncratic return volatility. In this section, we further investigate the impact of IFRS firms' reporting choices on idiosyncratic risk. Building on those studies, we expect that companies having high risk relevance related to accounting information exhibit low levels of idiosyncratic risk.

Following Ferreira and Laux (2007), we use three indices to measure idiosyncratic risk: (1) annualized monthly idiosyncratic volatility estimated from the market model, (2) the logarithm of idiosyncratic volatility relative to market-wide volatility, and (3) idiosyncratic volatility to total volatility.

Table 7 reports the idiosyncratic risks of the ADRs and the matched U.S. firms before and after eliminating Form 20-F reconciliation, as well as the idiosyncratic risks of IFRS firms with different types of reporting choices. Panel A of Table 7 shows that the idiosyncratic risks of IFRS firms do not change significantly with the exception of $\text{IFRS}^{\text{Both}}$. In Column (2) of Panel A, the mean idiosyncratic variance declines significantly from 0.149 to 0.106 after $\text{IFRS}^{\text{Both}}$ choose to report accounting numbers under both IFRS and U.S. GAAP. In Column (2) of Panel B, the idiosyncratic risk relative to market-wide risks declines significantly by 0.216, which indicates that $\text{IFRS}^{\text{Both}}$ have lower idiosyncratic risk relative to market-wide risks following their decisions. The outcomes in Panel C are quite similar to those in Panel B. $\text{IFRS}^{\text{Both}}$ have the lowest growth rate in idiosyncratic to total risks.

Collectively, the results in Table 7 suggest that the IFRS firms reporting both IFRS and U.S. GAAP information have lower levels of idiosyncratic risk following their decisions.

[Insert Table 7 here]

We next further conduct a multivariate analysis. As shown in Equation (5), the idiosyncratic risk is regressed on an indicator variable that represents the period following the elimination of Form 20-F reconciliations or a change in disclosure policies, as well as several variables that control for size, growth opportunities, and legal system.

$$IdioMRisk_{it} = \gamma_0 + \gamma_1 ELIMINATE + \gamma_2 SIZE_{it} + \gamma_3 MB_{it} + \gamma_4 CIVIL + \varepsilon_{it}, \quad (5)$$

where $IdioMRisk_{it}$ is annualized monthly idiosyncratic volatility estimated from the market model. *ELIMINATE* is a dummy variable that equals 1 if the year is after 2007 or the year in which the firm changed its disclosure policies, and 0 otherwise. *ONLYIFRS* is a dummy variable that equals 1 if an IFRS firm shifts to reporting only IFRS information after the elimination of Form 20-F reconciliation, and 0 otherwise. $SIZE_{it}$ is the logarithm of total assets of the *i*th firm in year *t*. MB_{it} is the market-to-book ratio of the *i*th firm in year *t*. *CIVIL* is a dummy variable that equals 1 if the firm is in a civil law country, and 0 otherwise.

Table 8 reports the results of the multivariate analysis. The coefficient on *ELIMINATE* in Column (2) is significantly negative (-0.043; $p<0.01$), indicating that the idiosyncratic variances for the $\text{IFRS}^{\text{Both}}$ decrease after companies decide to provide both IFRS and U.S. GAAP information. By contrast, there is no significant change in the idiosyncratic variances for other types of IFRS firms, evidenced by insignificant coefficients on *ELIMINATE*.

[Insert Table 8 here]

Value Relevance of IFRS and U.S. GAAP

In this section, we examine whether dual-reporting IFRS firms provide incremental, value-relevant accounting information. According to CAPM, systemic risk is the major determinant of a capital asset's required rate of return, which is related to its value. Based on this logic, we therefore infer that firms with dual disclosure, which provide more risk-relevant accounting information, might also be more conducive to value-relevant accounting information.

We examine the explanatory power of three value-relevance metrics commonly used in empirical studies[14]:stock price, stock return, and cash flow. In addition to firm-specific variables, the value-relevance metrics include an indicator variable that represents economic downturn during the sample period. For each value-relevance metric, we focus on the difference in R-squared from the regression models before and after the firm's decision. Based on prior research, we interpret a higher R-squared as evidence of greater value relevance. Equations (6), (7), and (8) express the value-relevance metrics. We estimate significance levels for all comparisons of R-squared using univariate analysis

$$P_{it} = \beta_0 + \beta_1 BVE_{it} + \beta_2 EPS_{it} + \beta_3 Crisis + \varepsilon_{it}\,, \tag{6}$$

$$Return_{it} = \beta_0 + \beta_1 \frac{EPS_{it}}{P_{it-1}} + \beta_2 \frac{\Delta EPS_{it}}{P_{it-1}} + \beta_3 LOSS_{it} + \beta_4 LOSS_{it} \times \frac{EPS_{it}}{P_{it-1}}$$
$$+ \beta_5 LOSS_{it} \times \frac{\Delta EPS_{it}}{P_{it-1}} + \beta_6 Crisis + \varepsilon_{it}\,, \tag{7}$$

$$CF_{it} = \beta_0 + \beta_1 \frac{EPS_{it}}{TA_{it-1}} + \beta_2 Crisis + \varepsilon_{it}\,, \tag{8}$$

where P_{it} is the mean value of the 12-month stock price three months after the beginning of the fiscal year. BVE_{it} is book value of equity per share of the *i*th firm in year *t*. EPS_{it} is net income before extraordinary items per share of the *i*th firm in year *t*. *Crisisit* is a dummy variable that equals 1 if the year is 2000 or 2008, and 0 otherwise. $Return_{it}$ is annualized monthly stock returns three months after the beginning of the fiscal year. $LOSS_{it}$ is a dummy variable that equals 1 if the EPS of the *i*th firm in year *t* is negative, and 0 otherwise. CF_{it+1} is net cash flow from operations of the *i*th firm in year *t+1*, scaled by lagged total assets. TA_{it-1} is one-year lagged total assets of the *i*th firm.

Table 9 reports the results. In the case of the stock price metric, the difference in R-squared values between the IFRS firms and the matched U.S. companies is significantly negative (-0.061; p=0.02) during the pre-change period, indicating that the IFRS firms have less value-relevant accounting information than U.S. companies. This difference becomes statistically insignificant during the post-change period. The change in difference is 0.121 and is statistically significant. In Columns (2) and (3), the results for the stock return and cash flow metrics are quite similar as well. This suggests that the value relevance of accounting numbers for ADRs increases over time.

We shed further light on the value relevance for each type of IFRS firm according to the forms of disclosure on Form 20-F. Before the change, $IFRS^{Both}$ has less value relevance than the matched U.S. companies. This is shown via the negative differences in R-squared values for all the metrics (-0.049 for *Price*, -0.002 for *Return*, and -0.121 for *Cash Flow*). $IFRS^{Both}$ exhibits significantly more value-relevant accounting information than U.S. companies during the post-change period, evidenced with significantly positive differences for all the

[14] Amir and Lev (1996), Collins, Maydew, and Weiss (1997), Harris and Muller (1999), Song, Thomas, and Yi (2010), and Barth et al. (2012).

metrics (0.177 for *Price*, 0.164 for *Return*, and 0.081 for *Cash Flow*). The differences in the changes in value-relevance for $\text{IFRS}^{\text{Both}}$ are all significantly positive, measured with the three metrics (0.227 for *Price*, 0.162 for *Return*, and 0.203 for *Cash Flow*). These results indicate value relevance increases when $\text{IFRS}^{\text{Both}}$ choose dual reporting under IFRS and U.S. GAAP. In the case of $\text{IFRS}^{\text{Only}}$, the difference in value relevance before and after the change is statistically insignificant. Consistent with Eng et al. (2014), this result suggests that single reporting under IFRS fails to offer incremental, value-relevant accounting information. Similarly, IFRS^{US} does not exhibit incremental value relevance after switching to reporting under U.S. GAAP.

Collectively, the findings in Table 9 suggest that dual reporting under IFRS and U.S. GAAP is necessary, even though accounting numbers under IFRS are sufficiently comparable to U.S. GAAP.

[Insert Table 9 here]

Alternative Measures of Earnings

Following Baran et al. (1980), we re-perform the analyses with three earnings variables: (a) net income before non-recurring items, divided by common equity, (b) net income before non-recurring items, divided by market value, and (c) net income before non- recurring items and depreciation, divided by market value. The unreported results indicate that the findings remain robust when we use these earnings variables.

6. Conclusions and suggestions

The main purpose of this study is to investigate if principle-based accounting standards provide more relevant information than rule-based accounting standards for evaluating systematic risk. Through a series of tests of ADRs and the matched U.S. companies from 1991 to 2012, we do not find a significant difference in risk relevance between principle-based and rule-based accounting standards. In the analysis according to ADR reporting choices, we find that dual reporting under IFRS and U.S. GAAP conveys incremental risk-relevant accounting information to external users compared to single reporting under IFRS.

We further investigate whether this incremental risk relevance is associated with lower idiosyncratic risks and more value-relevant accounting information.

The findings show that ADRs selecting dual reporting under IFRS and U.S. GAAP have lower idiosyncratic risks and value relevance following their decisions. This implies that dual disclosure helps eliminate information asymmetry, which reduces firm-specific risks and is conducive to value-relevant accounting information. Although our findings that single reporting under IFRS fails to offer incremental value-relevant accounting information is consistent with those of a previous study (i.e., Eng et al. 2014), we find that dual reporting under IFRS and U.S. GAAP is important, although accounting numbers under IFRS are sufficiently comparable to U.S. GAAP. Finally, we change different earning measures following Baran et al. (1980) for our tests and still obtain consistent results.

The findings must be tempered by several limitations. First, although we assume a linear relationship between accounting and market betas, the relationship could be nonlinear. However, this is beyond the scope of our research. Second, although 20-F reconciliations provide useful descriptive evidence on the magnitude and direction of the differences between IFRS and U.S. GAAP, the findings may not apply to all U.S. firms and hence should be interpreted cautiously.

Based on the aforementioned limitations, we propose several avenues for future research. First, future studies could provide direct evidence by conducting field research. Furthermore, future studies could embrace the nonlinear relationship between the IFRS and the U.S. GAAP when comparing differences in risk-relevance. In addition, future studies could investigate how to improve the risk relevance of accounting information.

Sample Selection

Panel A: Sample Selection

Criterion	**Firm-Years**	**Firms**
Preliminary merged ADRs with required financial and stock return data available on *Compustat* (1991-2012).	10,702	989
Less: Missing values of variables required for the regression analyses and the top and the bottom 1% and 99% of all variables, as well as financial institutions	(2,680)	(142)
Less: ADRs that do not have data for at least two years before and one year after 2007, the first year IFRS firms changed their accounting principles, and filings of Form 20-F unavailable in the EDGAR system.	(2,939)	(512)
Data available	5,083	335
Less: control firms unavailable	(895)	(61)
Final matched sample of ADR firms	4,188	274

Panel B: Sample Distribution of IFRS Firms by Disclosure Policies in Form 20-F

Types of Disclosure after Elimination	**Firm-Years**	**Firms**
(1) $IFRS^{Both}$	1,168	73
(2) $IFRS^{Only}$	1,957	127
(3) $IFRS^{US}$	30	2
Total	3,155	189

Notes: $IFRS^{Both}$ refers to IFRS firms that provide both IFRS and U.S. GAAP information. $IFRS^{Only}$ refers to IFRS firms that merely provide IFRS information. $IFRS^{US}$ refers to IFRS firms that became U.S. companies and followed U.S. GAAP when the U.S. ownership exceeds 50% of issued share capital, or the firms reincorporated in the United States.

Table 2
Industry and Time Sample Distribution of ADR firms

Panel A: Industry Distribution

Two-Digit SIC Code	Description	Firm-Years	% of Sample
10	Metal, Mining	189	4.5
12	Coal Mining	15	0.4
13	Oil and Gas Extraction	116	2.8
16	Heavy Construction, Except Building	20	0.5
20	Food and Kindred Products	251	6.0
21	Tobacco Products	36	0.9

MBeta	0.992	0.974	0.018 [0.30]	0.872	0.785	0.087 [1.38]

Notes: *refers to significant at the 10% level; ** refers to significant at the 5% level; *** refers to significant at the 1% level, using a two-tailed test. t-statistic/z-statistics for the difference in means/Wilcoxon sign-rank test for the difference of medians. T-statistics are given in brackets. Table 3 compares 274 ADRs (4,188 firm-years) with their matched U.S. firms in the year 2007 or in the year in which the ADR firms changed their disclosure policies. Market-to-Book ratio is determined by dividing market capitalization by total stockholders' equity. Debt ratio is determined by dividing total liabilities by total assets. Accounting Beta (*ABeta*) is the slope coefficient estimated from Equation (1). Market Beta (*MBeta*) is the slope coefficient estimated from Equation (2).

Table 4
Correlation between Market and Accounting Betas

	Test Sample					Control Sample
	Sample Subgroups of ADRs					
	(1) ADRs	(2) IFRS^{Both}	(3) IFRS^{Only}	(4) IFRS^{US}	(5) Other ADRs	(6) US Firms
Pre-Period Correlation	0.121***	0.142***	0.153***	0.500**	0.072*	0.038**
(p-value)	(<0.01)	(<0.01)	(<0.01)	(0.02)	(0.06)	(0.02)

(p-value)	(<0.01)	(<0.01)	(<0.01)	(<0.01)	(0.05)	(<0.01)

Notes: *refers to significant at the 10% level; ** refers to significant at the 5% level; *** refers to significant at the 1% level. The correlation of the accounting and the market betas is the Pearson Correlation between the two betas. The ADRs are classified into four subsamples depending on firm disclosure policies after the Form 20-F reconciliation elimination. IFRS^{Both} represents the ADRs that disclosed both IFRS and U.S. GAAP information. IFRS^{Only} represents the ADRs that only disclosed IFRS information. IFRS^{US} represents the ADRs that changed from disclosing IFRS to disclosing U.S. GAAP information. *Other ADRs* represents the firms that disclosed reconciled U.S. GAAP and local GAAP information. *US Firms* represents the matched U.S. companies. The pre- or post-elimination periods are separated based on the year 2007 or the year in which the firms change their disclosure policies.

N	4,188	1,168	1,957	30	1,033	4,985

Notes: *refers to significant at the 10% level; ** refers to significant at the 5% level; *** refers to significant at the 1% level. P-values are given in parentheses. The samples consist of 4,188 ADR firms and 4,985 U.S. firm-year observations from 1991-2012.

The ADRs are classified into four subsamples depending on firm disclosure policies after the Form 20-F reconciliation elimination. $IFRS^{Both}$ represents the ADRs that disclosed both IFRS and U.S. GAAP information. $IFRS^{Only}$ represents the ADRs that only disclosed IFRS information. $IFRS^{US}$ represents the ADRs that changed from disclosing IFRS to disclosing U.S. GAAP information. *Other ADRs* represents the firms that disclose reconciled U.S. GAAP and local GAAP information. *U.S. Firms* represents the matched U.S. companies.

$MBeta_{it}$ is the market beta of the ith firm in year t, estimated from equation (2). $ABeta_{it}$ is the accounting beta of the ith firm in year t, estimated from equation (1). *ELIMINATE* is a dummy variable that equals 1 if the year is within the years after year 2007 or the year in which the firms change their disclosure policies, and 0 otherwise. $SIZE_{it}$ is the logarithm of total assets of the ith firm in year t. DOL_{it} is the firm's degree of operating leverage, measured by the ratio of percentage change in earnings before interest and taxes to percentage change in sales in year t. DFL_{it} is the firm's degree of financial leverage, measured by the ratio of percentage change in earnings per share to percentage change in earnings before interest and taxes in year t. IBR_{it} is the firm's intrinsic business risks, measured following Mensah (1992). ΔGDP is annual percentage change in gross domestic product in year t. *CIVIL* is a dummy variable that equals 1 if the firm is in a civil law country, and 0 otherwise.

This papers examines the investment performance of a sample of US ethical equity mutual funds relative to the market and a matching sample of traditional equity mutual funds using a survivorship-bias-free database and a comprehensive and integrated model to simultaneously capture stock selection and market timing skill of fund managers. Our empirical results indicate that the ethical funds perform no worse that their traditional counterparts, although the ethical and traditional funds do not outperform the market. We found some evidence of superior security selection and/or market timing skill among a small number of ethical and traditional funds. It appears that the matching traditional funds have slightly more abnormal (superior as well as inferior) performance than the ethical funds in our sample.
Keywords: Ethical investment, socially responsible investment (SRI), stock screening, positive screening, negative screening, portfolio management, trading strategy, performance evaluation, security selection, market timing.

JEL Classification: A13, G11, G12, G20, G23, M14

1. Introduction

Ethical investing, more popularly known as sustainable, socially conscious, "green" or socially responsible investment (SRI) is the application of ethical as well as financial considerations or screens in investment decision-making. It is an investment strategy based on normative ethical and social values. According to Cowton (1994), ethical investing is "the exercise of ethical and social criteria in the selection and management of investment portfolios." Ethical investment has been defined as putting your money where your morals are, or investing according to your beliefs (Brownlow, 2009). Traditional investment is driven by only financial considerations such as maximizing return or wealth, diversifying risk, and maintaining liquidity. Ethical investing is driven by societal needs and benefits and takes into account non-financial criteria, such as certain attributes of the companies in which money is invested, in addition to the financial considerations of traditional investors. Ethical considerations may include, among others, religious affiliations, beliefs, or values.[1] Knoll (2002) pointed out that ethical considerations might be a screening process or a variable in the selection process. Screens can be either negative (exclusionary) or positive (inclusionary). Negative screening excludes companies that are incompatible with the investors' ethical values while positive screening seeks out companies that act in a manner consistent with the investors' ethical values. Examples of negative screening are excluding companies that are engaged in gambling, pornography, production and distribution of alcohol, tobacco, and weapons, employing under-age workers, damaging the environment, and exploiting animals for cosmetics and apparels. Examples of positive screening include investing in companies that promote environmental improvement, pollution control, community engagement, energy conservation, sustainability, consumer protection, human rights, diversity, and such other stakeholder-friendly activities as well as companies serious about product safety, improved working condition for employees, seeking renewable energy to replace fossil fuels, *etc*. Ethical investing aims at rewarding ethical corporate behavior through positive screening and rebuking unethical corporate behavior through negative screening. The demand for ethical investment opportunities has been growing very rapidly. Assets under management (AUM) of global ethical investment funds climbed to $13.6 trillion at the start of 2012, a 22 percent increase since 2010, according to Global Sustainable Investment Alliance (GSIA), and this represents 21.8 percent of the total global AUM (Global Sustainable Investment Alliance, 2013). In the US alone, sustainable, responsible and impact investing assets have expanded 76 percent in two years: from $3.74 trillion at the start of 2012 to $6.57 trillion at the start of 2014, according to the US SIF Foundation's latest biennial survey, the Report on US Sustainable, Responsible and Impact Investing Trends 2014. As a result, AUM of US ethical funds now accounts for more than one out of every six dollars under professional management in the US (USSIF, 2014).

The purpose of this paper is to examine the investment performance of ethical equity mutual funds in the US using a comprehensive and integrated model. Several prior studies examined investment performance of ethical mutual funds and unit trusts in the US (Hamilton, Jo, and Statman, 1993, Statman, 2000, Bauer, Koedijk, and Otten, 2005, and Benson and Humphrey, 2008) and other countries (Mallin, Saadouni, and Briston, 1995, Gregory, Matatko, and Luther, 1997, Cummings, 2000, Tippet, 2001, Bauer, Koedijk, and Otten, 2005, Kreander, Gray, Power, and Sinclair, 2005, Jones, Laan, Frost, and Loftus, 2008, Renneboog, Horst, and Zhang, 2008a, and Cortez, Silva, and Areal, 2009).[2] Most of these studies examined investment performance of ethical funds employing unconditional risk-adjusted performance measures such as Sharpe's reward to variability ratio, Treynor's reward to volatility ratio, and Jensen's alpha or its multi-factor version based on Fama and French (1993) and Carhart (1997). One weakness of all these measures is focus on fund managers' security selection or selectivity skill only while totally disregarding the manager's ability to time the market. A few studies examined fund managers' market timing skill using a rudimentary market timing model of Treynor and Mazuy (1966) [Gregory and Whittaker, 2007 and Renneboog, Horst, and Zhang, 2008a] or a less sophisticated model of Hendriksson and Merton (1981) [Kreander, Gray, Power, and Sinclair, 2005]. However, the studies using the Treynor-Mazuy model did not correct for heteroscedasticity of regression errors resulting from the fund manager's attempt to time the market. A comprehensive and integrated model to simultaneously capture stock selection and market timing skill has been developed by Jensen (1972) by extending the Treynor-Mazuy model. Bhattacharya and Pfleiderer (1983) further refined the Treynor-Mazuy model and Lee and Rahman (1990) developed the econometric methodology to apply the model in empirical investigation. This refined model has been used to examine investment performance of US equity mutual funds (Lee and Rahman, 1990, 1991) and US equity pension funds (Coggin, Fabozzi, and Rahman, 1993). These studies found evidence of security selection and/or market timing skill in a small number of funds. There is no prior research work in the extant literature examining the investment performance of ethical funds using such a refined model. This paper fills the void in the literature by examining the investment performance of a sample of ethical funds in the US using the Bhattacharya-Pfleiderer model. Another weakness of the majority of previous studies is survivorship bias. These studies excluded funds that disappeared via merger, acquisition or liquidation. In their empirical investigation, Grinblatt and Titman (1989) and Brown and Goeszmann (1995) found survivorship bias of approximately .5 percent per year and this could overstate the performance measures to some extent. This paper is free from survivorship bias as it uses a survivorship-bias-free database. This paper is organized as follows: section II briefly traces the development of the Bhattacharya-Pfleiderer model and discusses its superiority over other measures and justification for using this model in empirical investigation of investment performance of managed portfolios. Section III discusses the data and econometric methodology used in this paper, section IV discusses the empirical results, and section V concludes the paper.

2. A Model for Security Selection and Market Timing Skill

The unconditional risk-adjusted performance measures of Sharpe's reward to variability ratio, Treynor's reward to volatility ratio, and Jensen's alpha assume that the risk level of managed portfolio under consideration is stationary through time and ignore the manager's market timing skill (*i.e.*, ability to shift the overall risk composition of the portfolio by moving into and out of segments of the market). Selling "winners" for realizing capital gains or "losers" for tax purposes and reinvesting the proceeds (not necessarily in the stocks of same risk-class) is one reason risk as measured by standard deviation (in Sharpe's reward to variability ratio) or beta (in Treynor's reward to volatility ratio) changes. Average turnover of mutual funds is another indication that risk changes. Mutual funds have an average turnover rate (*i.e.*, the percentage of a fund's holdings that change every year) of approximately 85 percent, meaning that funds are turning over or selling nearly all of their holdings every year (Barker, n.d). This results in violation of the stationarity assumption of risk made in Sharpe's or Treynor's measure. When fund managers adopt a market-timing strategy, the unconditional measure of Jensen's alpha becomes biased. Jensen (1968) acknowledged the ability of the fund managers to change the risk level of their portfolios in anticipation of broad market movements. Fama (1972) and Jensen (1972) addressed this issue and suggested a somewhat finer breakdown of performance. Fama (1972) suggested that the portfolio manager's forecasting skill could be partitioned into two distinct components: (1) forecasts of price movements of selected individual stocks (selectivity or microforecasting), and (2) forecasts of price movements of the general stock market as a whole (market timing or macroforecasting). This partitioning of forecasting skills is also evident in Treynor and Black (1973) who have shown that portfolio managers can effectively separate actions related to security analysis from those related to market timing. When managers successfully time the market, the measures without controlling market timing behavior are biased (Ferson and Schadt, 1996). Jensen (1968) demonstrated that, in the presence of market timing ability, the estimated measure of systematic risk or beta will be biased downward and the estimated performance measure (Jensen's alpha) will be biased upward. Grant (1978) explained how market timing actions would affect the results of empirical tests that focus only on microforecasting skill.

Admati and Ross (1985) discussed the failure of traditional measures based on CAPM (Treynor's reward-to-volatility ration and Jensen's alpha) to evaluate the fund manager's performance in the presence of changing risk level and information asymmetry. When there is information asymmetry, the manager changes the composition of the portfolio in response to the private information he or she receives. Based on information signal received, the manager forms his or her posterior distribution of assets' returns that is unknown to others and varies over time (depending on what the information happens to be). The true and relevant risk actually carried by the manager now changes over time though other parameters are stationary (Lee and Rahman, 1994). Admati and Ross (1985) also showed that the weakness of CAPM-based measures is applicable to Sharpe's reward-to-variability ratio that is independent of CAPM. Intuitively, although better information implies higher expected returns, it also leads to a larger variance. This results in lower reward-to-variability ratio for better-informed managers (see Lee and Rahman, 1994, for details).

It is apparent that fund managers be evaluated by both selection ability and timing skill. This necessitates modeling selection skill and timing simultaneously. Market timing is common among fund managers. Same fund managers manage ethical and traditional funds and while managing ethical funds, they are primarily driven by investment objectives and constraints of respective funds rather than their own ethical belief. They are more likely to try to time the market (in traditional as well as ethical funds) to increase portfolio returns. It is, therefore, appropriate to examine selectivity and market timing skill of ethical fund managers so that there is no model misspecification leading up to biased estimates. However, whether they are successful market timer is an empirical question.

Using the option-pricing model, Merton (1981) and Henriksson and Merton (1981) developed a measure that permits identification and separation of selectivity and timing skills of fund managers. In their model, the fund manager forecasts whether the stock market will provide a higher or lower return than the risk-free rate. The forecaster does not attempt or is not able to predict by how much stocks will outperform or underperform the risk-free rate. Based on their forecasts, fund managers adjust the relative weight of the market portfolio and the risk-free asset. Merton (1981) demonstrated that the returns on the portfolio using the indicated market timing rule is same as those that would be generated by a strategy of investing in the market portfolio and risk-free asset and acquiring free put options on the market portfolio with an exercise price equal to the risk-free rate. The forecasters in this model are less sophisticated than those of Jensen (1972) where the fund managers have ability to forecast how much better the superior investment will perform. The Henriksson-Merton model, on the other hand, assumes that the managers have a coarse information structure in which binary signals (up or down) are only indicative of the sign or direction (and not the size) of the excess of the market return over the risk-free rate. One weakness of the Henriksson-Merton model is that information is measured but there is no test of whether information is being used correctly (Dybvig and Ross, 1985). In their empirical analysis, Cheng and Lewellen (1984) and Henriksson (1984) found a large number of negative timing coefficients reflecting irrational behavior on the part of the fund managers. In order to generate a negative timing coefficient, the fund managers must possess superior information and employ it irrationally, that is, raise (lower) market risk when the signal indicates that the market will fall (rise). Connor and Korajczyk (1991) termed this behavior *perverse timing*.

Treynor and Mazuy (1966) observed that if the fund managers can forecast market returns, they will hold more high beta stocks or a greater portion of the market portfolio when they expect the market to go up to increase portfolio return. Conversely, they will hold more low beta stocks or a smaller portion of the market portfolio when they expect the market to go down to reduce capital losses. Thus, the portfolio return will be a nonlinear function of the return on the market portfolio. To capture this, the authors added a quadratic term to standard CAPM version of Jensen's alpha:

$$R_{pt} = \alpha_p + \beta_p R_{mt} + \gamma(R_{mt})^2 + \varepsilon_{pt} \tag{1}$$

where R_{pt} is the excess (net of risk-free rate) return on the fund, R_{mt} is the excess (net of risk-free rate) return on the market portfolio, α_p is a measure of security selection skill, β_p measures the sensitivity of the fund return to the market return, γ measures fund manager's market timing skill, and ε_{pt} is a random error with an expected value of zero. Thus, the fund return will be a convex function of the market return. Using annual returns for fifty seven open-end mutual funds, they found that the hypothesis of no market-timing skill can be rejected with 95 percent confidence for only one of the funds.

Jensen (1972) developed a model similar to Treynor-Mazuy model to detect selectivity and timing skill of fund managers. In the Jensen analysis, the fund manager forecasts the market return and the forecasted and actual market return are assumed to have a joint normal distribution. Jensen showed that the fund manager's market timing skill could be measured by the correlation between the forecasted and actual market return. Bhattacharya and

Pfleiderer (1983) corrected an error in Jensen's model and showed that one could use a regression technique to detect selectivity and timing.[3] They specify a relationship in observed variables that is similar to Treynor-Mazuy model:

$$R_{pt} = \alpha_p + \theta\ E(R_{mt})\ (1 - \Psi)\ R_{mt} + \Psi\theta(R_{mt})^2 + \theta\Psi\ \zeta_{pt}\ R_{mt} + \mu_{pt} \tag{2}$$

where

θ = the fund manager's response to information

Ψ = the coefficient of determination between the manager's forecast and excess market return

ζ_{pt} = the error of the manager's forecast

$E(R_{mt})$ = expected excess market return

The quadratic regression of R_{pt} on R_{mt} and $(R_{mt})^2$ allows us to detect manager's selectivity skill from α_p. The error term of eq. (2):

$$\omega_t = \theta\Psi\ \zeta_{pt}\ R_{mt} + \mu_{pt} \tag{3}$$

provides the information to detect the manager's timing skill. We can extract this information by regressing $(\omega_t)^2$ on $(R_{mt})^2$. This regression produces a consistent estimator of $\theta^2\Psi^2\sigma^2_\zeta$, where σ^2_ζ is the variance of the manager's forecast error. We now divide $\theta^2\Psi^2\sigma^2_\zeta$ by the square of $\theta\Psi$ which is the estimated coefficient of $(R_{mt})^2$ in eq. (2), to obtain an estimate of σ^2_ζ . This coupled with knowledge about σ^2_π , the variance of excess market return, allows us to estimate $\Psi = (\sigma^2_\pi)/[\ \sigma^2_\pi + \sigma^2_\zeta] = \rho^2$, where ρ is the correlation coefficient between the manager's forecast and excess return on the market. Finally, we calculate ρ, which truly measures the quality of the manager's timing skill. This model is a refinement of the Treynor-Mazuy model and it is the first model that analyzes the error term to identify a manager's forecasting skill. Such a refinement makes the model more powerful than other competitive models.

3. Data and Methodology

The data for this study consists of monthly returns for the period January 2004 through December 2013 (120 months) for a sample of 67 ethical equity mutual funds in the US with no missing data for the entire sample period or inception through December 2013 for those funds that started after January 2004. This resulted in a maximum number of 120 monthly observations and a minimum number of 49 monthly observations. The list of funds came from US SIF – the Forum for Sustainable and Responsible Investment and the monthly return observations and monthly total net assets were collected from the CRSP survivorship-bias-free US mutual fund database. The monthly returns are net of all management expenses and 12-b fees, but before deducting front- and back-end load fees. These returns are appropriate when evaluating the investment performance of fund managers without regard to whether the managed funds are load or no-load funds. The fund managers do not control load fees which are decided by fund administrators and fund managers should not be evaluated based on returns net of load fees, if there is any. A matched sample of another 67 traditional equity funds was generated from the CRSP mutual fund database to compare the performance of each ethical fund with that of a traditional counterpart. Each ethical fund was matched with a traditional fund that was nearest to it in asset size (measured by monthly total net assets) on December 31st, 2008—the mid-point of the sample period. The matched sample is also free from survivorship-bias as the sample includes funds that disappeared from the database before December 2013—the end of sample period—because of merger, acquisition, or termination. The monthly return on the CRSP value-weighted index including dividends is used for market return. Monthly observations of the 91-day Treasury bill rate are used as a proxy for the risk-free rate.

To compare results, we examined investment performance of fund managers using both the Treynor-Mazuy and the Bhattacharya-Pfleiderer model. It is necessary to correct for heteroscedasticity in both models. In the Treynor-Mazuy model, the error term exhibits conditional heteroscedasticity because of the fund manager's attempt to time the market, even though security returns are assumed to be independent and identically distributed through time. To correct this, following Breen, Jagannathan, and Ofer (1986) and Lehmann and Modest (1987), Coggin, Fabozzi, and Rahman (1993) used heteroscedasticity-consistent covariance matrix estimators proposed by White (1980), Hansen (1982), and Hsieh (1983). Long and Ervin (2000) found this estimator to have weak small sample properties often resulting in incorrect inferences. MacKinnon and White (1985) introduced three alternative heteroscedasticity-consistent covariance matrix estimators that are all asymptotically equivalent to the estimator proposed by White (1980) but typically have strong small sample properties. MacKinnon and White (1985) and Long and Ervin (2000) examined the performance of these estimators in small samples using Monte Carlo simulations in regression models and strongly recommended using the alternative known as HC3 if the sample size is less than 250. We used the HC3 estimator to correct for heteroscedasticity in Treynor-Mazuy model. In the Bhattacharya-Pfleiderer model, the disturbance terms in eq. (2) and (3) are heteroscedastic and standard regression technique does not produce the most efficient estimates. We use the following GLS procedure to obtain efficient estimates of parameters by taking into account the changing variances of the error terms. First, we divide all the variables (on both sides) of eq. (2) by the variance of error term in eq. (2) and all the variables (on both sides) of eq. (3) by the variance of error term in eq. (3). We then apply OLS regression to the transformed observations of eq. (2) and (3) to obtain more efficient estimates [see Lee and Rahman (1990) for details]. The significance tests reported in the next section are based on heteroscedasticity-adjusted t-statistics.

One weakness of the Bhattacharya-Pfleiderer model is its failure to detect negative or inferior market timing (Coggin and Hunter, 1993). We resolve this issue by examining the sign of the coefficient of the squared excess market return in eq. (3) following Coggin, Fabozzi, and Rahman (1993). Intuitively, in the spirit of the Treynor-Mazuy model, the sign of this coefficient is indicative of the nature of the fund manager's timing skill. If this coefficient is negative, we designate timing skill (as measured by ρ) to be poor or negative. This modification makes the model more realistic. A similar adjustment of the Bhattacharya-Pfleiderer model was implicitly introduced in Jagannathan and Korajczyk (1986).

4. Empirical Results

Table 1 presents summary empirical results from employing the Treynor-Mazuy model and the Bhattacharya-Pfleiderer model to the time series of monthly returns of ethical and traditional equity mutual funds. These results show some evidence of selectivity and market timing at the individual fund level. There are some noticeable differences between the Treynor-Mazuy model and the Bhattacharya-Pfleiderer model in detecting abnormal performance of ethical as well as traditional funds. Thirty three out of sixty seven ethical funds have positive selectivity measure of the Treynor-Mazuy model only two of which are statistically significant at the .05 level. Twenty three out of sixty seven traditional funds have positive selectivity measure of the Treynor-Mazuy model only five of which are statistically significant at the .05 level. Thirty four ethical and forty two traditional funds have negative selectivity measure of the Treynor-Mazuy model and these measures are statistically significant at the .05 level for seven ethical and seventeen traditional funds. Twenty seven ethical and thirty seven traditional funds have positive timing measure of the Treynor-Mazuy model and these measures are statistically significant at the .05 level for two ethical and ten traditional funds. For the Bhattacharya-Pfleiderer model, thirty five ethical funds have positive selectivity measure only two of which are statistically significant at the .05 level and twenty nine traditional funds have positive selectivity measure only six of which are statistically significant at the .05 level. Thirty two ethical and thirty eight traditional funds have negative selectivity measure of the Bhattacharya-Pfleiderer model and these measures are statistically significant at the .05 level for seven ethical and seventeen traditional funds. One ethical and seven traditional funds have positive timing measure of the Bhattacharya-Pfleiderer model and these measures are statistically significant at the .05 level one ethical and three traditional funds. Fifteen ethical funds have both positive selectivity and timing measure of the Treynor-Mazuy model and two of those funds have statistically significant selectivity and timing measure. Twenty two traditional funds have both positive selectivity and timing measure of the Treynor-Mazuy model and three of those funds have statistically significant selectivity and timing measure. Only one ethical fund has both positive selectivity and timing measure of the Bhattacharya-Pfleiderer model and its timing measure only is statistically significant. Two traditional funds have both positive selectivity and timing measure of the Bhattacharya-Pfleiderer model and none of these two has statistically significant selectivity and timing measure.

The results show that traditional funds have more abnormal (superior as well as inferior) performance than their ethical counterparts. While restricted (because of screening criteria) investment opportunities require managers of ethical funds to be more efficient and disciplined in picking “winners” and avoiding “losers” to keep their transaction costs low and portfolio return reasonably high, enlarged boundary of unrestricted feasible investment opportunity set makes managers of traditional equity funds wonder around unsuccessfully searching for mispriced assets and thereby generate too many transaction costs that drives down their portfolio returns. It appears that both traditional and ethical funds do not outperform the market judged by risk-adjusted performance measures as neither group has a large number of funds demonstrating superior performance on a risk-adjusted basis. Our results are consistent with those of prior studies of investment performance of managed portfolios. (See, for example, Jensen, 1968, Kon, 1983, Chang and Lewwellen, 1984, Henrikkson, 1984, Cumby and Glen, 1990, Lee and Rahman, 1990, Connor and Korajczyk, 1991, and Coggin, Fabbozi, and Rahman, 1993). These results are also consistent with efficient market hypothesis, which states that no investors (individual or institutions) can consistently generate superior risk-adjusted returns.

We employed parametric matched-pairs t-test and nonparametric Wilcoxon matched-pairs signed-rank test to investigate if ethical funds and traditional funds differ significantly in terms of risk-adjusted performance measures. Both matched-pairs t-test and Wilcoxon matched-pairs signed-rank test fail to reject the null hypothesis of no significance difference between ethical and traditional funds in timing measure of the Treynor-Mazuy model and both selectivity and timing measure of the Bhattacharya-Pfleiderer model. However, both

Table 1:

matched-pairs t-test and Wilcoxon matched-pairs signed-rank test reject the hypothesis of no significant difference between ethical and traditional funds in selectivity measure of the Treynor-Mazuy model. As discussed earlier, the Bhattacharya-Pfleiderer model of measuring investment performance of managed portfolios is more robust and econometrically and methodologically superior to and improvement over the Treynor-Mazuy model. It appears that empirical results based on the Bhattacharya-Pfleiderer model are consistent with those of prior studies (Hamilton, Jo and Statman 1993, Mallin, Saadouni, and Briston, 1995, Goldreyer, Ahmed, and Diltz, 1999, Statman, 2000, Kreander, Gray, Power, and Sinclair, 2005, Geczy, Stambaugh, and Levin, 2006, Bauer, Koedijk, and Otten, 2005, Bauer, Derwall, and Otten, 2007, and Jones, Laan, Frost, and Loftus, 2008) that found that ethical funds perform no worse than their traditional counterparts. However, we observe that there are slightly more outliers (superior and inferior performer) in traditional funds than in ethical funds. The Bhattacharya-Pfleiderer model used in this paper has resolved all methodological and econometric issues that confound the empirical results of the previous studies and our results are free from any specification error. Moreover, our results are free from survivorship-bias that partially distorts empirical results of the prior studies.

Ethical mutual funds are at an apparent disadvantage compared to traditional mutual funds because the ethical screening process reduces the set of stocks available for efficient diversification and risk-reduction. It is possible to improve the efficient frontier and further reduce systematic risk by adding stocks from enlarged global market to the portfolio because stocks in a larger sample are likely to be uncorrelated, less positively correlated, or somewhat negatively correlated (Solnik, 1974). However, a subset of stocks from enlarged global market may not be compatible with an ethical fund's screening criteria and the manager of an ethical fund may encounter "lost opportunity." This smaller asset universe to be considered in the portfolio formation process may negatively affect investor's efficient frontier and risk-reduction via diversification. The empirical evidence in this paper and other previous studies that ethical funds match the performance of traditional funds on a risk-adjusted basis goes against conventional wisdom, which states that limited opportunity for risk reduction via diversification along with incremental expenses associated with implementing the ethical screening process and monitoring the acceptable companies to ensure reasonable compliance with designated ethical values will result in lower risk-adjusted return for ethical funds compared to traditional funds with unrestricted investment and diversification opportunity. Advocates of ethical investing may argue that competitive returns to ethical funds arise because screening tools allow fund managers to identify the best companies in terms of potential for profits (Cortez, Silva, and Areal, 2009).

Empirical findings of this paper have important implications for investors of ethical funds. Ethical fund may have diverse clientele base including "devoted" ethical investors who are willing to sacrifice a fraction of risk-adjusted return for ethical values and "profit-maximizing" ethical investors who are unwilling to accept risk-adjusted return lower than that of a traditional fund in a comparable risk class. The empirical results of this paper are good news for both of these investors. Devoted ethical investors do not have to sacrifice return to invest in ethical funds and profit-maximizing ethical investors will get what they want.

5. Conclusions

The demand for ethical investing has been growing very fast in the recent decades and along with it asset under management of ethical equity mutual funds is experiencing phenomenal growth. It is of utmost importance to evaluate the performance of managers of ethical funds using risk-adjusted performance measures for managed portfolios so that individual investors of ethical funds can select appropriate funds based on their risk-tolerance and investment objectives. The performance of ethical funds should be compared to those of traditional funds so that investors can determine if they are sacrificing a fraction of risk-adjusted return for adhering to cherished ethical values. This paper examines investment performance of a sample US equity ethical funds and compares their performance with that of a comparable traditional fund based on fund size. This paper employs a sophisticated model to resolve all methodological and econometric issues that confound the empirical results of the previous studies of investment performance. Using a survivorship-bias-free data base from US market, this paper compares and contrasts investment performance of a sample of ethical and traditional funds. The empirical results presented in the paper demonstrates that ethical funds perform no worse than their traditional counterparts, although ethical and traditional funds as a group do not outperform the market which is consistent with prior studies of mutual fund performance. The ability of the ethical funds to match the performance of the traditional funds implies that ethical investors are not making financial sacrifice as a price for adhering to their precious ethical values. We also find that a small number of ethical and traditional funds exhibit superior security selection skill and/or market timing skill although we notice that traditional funds have more abnormal (superior as well as inferior) performance relative to the market. These results have important implications for investors of ethical funds regardless of their preferred utility maximization formula, *i.e.*, whether they are "dedicated" ethical or "profit-maximizing" ethical investors.

Our paper explores how corporate governance affects the valuation of tax avoidance. We argue that better governance enhances investor valuation of tax avoidance primarily through deterring managers from misallocating tax savings to pursue their private benefits. By exposing cross-country data, we find that investors on average negatively value corporate tax avoidance and such negative valuation is attenuated in countries with strong protection for investor rights. Furthermore, in countries with weaker investor protection managers are more likely to misuse tax savings on suboptimal investments and this leads tax avoidance to negatively impact firm operating performance. Our findings suggest that the primary agency issue concerning tax avoidance is the misallocation of tax savings instead of managers exploiting tax avoidance to shield their rent extraction.

Keywords: tax avoidance; firm value; corporate governance

JEL Classification: G3; H25; H26

1. Introduction

Our study explores how corporate governance affects investor valuation of corporate tax avoidance.[1] We find that better governance enhances the value of tax avoidance primarily through deterring managers (i.e. controlling shareholders in non-US countries) from using tax savings to pursue private benefits. Our study is motivated by the debates regarding the corporate governance view of tax avoidance (Desai and Dharmapala 2006, 2009; Desai et al. 2007).

Specifically, the corporate governance view of tax avoidance argues that tax avoidance does not naturally increase firm value because tax avoidance facilitates managers to extract rent[2] by allowing them to exploit the opaqueness of tax avoidance activity to shield their rent extraction behaviors (tax-shielded rent extraction). In this regard, this view further argues that good governance can reduce tax-shielded rent extraction and therefore leads to higher valuation of tax avoidance. By incorporating agency conflicts into analysis, the corporate governance view of tax avoidance has received considerable attention in recent literature (e.g., Hanlon and Slemrod 2009; Chen et. al., 2010; Kim et al. 2010; Dhaliwal et al. 2011).

However, some recent studies find results contradicting the prevalence of the tax-shielded rent extraction (e.g., Wang 2010; Blaylock 2011).[3] In fact, evidence in support of tax-shielded rent extraction is primarily anecdotal (e.g., the cases of Enron and Dynegy), while the only empirical evidence comes from studies exploring Russian firms (Desai et al. 2007; Mironov 2013) and whether results of these studies can generalize to other countries is unclear. The scarcity of empirical evidence suggests that tax-shielded rent extraction is either

---

[1] Following Hanlon and Heitzman (2010), we broadly define tax avoidance as the reduction of explicit taxes per dollar of pre-tax accounting earnings. However, to correspond with the theory of Desai and Dharmapala (2006, 2009) and Desai et al. (2007), in our study tax avoidance specifically refers to tax avoidance with aggressive forms that require some extent of obfuscation.

[2] Following prior studies (Desai and Dharmapala 2006, 2009; Desai et al. 2007; Blaylock 2011), the term "extract rent" is defined as managerial opportunism that managers somehow extract personal benefits through corporate tax avoidance activity.

[3] By exploring a large panel of US firms, Blaylock (2011) find no consistent evidence that tax avoidance is related to managerial rent extraction and he concludes that the managerial rent extraction from tax avoidance is on average not economically significant among US firms. Wang (2010) report that transparent firms avoid more taxes relative to their opaque counterparts, which suggests that managers engage in tax avoidance transactions mainly to enhance shareholder wealth.

difficult for outsiders to detect or it may only occur in extreme cases. In this regard, it is doubtful that corporate governance affects the valuation of tax avoidance just because it alleviates an agency issue that rarely occurs and difficult to detect in real world. Therefore, there may be alternative explanation for why governance affects investor valuation of tax avoidance.

We propose the "*misallocation argument*" as an alternative explanation beyond the tax-shielded rent extraction argument. Specifically, the general consequence of tax avoidance is to produce cash savings, but this does not necessarily enhance firm value because managers may misallocate these cash savings to advance their personal benefits (Christie and Nanda 1994) and tax avoidance will be worth less if there is more chance that tax savings are going to be wasted or expropriated (Pinkowitz et al. 2006).[4] Investors of poor-governed firms may negatively value corporate tax avoidance because their firms afford the costs of tax avoidance while the benefits of tax savings are expropriated by managers. In this regard, good corporate governance can rectify the misallocation of tax savings by redeploying them to more productive uses, as it is well documented that good governance induces managers to use firm liquid resources more efficiently (e.g., Dittmar et al. 2003; Dittmar and Mahrt-Smith 2007; Harford et al. 2008; Iskandar-Datta and Jia 2013).[5]

The misallocation argument is consistent with the corporate governance view of tax avoidance that managers can extract rent from tax avoidance and better governance can enhance the value of tax avoidance, but the novelty here is that managers extract rent through misusing tax savings rather than through exploiting the opaqueness of tax avoidance to shield rent extraction. The misallocation argument emphasizes a more general concern regarding how managers use tax savings. With this emphasis, better governance can still enhance the value of tax avoidance by inducing managers to use tax savings more efficiently even if managers do not exploit the opaqueness of tax avoidance to conceal their rent extraction. In contrast, the tax-shielded rent extraction argument does not rely on actual tax savings but

---

[4] This notion is similar to the finding of Pinkowitz et al. (2006) that corporate cash holdings are valued at a discount in countries with weak investor protection due to the increased opportunities for managers (or controlling shareholders) to misuse or tunnel these liquid resources.

[5] For example, Dittmar and Mahrt-Smith (2007) and Harford et al. (2008) report that the use of cash is more likely to enhance future operating performance for firms that are well governed. By conducting an international research, Iskandar-Datta and Jia (2013) also show that greater shareholder rights lead to a positive relation between cash depletion and firm performance.

instead emphasizes that tax avoidance facilitates rent extraction by providing managers with an excuse for entering into obscure tax avoidance transactions to shield their rent extraction, although such shielded behaviors may be not prevalent in reality.

Our study explores an international setting because this allows us to measure governance quality with country-level investor protection measures (La Porta et al.1998, 2000). This increases the power of our research design since the cross-country variation in the extent to which manager can extract rent from tax avoidance is likely to be more substantial than the cross-firm variation within a particular country (Desai et al. 2007; Blaylock 2011).[6] Moreover, using international data also avoids potential sample selection-bias that biases our test toward finding insignificant results, while this bias is more salient if we explore only single country and in this country managers inherently have little opportunities to extract rent (e.g., US).

Our study uses a sample that spans 34 countries and 17 years. We find that investors in the U.S. positively value tax avoidance but this result is insignificant, consistent with the finding of Desai and Dharmapala (2009). In addition, investors in non-US countries on average negatively value tax avoidance, so the idea that tax avoidance does not increase firm value holds not only for the U.S but also for other countries. This negative valuation may arise because investors perceive that most tax savings are going to be misused and the remaining tax savings cannot cover the costs of tax avoidance incurred by their firms. We also find that the valuation of tax avoidance is higher in countries with stronger investor protection, which finding suggests that the value of tax avoidance is a function of corporate governance.

However, our finding that better governance leads to higher valuation of tax avoidance is consistent with both the tax-shielded rent extraction argument and the misallocation argument. To determine which argument dominates, we follow the specification of Almeida et al. (2004) to examine the relation between tax avoidance and cash flow, as the tax-shielded

---

[6] Blaylock (2011) finds that the magnitude of rent extracted from tax avoidance is not distinct between poor-governed and well-governed firms. Desai et al (2007) report that country-level tax enforcement can hinder rent extraction of tax avoidance. These results suggest that country-level granting and enforcing of investor protection may be more important than firm-level governance mechanisms in the determination of the extent to which managers can extract rent from tax avoidance. This argument makes sense because firm-level governance mechanisms cannot effectively mitigate managerial entrenchment in an environment with weak protection for investor rights as prior studies (e.g. Doidge et al. 2007; Aggarwal et al. 2009) show that countries' institutions are major forces in shaping firm-level governance mechanisms.

rent extraction argument predicts that tax avoidance does not necessarily relate to actual cash savings while the misallocation argument makes an opposite prediction.

Consistent with the misallocation argument, we find that tax avoidance generally produces cash savings and this finding holds even for countries with weak investor protection. As tax-shielded rent extraction should be most prevalent in a poor-governed environment, this result suggests that tax-shielded rent extraction may be not as general as argued by prior studies. We further find that cash savings from tax avoidance is lower when firms have more capital and R&D investments, and this finding suggests that managers use tax savings to fund investments. As corroborating evidence, we find that tax avoidance is positively related to investment expenditures.

We further investigate how tax avoidance affects investment efficiency. We find that tax avoidance relates to overinvestment (Richardson 2006) and this relation is attenuated in countries with strong investor protection. This result suggests that managers may squander tax savings on projects that advance their personal benefits and better governance can rectify such squandering behavior. We also examine how tax avoidance impacts operating performance. If tax avoidance leads to overinvestment, then it should also lead to lower operating performance (Blaylock 2011). As anticipated, we find that tax avoidance negatively impact performance and this negative impact is mitigated in countries with strong investor protection.

Our additional tests show that tax avoidance is positively related to excess cash holdings (Dittmar and Mahrt-Smith 2007; Harford et al. 2008), but this positive relation is attenuated in countries with strong investor protection. This result contradicts the tax-shielded rent extraction argument as it predicts that excess cash should be lower because managers may shield their diversion of firm cash with tax avoidance transaction. This result implies that in countries with poor investor protection managers are more likely to employ tax avoidance transactions to serve their own interests instead of to meet their firm's normal needs. Managers hoard as much cash as they can in a poor-governed environment (Dittmar et al. 2003) while tax avoidance is one means that facilitates them to do so.

We also find that tax avoidance is negatively related to payouts to shareholders, while this negative relation is attenuated by strong investor protection. This implies that managers appear to be reluctant to disgorge tax savings to shareholders, but strong investor protection induces them to do so, consistent with the outcome model as elaborated in La Porta et al. (2000b). Moreover, we find that the negative valuation implication for tax avoidance is more pronounced when firms hold excess cash. Therefore, investors perceive that tax savings exacerbate the agency problem of excess cash.

Our study makes following contributions to the literature. First, we contribute to the emerging literature examining the agency cost implications of corporate tax avoidance. Overall, our findings suggest that the primary agency issue concerning tax avoidance is how managers use tax savings instead of how managers exploit tax avoidance to mask their rent extraction as argued by Desai and Dharmapala (2006, 2009) and Desai et al. (2007). We find that strong investor protection can deter managerial misallocation of tax savings, and this finding helps to clarify how good governance enhances the value of tax avoidance. Because the magnitude of tax savings is typically substantial,[7] we believe that our misallocation argument is more general than the tax-shielded rent extraction argument.

In addition, our results suggest that the extent to which managers can extract rent from tax avoidance depends on investor protection. These results explain why prior studies (e.g., Wang 2010; Blaylock 2011) fail to find significant relation between tax avoidance and rent extraction among US firms and a possible explanation for this finding is that investors in the U.S. enjoy good protection so that managers have few opportunities to extract rent. In this regard, our results corroborate that the corporate governance view of tax avoidance is more appropriate to firms in countries with weaker investor protection (e.g., Russia) than those in countries with stronger investor protection (e.g., U.S.).

Our study also contributes to the literature examining heterogeneity in investor valuation of tax avoidance. With this respect, we find that country-level investor protection is an important determinant of how investors perceive the value of corporate tax avoidance. Our international setting is particularly relevant given that there is little systematic evidence on exploring the valuation of tax avoidance outside the U.S. market. Our paper also relates to the broad literature on the agency issue of holding cash (e.g., Harford et al., 2008; Dittmar and Mahr-Smith, 2007). Prior literature suggests that the misuse of internal funds can be substantial. We extend this stream of literature by showing that as one source of internal funds, tax savings also encounter with managerial misuse.

[7] The importance of tax savings is salient as Mills et al. (1998) estimate that firms generate $4 of tax savings for each $1 invested in tax planning and Rego and Wilson (2012) note that in a recent study of tax shelters, firms were able to generate annual tax deductions large enough to shield income equal to almost 10 percent of assets.

The second section develops our hypothesis. The third section describes our empirical design and sample selection. The fourth section discusses the empirical results, the fifth section describes our additional analysis, and the sixth section concludes.

2. Literature review and hypothesis development

2.1. *The effect of corporate governance on the valuation of tax avoidance*

Prima facie, tax avoidance produces tax savings and thereby enhances firm value. In contrast to this intuition, the corporate governance view of tax avoidance argues that tax avoidance does not necessarily increase firm value because tax avoidance transactions facilitate managers to extract rent from the firm (Desai and Dharmapala 2008).[8] Specifically, to shield income from tax authorities managers often attempt to obscure the underlying intent of tax avoidance transactions and this limits firm-specific information flow to the public (Kim et al. 2010). The proprietary and obfuscatory feature of tax avoidance facilitates rent extraction by providing managers with a shield to conceal their opportunistic behaviors. Accordingly, better governance leads to higher valuation of tax avoidance (e.g., Desai and Dharmapala 2009; Wilson 2009).[9]

However, the positive influence of good governance on the valuation of tax avoidance is not naturally attributed to the tax-shielded rent extraction argument. Another explanation is

[8] Desai and Dharmapala (2008) describe an example of how tax avoidance relates to rent extraction. Suppose that managers of a firm begin creating several special purpose entities (SPEs) in tax havens. These entities are rationalized as providing the means for reducing tax obligations. The details of the structures and transactions cannot be explicated fully or widely due to the likelihood of detection by the tax authority and the revocation of those benefits. Such structures may allow managers to engage in various activities harmful to shareholders, such as earnings manipulation (by creating vehicles that can manufacture earnings without enabling investors to understand their source), concealment of obligations (by taking on debt that is not fully consolidated), or outright diversion (by allowing for insider transactions that are not reported widely).

[9] Desai and Dharmapala (2009) find that the effect of tax avoidance on firm value is a function of firm governance and only for well-governed firms will tax avoidance increase firm value. By exploring market reaction to news about tax shelter involvement, Wilson (2009) contends that tax sheltering creates wealth for shareholders in well-governed firms.

that better governance deters managers from using tax savings to pursue personal benefits.[10] In an environment with poor governance, even if tax avoidance produces cash savings to the firm, investors are difficult to capture the value of tax savings. In this regard, investors will negatively value corporate tax avoidance because their firm affords the costs of tax avoidance[11] while they enjoy no benefit from tax savings, given that managers expropriate the benefit of tax savings for personal purposes.

Which argument drives the positive valuation implication of good governance is an open empirical issue. As a first step to explore this issue, we examine whether the influence of governance on the valuation of tax avoidance can extend to an international setting. Specifically, we anticipate that strong investor protection leads to higher valuation of tax avoidance, as it is well documented in the literature (e.g., La Porta et al. 1998, 2000a, 2000b) that in an environment with more protection for their rights investors can better fight against managerial opportunisms so that they can capture more value from corporate tax avoidance. Consistent with our argument, Cloyd et al. (2003) find that US market often negatively reacts to firms' expatriation announcements and the authors attribute this result to the reasoning that tax haven countries usually have low level of investor protection. Accordingly, we propose our first hypothesis as follow.

H1: *Ceteris paribus, valuation of tax avoidance is higher in countries with better protection for investor rights.*

2.2. *Tax avoidance and firm cash policy*

To determine which argument drives the result of H1, we further explore the relation between tax avoidance and firm cash flow as the tax-shielded rent extraction and the misallocation arguments have different predictions regarding this relation. If the misallocation argument dominates and the primary agency issue is how managers use tax savings, we should observe

---

[10] Similar to this notion, Goh et al. (2013) find that corporate tax avoidance reduces a firm's cost of equity and such reduction is stronger for firms that likely realize higher marginal benefits from tax savings. Their results suggest that how investors perceive the value of corporate tax avoidance depends on how tax savings are used.

[11] Tax avoidance can impose significant costs on firms. For example, these costs include fees paid to tax experts, time devoted to the resolution of tax audits, reputational penalties, and penalties paid to tax authorities. Even without costs, tax savings can still destroy firm value because cash flows from tax avoidance may reduce managers' incentive to operate efficiently. It is also likely that tax avoidance transactions change a firm's organizational structure so that its operation is distorted, which deteriorates its operating performance.

a positive relation between tax avoidance and cash flow because the prerequisite of misallocating tax savings is that tax avoidance can generally produce cash flow to the firm. In contrast, if the tax-shielded rent extraction argument dominates and managers employ tax avoidance primarily to conceal their rent extraction, then we should observe no specific relation between tax avoidance and cash flow. Because the direction of how tax avoidance affects cash flow is an open empirical issue, we state our second hypothesis non-directionally as follow.

H2: *Ceteris paribus, tax avoidance is associated with firm cash flow.*

2.3. *Tax avoidance and investment policy*

To support our misallocation argument, we must examine not only whether tax avoidance generates cash savings but also how these cash savings are used, and the most direct type of misallocation is that managers squander tax savings on perk projects or empire building. Consistent with this notion, Khurana and Moser (2011) find that firms with higher levels of tax avoidance generally have higher level of excess capital expenditures and such excess capital expenditures are more pronounced for poor-governed firms. Accordingly, if the misallocation argument holds, we expect that tax avoidance relates to overinvestment, while in countries with good investor protection this relation is attenuated as good governance reduces the opportunities for managers to overinvest (Richardson 2006). This leads to our third hypothesis:

H3: *Ceteris paribus, tax avoidance is related to overinvestment and this relation is attenuated in countries with better protection for investor rights.*

2.4. *Tax avoidance and firm operating performance*

One concern for H3 is that overinvestment only reflects one dimension of squandering tax savings, while managerial misuse may extend to outlays other than corporate investments. In fact, the exact nature and scope of misusing tax savings are difficult to pin down, because managers can adopt many varied and often subtle ways to extract private benefits from tax savings. To capture a broader scope of this effect, we explore the relation between tax avoidance and firm operating performance as any managerial actions will ultimately reflect on firm performance. Because good governance can mitigate misallocation of tax savings, we expect that tax avoidance is related to higher firm performance in countries with stronger investor protection as in these countries managers are more likely to use tax savings to advance firm operating performance instead of to benefit themselves. This leads to our fourth hypothesis:

H4: *Ceteris paribus, tax avoidance is related to higher firm operating performance in countries with better protection for investor rights.*

It is noteworthy that our H3 and H4 do not argue that tax avoidance itself affects performance or overinvestment. Instead, what we argue is that it is the agency issues arising from tax avoidance, instead of tax avoidance itself, that result in lower performance and overinvestment, and strong investor protection is expected to alleviate such result by mitigating the agency issues of tax avoidance.

3. Research design and sample

3.1. *Test of H1: whether the valuation of tax avoidance is higher in countries with better investor protection*

3.1.1. *Valuation specification*

Following the specification of Desai and Dharmapala (2009), we estimate regression (1) to test H1.[12] Definitions of variables used in our main tests are shown in the appendix.

$$MV_{it} = \alpha_0 + \alpha_1 \cdot TA_{it} + \alpha_2 \cdot TA_{it} \cdot INP_j + \alpha_3 \cdot TA_{it} \cdot TAXEF_j + \alpha_4 \cdot TA_{it} \cdot CMARD_{jt} + \alpha_5 \cdot INP_j + \alpha_6 \cdot TAXEF_j + \alpha_7 \cdot CMARD_{jt} + \alpha_8 \cdot GDP_{jt} + \sum_{k=9}^{17} \alpha_k \cdot FSCONTROL + Fixed\ effects + \varepsilon_{it} \quad (1)$$

where *MV* is the market value of the firm; *TA* represents the level of corporate tax avoidance; *INP* is the level of protection for investor rights; *GDP*,*TAXEF* and *CMARD* are country-level control variables; *FSCONTROL* is firm-specific control variables; *Fixed effects* represent year and industry fixed effects. Subscripts *i*, *j*, and *t* denote firm, country, and year, respectively.

MV is measured with Tobin's *q* ratio, which is defined as the sum of the market value of equity and the book value of debt minus deferred tax expense[13] and then divided by the book value of total asset.

[12] For regression here and those afterward, we adjust the standard error of coefficient by the procedure of Newey-West (1987).

INP is measured with *LAW* and *CORUP*. *LAW* is a combined index of the legal protection for shareholders, which equals the anti-director rights index plus 50 percent[14] of the rule of law index (La Porta et al. 1998). As contended by La Porta et al. (1998, 2000a, 2000b), controlling shareholders (i.e. managers in our case) in countries with strong investor legal protection have few opportunities to extract private benefits of control. Prior studies (e.g. Doidge et al. 2007; Aggarwal et al. 2009) also show that countries' institutions are major forces in shaping corporate governance practices. *CORUP* is the corruption index (La Porta et al. 1998), which assesses the risk of corruption of high government officials and a lower value of this index represents a higher level of corruption. We use *CORUP* because it is difficult for investors to use their formal rights in an environment where corruption is rampant.

Our H1 predicts a positive coefficient on *TA·INP*, which suggests that the valuation of tax avoidance is higher in countries with better protection for investor rights.[15] This result implies that better governance leads to higher valuation of tax avoidance.

3.1.2. *Tax avoidance measures*

TA is proxied by three measures: book-tax difference (*BTD*), residual book-tax difference (*RBTD*), permanent book-tax difference (*PBTD*). There is no universally accepted definition of tax avoidance in the literature so we use multiple measures to increase the robustness of our results.

Book-tax difference (*BTD*) is calculated as [pretax book income – (domestic current tax expenses+ foreign current tax expenses) / top corporate statutory tax rate] / total assets.[16]

---

[13] Following Desai and Dharmapala (2009), we exclude deferred tax expense from the calculation of *q* measure, because current tax avoidance activity may result in changes to future tax liabilities and thus create a mechanical correlation between the dependent variable and the measure of tax avoidance.

14 We use 100 percent of the anti-director rights index and 50 percent of the efficiency of judicial system index and the rule of law index because the former ranges from 0 to 5, while the latter two range from 0 to 10. Prior studies such as Berkman and Nguyen (2010) or Choi and Wong (2007) also use similar combined index. We use a combined index because the quality of investor legal protection depends not only on the contents of regulations (i.e., anti-director rights index) but also on the proper enforcement of these regulations (i.e., efficiency of judicial system and rule of law indexes).

15 Note that the relation between TA and MV as explored in regression (1) may be endogenous since MV can also represent growth opportunities which may reversely explain firms' incentives to avoid taxes. However, this concern is mitigated as our focus on interaction effect TA·INP makes it hard to argue for reverse causality.

Prior studies suggest that larger book-tax difference is associated with higher probability of engaging in actual tax shelter activity (Mills 1998; Manzon and Plesko 2002; Desai and Dharmapala 2009; Wilson 2009). By exploring an international setting, Goncharov (2009) find that large book-difference is associated with tax evasion and this result suggests the feasibility of using *BTD* as a measure of tax avoidance in an international setting.

We use *BTD* to measure tax avoidance because this makes our results to be comparable with those of Desai and Dharmapala (2006, 2009) and because *BTD* captures more aggressive forms of tax avoidance.[17] If we use a less aggressive measure such as accounting effective tax rate, then our results will be biased toward to reject the tax-shielded rent extraction argument as tax-shielded rent extraction must be accomplished by aggressive forms of tax avoidance. However, one concern of using *BTD* is that the effect of book-tax difference may be confounded by earnings management. We thus use residual book-tax difference to mitigate this concern.

Residual book-tax difference (*RBTD*) (Desai and Dharmapala 2006) is the residual from a firm fixed-effect regression of *BTD* on total accruals that is estimated for each country, where total accruals is calculated as (net income before extraordinary items - operating cash flow) / total assets. Excluding the effect of total accruals eliminates, at least partially, the effect of earnings management embedded in *BTD*. In this regard, *PBTD* is expected to capture the effect of tax avoidance. Excluding the effect of total accruals also alleviates the concern that

[16] When current tax expense is missing, we infer it with total tax expense less deferred taxes when both domestic and foreign data are available. We exclude observations where current tax expense is missing and we have no required data to infer it.

[17] Aggressive forms of tax avoidance provide complexity and opacity to conceal managers' intent to extract rent and thus they conceptually fit the tax-shielded rent extraction story than less aggressive ones. Lisowsky et al. (2012) suggest that the probability of engaging in tax sheltering, discretionary permanent book-tax difference, permanent book-tax difference, book-tax difference, cash effective tax rate, and book effective tax rate capture the varying degree of tax aggressiveness, from most aggressive to least aggressive. Due to data availability, we cannot calculate discretionary permanent book-tax difference and the probability of engaging in tax shelter so the use of book-tax difference yields the best measure that can be obtained using publicly available data in our international setting.

difference in accounting rules across countries may introduce a noise to using book-tax difference as a proxy of tax avoidance.[18]

Permanent book-tax difference (*PBTD*) is computed as [pretax book income – (deferred tax expense + domestic current tax expenses+ foreign current tax expenses) / top corporate statutory tax rate] / total assets. Compared with *BTD*, *PBTD* captures more aggressive forms of tax avoidance as prior research (e.g., Shevlin, 2002; Wilson 2009) suggests that an ideal tax shelter or tax avoidance investment creates a permanent rather than a temporary book-tax difference.

It is cautious that in addition to errors in inferring taxable income, the use of book-tax difference contains measurement error that arises from the mechanical difference in the calculations of book income and taxable income.[19] However, this is not a serious concern since our main focus is on the interaction between investor protection and tax avoidance so any measurement error in tax avoidance is not expected to systematically affect our empirical results. We will further assess whether this measurement error affect our results in the robustness test section.

3.1.3. *Control variables*

Firm-specific control variables include the natural log of total assets (*SIZE*) in US dollar.[20] We also include the closely-held shares percentage[21] (*CHS*) and dividend amount (*DIV*) because higher insider stock ownership and dividend payment affect agency problems and

[18] The use of *RBTD* also helps to rule outs the confounding interpretation that investor view large book-tax differences as an indicator of earnings management and thus a positive coefficient of *BTD·INP* implies the effect of strong investor protection on restraining earnings management.

[19] The mechanical difference arises because some items that directly lower tax expense affect the computed taxable income even if the items are not true differences between book and taxable incomes. For example, research and development and other credits decrease tax expense and, thus, decrease taxable income and increase book-tax differences.

[20] The use of total assets could be mechanically correlated with *q* ratio because total assets are used to calculate *q* ratio. As a robustness test, we use total sales to replace total assets and this does not change our conclusion.

[21] Closely-held shares correspond to shares held by insiders. Insiders are considered to be officers, directors, and their immediate families, shares held in trusts, shares held by another corporation (except shares held in a fiduciary capacity by financial institutions), shares held by pension benefit plans, and shares held by individuals who hold 5% or more of the outstanding shares. For Japanese firms, closely held shares represent the holdings of the ten largest shareholders.

thus in turn affect firm value.[22] To control for the effect of tax shields, we include capital expenditures (*CAP*), book value of total debt (*LEV*), and interest expenses (*INT*), as tax shields may affect the value of engaging in tax avoidance. Interest expenses are included as an additional proxy for debt tax shields since the book value of debt may capture both the effect of financial distress and tax shields. Research and development expenses (*RD*) is included to control for the possibility that some intangibles are not imperfectly measured in book value of assets but are reflected on market value. Two-year (year t to t-1) average sales growth rate (*GROWTH*) is included to control for growth opportunities. We also include income tax credit (*TAXCR*) because it can affect the incentives to engage in tax avoidance and because the realization of tax deductions may also lead the incidence of book-tax difference that is mechanical in nature and has no relation with tax avoidance. Similar to *BTD*, all control variables are scaled with book value of total assets except for *SIZE*, *CHS*, and *GROWTH*.[23]

For country-level control variables, we include the natural log of gross domestic product per capita in US dollar (*GDP*) to control for the effect of economic development on firm value. We also include the perceived strength of tax enforcement (*TAXEF*) (Dyck and Zingales 2004) because strong tax enforcement increases the probability of tax avoidance being challenged by tax authorities (Atwood et al. 2012) and this reduces the value of tax avoidance. More importantly, strong tax enforcement may confound the interpretation of our results because stronger tax enforcement can also deter managerial opportunistic behaviors (Haw et al. 2004; Desai et al. 2007).[24] Accordingly, we include *TA·TAXEF* to ensure that our finding concerning *TA·INP* does not reflect the effect of tax enforcement on deterring managerial opportunisms due to the potential correlation between investor protection and tax enforcement.

We also include the degree of capital market development (*CMARD*), calculated as the sum of stock market capitalization and domestic credit provided by banking normalized by

---

[22] Desai and Dharmapala (2006) suggest that the equity-based executive compensation plays a central role in managerial tax avoidance decisions and the inclusion of *CHS* can partially capture this effect.

[23] When the value of *CAEXP*, *RD*, or *DIV* is missing, we set it to zero.

[24] Desai et al. (2007) find that increases in tax enforcement by the Russian government lead to significantly positive market reactions, despite the fact that these firms would likely pay higher future taxes that reduce firm value. They interpret this finding as evidence that outside investors expected less rent extraction by managers due to the increased monitoring provided by the government.

gross domestic product (Dittmar et al. 2003). *CMARD* is used to control for external financing opportunities, as recent studies suggest that financial constraint is one determinant of tax avoidance (Edwards et al. 2012). Because counties with high investor protection are usually those with well-developed capital markets, we include *TA·CMARD* to control for the confounding interpretation that the effect of *TA·INP* reflects the difference in opportunities for accessing external financing.

3.2. *Test of H2: Tax avoidance and cash flow*

To test H2 we draw from Almeida et al. (2004) to specify the relation between tax avoidance and cash flow. Borrowing insights from the literature on cash management (Kim et al. 1998; Opler et al. 1999; Harford 1999), Almeida et al. model the change in firm's cash holdings as a function of several funding sources and uses. If tax avoidance generates cash savings, it should represent a funding source and thus has a positive association with cash flow. To test H2, we explore following empirical specification.

$$\begin{aligned} \Delta Cash_{it} = {} & \beta_0 + \beta_1 \cdot TA_{it} + \beta_2 \cdot CashFlow_{it} + \beta_3 \cdot \Delta NWC_{it} + \beta_4 \cdot \Delta STD_{it} + \beta_5 \cdot MV_{it} + \beta_6 \cdot SIZE_{it} + \\ & \beta_7 \cdot INVEST_{it} + \beta_8 \cdot INP_j + \beta_9 \cdot TAXEF_j + \beta_{10} \cdot CMARD_{jt} + \beta_{11} \cdot GDP_{jt} + \\ & Fixed\ effects + \varepsilon_{it} \end{aligned} \quad (2)$$

where Δ*Cash* is the change in cash holdings scaled by total assets; *CashFlow* is cash flow from operations minus dividend scaled by total assets; Δ*NWC* is change in noncash net working capital scaled by total assets; Δ*STD* is change in short-term debt scaled by total assets; *INVEST* is defined as (capital expenditures + research and development expense - proceeds from sale of fixed assets - depreciation) / the average total assets of years t and t-1;[25] remaining variables are defined as in previous section.

In regression (2), *CashFlow* is included to accommodate the precautionary allocation of cash flows into cash savings (Almeida et al. 2004).[26] We control for Δ*NWC* because working

---

[25] Proceeds from the sale of fixed assets are excluded, since replacing one asset with another of similar value is not counted as new investment. Depreciation expense is subtracted because it proxies for the amount of investment necessary to maintain current stock of assets.

[26] In addition to explore precautionary cash saving from operating cash flow, the model of Almeida et al. (2004) can also extend to other topics. For example, Fresard (2012) modify the model of Almeida et al. (2004) to examine whether corporate cash savings are more sensitive to stock price when the price contains more

capital can be a substitute for cash (Opler et al. 1999) or it may compete for the available pool of cash reserves. Similarly, ΔSTD is included because short-term debt could be a substitute for cash or firms may use short-term debt to build cash reserves. *SIZE* is included to control for economies of scale with respect to cash management. *INVEST* is included since firms may draw down on cash reserves in a given year to pay for investment expenditures. *MV* is included to control for growth opportunities available to the firm because firms may reserve cash today to meet future investment opportunities. We use *MV* to proxy for growth opportunities because omitting it may make *TA* to absorb its effect, as our test of H1 in regression (1) implies that *TA* is associated with *MV*.[27]

If the main agency issue of tax avoidance is tax-shielded rent extraction as argued by Desai and Dharmapala (2006, 2009) and Desai et al. (2007), we will find a negative coefficient on *TA* in regression (2). In contrast, if the main agency issue of tax avoidance is the misallocation of tax savings, we will find a positive coefficient on *TA*.

3.3. *Test of H3: Tax avoidance and investment policy*

To test H3, we follow Richardson (2006) by running regression (3.1) and the residual from this regression is the measure of overinvestment (positive) or underinvestment (negative).

$$\begin{aligned} INVEST_{it} = {} & \theta_0 + \theta_1 \cdot LEV_{it-1} + \theta_2 \cdot CASH_{it-1} + \theta_3 \cdot SIZE_{it-1} + \theta_4 \cdot INVEST_{it-1} + \theta_5 \cdot MV_{it-1} + \\ & Fixed\ effects + \varepsilon_{it} \end{aligned} \tag{3.1}$$

where LEV_{t-1} is lagged book value of total debt over average total assets; $CASH_{t-1}$ is lagged cash and cash equivalent over average total assets; $SIZE_{t-1}$ is the natural log of lagged total assets in US dollar. *INVEST* is defined as in previous section. We estimate regression (3.1) separately for each country.

We then test whether tax avoidance relates to overinvestment with regression (3.2).

$$\begin{aligned} INVEST^{\varepsilon}{}_{it} = {} & \eta_0 + \eta_1 \cdot TA_{it} + \eta_2 \cdot TA_{it} \cdot INP_j + \eta_3 \cdot TA_{it} \cdot TAXEF_j + \eta_4 \cdot TA_{it} \cdot CMARD_{jt} + \eta_5 \cdot INP_j + \\ & \eta_6 \cdot TAXEF_j + \eta_7 \cdot CMARD_{jt} + \eta_8 \cdot GDP_{jt} + \eta_9 \cdot FCF_{it} + \varepsilon_{it} \end{aligned} \tag{3.2}$$

---

information that is unknown to managers. The argument of Almeida et al. (2004) is also tested in an international setting by prior studies (e.g., Kusnadi and Wei 2011).

[27] We also repeat our tests by replacing *MV* with the two-year average sales growth rate (*GROWTH*) to proxy for investment opportunities and the results remain qualitatively unchanged.

where $INVEST^{\varepsilon}$ is the residual from regression (3.1); *FCF* is free cash flow, calculated as (cash from operations + research and development expense - depreciation expense) / average total assets minus the predicted value of *INVEST* from regression (3.1).

Our test in regression (3.2) includes observations with positive value of $INVEST^{\varepsilon}$ that represents overinvestment. H3 argues that tax avoidance is positively related to overinvestment and strong investor protection can mitigate this relation. In this regard, we expect to observe a positive coefficient on *TA* and a negative coefficient on *TA·INP*.

3.4. *Test of H4: Tax avoidance and operating performance*

To test H4 that investor protection affects the relation between tax avoidance and firm performance, we explore regression (4) as below.

$$\begin{aligned} ROA_{it+1} = {} & \tau_0 + \tau_1 \cdot TA_{it} + \tau_2 \cdot TA_{it} \cdot INP_j + \tau_3 \cdot TA_{it} \cdot TAXEF_j + \tau_4 \cdot TA_{it} \cdot CMARD_{jt} + \tau_5 \cdot INP_j + \\ & \tau_6 \cdot TAXEF_j + \tau_7 \cdot CMARD_{jt} + \tau_8 \cdot GDP_{jt} + \tau_9 \cdot SIZE_{it} + \tau_{10} \cdot MV_{it} + \tau_{11} \cdot PPE_{it} + \\ & \tau_{12} \cdot CHS_{it} + \tau_{13} \cdot LEV_{it} + Fixed\ effects + \varepsilon_{it} \end{aligned} \tag{4}$$

ROA_{t+1} is industry-adjusted return on assets, defined as operating income of year t+1 divided by the average total assets of t and t+1 and then adjusted with industry median value.[28] Definitions of all variables in regression (4) are defined as in previous section. The specification of regression (4) refers to those in Core et al. (1999), Dittmar and Mahrt-Smith (2007) and Harford et al. (2008).

To support H4, we expect a positive coefficient on *TA·INP* in regression (4), which implies that better investor protection makes managers to be more likely to use tax savings on enhancing firm performance.

Following Blaylock (2011), regression (4) explores future performance instead of current performance because managers may undertake tax avoidance transaction to artificially inflate current earnings (e.g., Enron) and this makes it difficult to interpret the coefficient on *TA* in regression (4). Because the effect of inflating earnings could be reversed due to the nature of accrual accounting, the use of future performance is more appropriate. As a robustness test, we also repeat the estimate of regression (4) with current performance and untabulated results show that this does not change our conclusions.

3.5. *Sample selection and summary statistics*

[28] Industry median is computed for each two-digit SIC industry in each country-year.

We retrieve all required financial information from the Worldscope database. Our sampling period begins from 1996 to 2012. We start our sampling period from 1996 because firm coverage in the database prior to this year is spare. The calculation of book-tax differences requires statutory corporate tax rates for each sample country, and we hand-collect statutory tax rates from a KPMG LLP online summary, PricewaterhouseCoopers LLP's online information, Coopers & Lybrand LLP's worldwide tax summary guides, and the website of OECD. These statutory corporate tax rates include both the federal income tax rate and the average effects of state, provincial, and other local government income tax rates.

For investor protection measures, the anti-director rights index, the rule of law index and the corruption index are all collected from La Porta et al. (1998). The perceived strength of tax enforcement is from Dyck and Zingales (2004). Microeconomic data including gross domestic product per capita, stock market capitalization, domestic credit provided by banking, and gross domestic product are all collected from statistics disclosed by the World Bank.

We exclude countries with missing value of statutory tax rates, investor protection measures, or required microeconomic data. Our initial sample consists of firms with all required data on estimating regression (1). We further delete firms with book values of total assets less than US$ 10 million because small firms may behave unlike ordinary firms and several of our control variables are scaled by total assets while small total assets will lead to extreme value. After imposing these data requirements, we obtain a sample of 161,376 firm-year observations[29] from 34 countries. To alleviate the concern of outliers, we winsorize all firm-level variables at the 1st and the 99th percentile levels.

[Insert Table 1 about here]

Table 1 presents the summary statistics of our main test variables and institutional variables for each country in our sample. The number of firm-year observations for each country is shown in the first column of Table 1, which ranges from 88 for Argentina to 57,977 for the United States. The considerable variation in the number of observations per country raises the concern that our results may be unduly influenced by countries with

---

[29] The number of firm-year observations 161,376 is for *BTD* and *PBTD*. For *RBTD* we have 154,670 firm-year observations. Because these numbers are meant to those can be used to estimate equation (1), the observation numbers used to test regressions (2) to (4) could be different from these numbers due to missing values of variables not included in regression (1) but included in these subsequent regressions.

extreme number of observations. We will further evaluate the effect of this concern in the robustness test section.

4. Main empirical results

4.1. *Test results of H1: The effect of investor protection on the valuation of tax avoidance*

In this section, we report our results of testing H1. We estimate equation (1) for the U.S. and non-US countries separately. This allows us to determine whether the idea that tax avoidance does not always increase firm value (Desai and Dharmapala 2009) is specific to the U.S. or it can also extend to other countries. The results are shown in Table 2.

[Insert Table 2 about here]

Panel A of Table 2 presents the estimate results of using only US observations. Column (1) shows that the coefficient on *BTD* is positive but insignificant. In Column (2) the coefficient on *RBTD* is negative but insignificant while in Column (3) the coefficient on *PBTD* is positive and significant at 10% level (p-value=0.069). These results suggest that investors in the U.S. market do not always perceive corporate tax avoidance as increasing firm value, consistent with the finidng of Desai and Dharmapala (2009).

Panel B of Table 2 presents the estimate results of using observations from non-US countries. Coefficients on our three tax avoidance measures across Columns (4) to (6) are all negative and significant at 1% level. This result suggests that investors in non-US countries generally perceive that corporate tax avoidance impairs firm value, so the idea that tax avoidance does not naturally increase firm value holds not only for the U.S market but also for other countries. This negative valuation result suggests that investors perceive that most tax savings will be misused and the remaining tax savings cannot cover the costs of tax avoidance incurred by their firms.

Contrasting results in Panel A and Panel B, we know that the negative market valuation of tax avoidance is attenuated in the US than in other countries, and this may be because protection for investor rights is usually more stringent in the US than in other countries. In this regard, results in Table 2 provide preliminary evidence to support our H1. For control variables, coefficients on most of them are significant at conventional level so it is necessary to include them in our estimate.

Results of estimating the full specification of equation (1) are shown in Table 3, where results of measuring investor protection with *LAW* and *CORUP* are presented separately.

[Insert Table 3 about here]

Consistent with H1, Table 3 shows that coefficients on *TA·INP* are all positive and significant at 1% level for the three tax avoidance measures and coefficients on *TA* are negative and significant in most columns. This result holds for measuring *INP* with either *LAW* or *CORUP*. Results in Table 3 suggest that market valuation of corporate tax avoidance is higher in countries with better legal protection for investor rights.

Moreover, Table 3 shows that coefficients on *TA·TAXEF* are positive in most columns, albeit they are insignificant. This result suggests that although strong tax enforcement provides additional monitoring from tax authorities on managerial opportunistic behaviors (e.g., Haw et al. 2004; Desai et al. 2007), investors perceive that this monitoring effect is offset by the correspondingly increased risk of tax avoidance being challenged by tax authorities. In addition, coefficients on *TA·CMARD* are consistently negative and significant at 1% level in all columns, which suggests that the valuation of tax avoidance is higher with more difficulty in accessing external capital, in which situation tax savings are an important source of internal funds.

Overall, results in this section suggest that strong investor protection enhances the valuation of corporate tax avoidance, consistent with H1. And the conclusion of Desai and Dharmapala (2009) that the value of tax avoidance is a function of firm governance can extend to an international setting.

4.2. *Test results of H2: Tax avoidance and firm cash policy*

In this section, we report results of testing H2 about whether tax avoidance positively or negatively affects cash flow. The results of estimating equation (2) are shown in Part I of Table 4. We present the results separately for using only US observations and non-US observations in high or low investor protection countries where the cutoff point is the median value of *LAW*.

[Insert Table 4 about here]

H2 argues that if the primary agency issue is how managers use tax savings, we should observe a positive relation between tax avoidance and cash flow because the prerequisite of misallocating tax savings is that tax avoidance can generally produce cash flows. Consistent with this argument, Part I of Table 4 shows that the coefficients on *TA* are all positive and significant at 1% level across all columns, which suggests that tax avoidance is a substantial funding source that provides firms with additional internal funds. In particular, results of columns (7) through (9) show that in countries with poor investor protection tax avoidance still produces cash savings. This result seems to suggest that tax-shielded rent extraction may not be as prevalent as thought by prior literature (e.g., Desai et al. 2007; Desai and Dharmapala 2006, 2009), given that tax-shielded rent extraction should be most prevalent in these countries so that producing cash flows is not the primary goal of corporate tax avoidance in these countries

However, finding a positive coefficient on *TA* does not necessarily mean that managers spend these tax savings on investment expenditures. It is also possible that managers hoard these tax savings for future uses. To resolve this concern and thus bridge the gap between H2 and H3, we investigate the association between tax avoidance and the cash outflow effect of investment expenditures.

Specifically, referring to Almeida et al. (2004), a larger coefficient on *TA* in regression (2) implies that firms save a larger portion of cash flow from tax avoidance as cash reserves. In this regard, if managers use tax savings to fund investment expenditures, then greater investment expenditures should lead to smaller coefficient on *TA*, because now some tax savings are used to invest and only a smaller portion of them is hoarded as cash reserves. This yields an empirical testable prediction that the coefficient on *TA* in equation (2) should be smaller with a larger amount of *INVEST*, and we explore this prediction by extending equation (2) with an interaction term *TA·INVEST*.

As shown in Part II of Table 4, coefficients on *TA·INVEST* are negative and significant at conventional levels in all columns, and this holds even for non-US countries with low investor protection. These results support our expectation that managers use tax savings to finance investment projects. Furthermore, coefficients on *TA·INVEST* are largely smaller (more negative) in Panel C of Part II than those in Panels A and B and this result seems to suggest that managers in countries with weak investor protection spend a larger portion of tax savings on investment expenditures.

4.3. *Test results of H3: Tax avoidance and investment policy*

H3 argues that tax avoidance relates to overinvestment because managers may misuse tax savings on perk projects or building empires and this relation is attenuated in countries with strong investor protection. However, H3 relies on two premises. The first is that managers use tax savings to fund investments and the second is that these investments are inefficient.

Results of Part II of Table 4 provide some support for the first premise, but this evidence is indirect. To further support the first premise we explore the association between tax avoidance and investment expenditures and the results are shown in Table 5.

[Insert Table 5 about here]

Table 5 shows that coefficients on *TA* are positive and significant at 1% level across all columns, so tax avoidance is positively associated with investment expenditures.[30] This positive association confirms that managers use tax savings to finance investment projects. In addition, coefficients on *TA·INP* are negative and significant in all columns, so the positive relation between tax avoidance and investment expenditures is attenuated in countries with strong investor protection. This suggests that a larger portion of tax savings are used to fund investments in countries with weak investor protection. Overall, results in Table 5 are consistent with those in Part II of Table 4.

Thus far our results imply that managers spend tax savings on funding investments and such spending is more salient in countries with weak investor protection. As investments for poor-governed firms are more likely to be inefficient, the higher investment expenditures in countries with weaker investor protection provide preliminary evidence to suggest managerial overinvestment of tax savings. However, it is also possible that firms in countries with weak investor protection rely more on tax savings to finance their investments because it is more difficult to raise capitals in these countries due to their less developed capital markets and financial institutions. Therefore, we further explore regression (3.2) to explore the association between tax avoidance and investment efficiency. The results are shown in Table 6.

[Insert Table 6 about here]

In Panel A of Table 6, coefficients on *TA* are positive and significant in most columns, consistent with H3 that tax avoidance is associated with overinvestment. This result together with results in Table 5 suggests that managers may immediately dissipate tax savings on suboptimal projects. Panel A of Table 6 also shows that coefficients on *TA·INP* are negative and significant at 1 % level in all columns, consistent with H3 that the overinvestment of tax savings is mitigated in countries with good investor protection.

[30] Coefficients on *TA* remain to be significantly positive in all columns when we remove the interaction terms between *TA* and other country-level variables (*INP*, *TAXEF*, and *CMARD*).

In Panel B of Table 6, we repeat the estimate of regression (3.2) by using one-year ahead overinvestment ($INVEST^{\varepsilon}_{t+1}$) as the dependent variable because managers may not immediately invest tax savings but instead wait until the following period. This specification also mitigates the endogeneity concern that tax avoidance and investment decisions are determined simultaneously. As shown in Panel B of Table 6, we find that all results are similar to those in panel A, which suggests that managers may hoard tax savings to invest in following period while this investment is also inefficient and good governance can mitigate this inefficiency.

Overall, results in this section suggest that tax avoidance relates to overinvestment because managers dissipate tax savings on suboptimal projects, while such investment inefficiency is alleviated in countries with strong investor protection. These findings support for the misallocation argument.[31]

4.4. *Test results of H4: Tax avoidance and firm operating performance*

H4 explores how tax avoidance relates to firm performance because misuse of tax savings on suboptimal projects suggests only one type of misallocation. It is also likely that managers squander tax savings on non-investment expenditures and such misallocation is usually more subtle and difficult to detect. Because good governance can rectify misallocation of tax savings by inducing managers to deploy tax savings to more efficient uses, we expect that tax avoidance leads to higher firm performance in countries with stronger investor protection. We estimate regression (4) to test H4, and the results are shown in Table 7.

[Insert Table 7 about here]

Table 7 shows that coefficients on *TA* are negative and significant in most cases, and this suggests that tax avoidance leads to lower operating performance. This result could be explained by the finding in Table 6 that tax avoidance relates to overinvestment since investment inefficiency usually deteriorates operating performance. This result also suggests

---

[31] An alternative explanation for the relation between tax avoidance and investment inefficiency is that firms with more tax avoidance activities may be more opaque (e.g., Balakrishnan et al. 2012) and poor transparency has been shown to reduce investment efficiency (Biddle and Hilary 2006). However, our finding about how tax avoidance affects investment efficiency cannot be merely explained by the opaqueness of tax avoidance, since we have shown that managers use tax savings to invest and that tax avoidance is positively related to investment expenditures.

that in addition to suboptimal investment projects, managers may also dissipate tax savings on non-investment outlays. Furthermore, *TA·INP* are positive and significant at 1% level in all columns of Table 7, consistent with H4 that tax avoidance leads to higher firm performance in countries with stronger investor protection. Therefore, results in this section provide evidence to confirm that misuse of tax savings has a negative impact on operating performance and this negative impact is more salient when managers are more entrenched as featured by weak investor protection.[32]

In sum, our results in Table 3 through Table 7 are more consistent with the misallocation argument than the tax-shielded rent extraction argument. We find that tax avoidance generate cash savings and managers use tax savings to fund investment, while in countries with weaker investor protection this investment is more likely to advance managerial self-interests and thus leads tax avoidance to be associated with lower operating performance. All these results suggest that the main agency issue of tax avoidance is how managers use tax savings instead of whether managers exploit tax avoidance to mask their rent extraction. We also find that all these negative consequences of tax avoidance is attenuated with strong external governance, and this explains why in Table 3 we find that investors place higher valuation on corporate tax avoidance in countries with stronger protection for their rights.

4.5. *Robustness test*

Our first robustness test examines whether our results are sensitive to different measures of investor protection. Because the legal regime quality for a country may change over time, we repeat our tests by using an anti-director rights index that is the average of the index developed in La Porta et al. (1998) and the index developed in Djankov et al. (2008), as the former is complied using laws prevailing in 1993 while the latter is complied using laws prevailing in 2003. We also use the expropriation index extracted from La Porta et al. (1998) that evaluates the threat of outright confiscation or forced nationalization. We also follow Huang et al. (2013) by using the time-series investor protection measure developed by

[32] We recognize that our argument regarding the relation between tax avoidance and performance should be more plausible on the condition of overinvestment. Therefore, we repeat our tests in Table 7 by using only observations with positive $INVEST^{\varepsilon}_{t}$ and we find that this does not change our conclusions.

Kaufmann et al. (2010).[33] We find that our results remain qualitatively similar with the use of these investor protection measures.

In addition, one potential concern for our international setting is that sample-concentration in some countries (e.g., US or Japan) may induce our results to be unduly influenced by these countries. To mitigate this concern, we refer to Atwood et al. (2012) by calculating country-year-industry mean value for each variable and using the resulting mean value to repeat our tests, where we now have only one observation per industry in each country-year. While this procedure reduces the influence that any particular country has on our results, it also removes much of the variation in the dependent variables and firm-specific variables and thus makes some of our results insignificant. However, this procedure does not change our conclusions.

Moreover, as mentioned previously, book-tax difference contains measurement error that arises from mechanical reasons due to different rules governing the calculations of book income and taxable income. Although finding results consistent with our hypotheses suggests that this measurement error is serious, we still conduct several tests to mitigate this concern.

First, we consider the variation in cross-country required book-tax conformity (*BTC*) that is estimated by following the approach of Atwood et al. (2010).[34] A high level of *BTC* implies that in many respects the determination of book income is the same as taxable income and this minimizes the measurement error of book-tax differences due to mechanical reasons. Untabulated results show that considering *BTC* in our tests does not affect our conclusions[35] and this suggests that our book-tax difference measures are less confounded by measurement error.

Second, we use firms that adopt the same accounting standards, because the recognition and calculation of tax expenses may differ when adopting different accounting standards and

---

[33] Kaufmann et al. (2010) provide a time series of six governance indices relating to voice and accountability, political stability and absence of violence or terrorism, government effectiveness, regulatory quality, rule of law, and control of corruption. We construct the Kaufmann et al.'s measure as the sum of these six country-level investor protection indicators for each country over our study period.

[34] Atwood et al. (2010) measure book-tax conformity based on the proportion of current tax expense that cannot be explained by pre-tax book income. We follow Atwood et al. (2010) to estimate this model by requiring at least 40 usable observations in a year for any specific country.

[35] Like stronger tax enforcement, higher level of required book-tax conformity also makes firms more difficult in evading taxes (Atwood et al. 2012). In this regard, the inclusion of both *TAXEF* with *BTC* may confound our estimates, so our robustness test herein replaces *TAXEF* with *BTC*.

this may hamper the comparability of book-tax differences across countries. We identify whether a firm adopts IFRS or US GAAP and repeat our tests by using two subsamples that adopt these two accounting standards separately, and we find that most of our results remain qualitatively unchanged for both subsamples.

Finally, we repeat our tests by using industry-adjusted tax avoidance measures.[36] The use of industry-adjusted measures partially removes the effect of cross-country difference in accounting standards, as financial reporting regulations are often developed with specific industry practices. This also mitigates the concern that differences in tax regulations across countries may introduce noise to our tax avoidance measure. We find similar results with the use of industry-adjusted tax avoidance measures.[37]

5. Additional tests

5.1. *Test of H1: alternative valuation specification*

In Table 2, we test H1 with the valuation specification of Desai and Dharmapala (2009). However, this specification raises the concern that the negative value implication of tax avoidance may be interpreted as market's expectation that firms will experience a negative shock on future performance so they evade more taxes and use tax savings as a buffer to mitigate this negative shock. To rule out this confounding interpretation, we repeat our test of H1 with the specification of Fama and French (1998), because it controls for determinants that are likely to affect investors' expectations of future cash flows as well as earnings. Specifically, we extend the specification of Fama and French as following regression (5):

[36] We subtract our three tax avoidance measures from their corresponding industry median values to obtain the industry-adjusted measures, where the industry median value is computed for each two-digit SIC industry in a yearly basis for each country.

[37] We also repeat our tests by using cash effective tax rate to measure tax avoidance as in Amiram et al. (2012) and we find that this does not change our conclusions. This result confirms that our findings with book-tax differences are indeed attributed to real cash saving from tax avoidance, even although cash effective tax rate captures less aggressive forms of tax avoidance.

$$\begin{aligned} MV_{it} = {} & \gamma_0 + \gamma_1 \cdot TA_{it} + \gamma_2 \cdot TA_{it} \cdot INP_j + \gamma_3 \cdot TA_{it} \cdot TAXEF_j + \gamma_4 \cdot TA_{it} \cdot CMARD_{jt} + \gamma_5 \cdot INP_j + \\ & \gamma_6 \cdot TAXEF_j + \gamma_7 \cdot CMARD_{jt} + \gamma_8 \cdot GDP_{jt} + \gamma_9 \cdot E_{it} + \gamma_{10} \cdot dE_{it} + \gamma_{11} \cdot dE_{it+1} + \gamma_{12} \cdot dA_{it} + \\ & \gamma_{13} \cdot dA_{it+1} + \gamma_{14} \cdot RD_{it} + \gamma_{15} \cdot dRD_{it} + \gamma_{16} \cdot dRD_{it+1} + \gamma_{17} \cdot INT_{it} + \gamma_{18} \cdot dINT_{it} + \\ & \gamma_{19} \cdot dINT_{it+1} + \gamma_{20} \cdot DIV_{it} + \gamma_{21} \cdot dDIV_{it} + \gamma_{22} \cdot dDIV_{it+1} + \gamma_{23} \cdot dMV_{it+1} + \\ & Fixed\ effects + \varepsilon_{it} \end{aligned} \tag{5}$$

where X_t is the level of variable X in year t divided by total assets; dX_t is the change in the level of X from year t-1 to year t (i.e., X_t - X_{t-1}) divided by total assets; dX_{t+1} is the change in the level of X from year t to year t+1 (i.e., X_{t+1} - X_t) divided by total assets; E is earnings before extraordinary items plus interest expenses; A is book value of total assets; remaining variables are defined as in previous sections. The results are presented in Table 8.

[Insert Table 8 about here]

Table 8 shows that controlling for investors' expectations does not change our conclusions. Coefficients on *TA* remain to be consistently negative and coefficients on *TA·INP* are still significantly positive, consistent with the results of Table 3. Therefore, our result regarding the negative valuation of tax avoidance does not merely reflect investors' expectations about firms' future performance.[38]

5.2. *Tax avoidance and cash holdings*

In this section we examine how tax avoidance affects firms' cash holding decisions, a topic that is underexplored in the literature. Our test herein is motivated by results of Table 6 that managers may hoard tax savings to invest in following period. We conjecture that such hoarding behavior may impact cash holdings. Results herein also help to distinguish whether the tax-shielded rent extraction argument or the misallocation argument is empirically more prevalent, as these two arguments make different predictions about the cash holding implication of tax avoidance.

Specifically, we examine the relation between tax avoidance and excess cash and how corporate governance affects this relation, where excess cash is defined as cash held by firms that is more than ''legitimate'' reasons such as investment opportunities, hedging needs,

[38] The inclusion of E_t in regression (5) alleviates the concern that the calculation of book-tax difference involves current book income so it may reflect the influence of current earnings. It also reduces the noise in measuring book-tax difference in an international setting because the influence of cross-country difference in accounting standards could be absorbed by E_t.

availability of alternative sources of liquidity, etc. (see, Dittmar and Mahrt-Smith 2007; Harford et al. 2008). We explore excess cash because it represents the amount of cash that is at risk of being turned into managers' private benefits and it considers that managers may not waste cash reserves that are needed to maintain normal operations. Thus, using excess cash offers a powerful test to detect whether managers divert firm cash. In this regard, the tax-shielded rent extraction argument predicts that tax avoidance leads to lower excess cash if managers exploit tax avoidance activity to hide their diversion of firm cash (Dhaliwal et al. 2011).

However, it is also likely that managers deliberately hoard too much tax savings as cash reserves because doing so offers them a private benefit option.[39] If managers exploit tax avoidance to generate tax savings and hoard them as cash reserves due to self-serving reasons,[40] then tax avoidance will positively relate to excess cash since hoarding cash reserves unrelated to operation needs will lead cash balance to deviate from normal level.[41] This is consistent with the misallocation argument because hoarding too much tax savings as cash reserves due to self-serving reasons also suggests a possible type of misallocating tax savings.

Following Fresard and Salva (2010), we estimate excess cash with regression (6.1) for each country, where excess cash is the residual from the regression.

$$\begin{aligned}\ln(Cash_{it}) = {} & \delta_1 \cdot CF_{it} + \delta_2 \cdot NWC_{it} + \delta_3 \cdot MB_{it} + \delta_4 \cdot SIZE_{it} + \delta_5 \cdot CAP_{it} + \delta_6 \cdot LEV_{it} + \delta_7 \cdot RD_{it} + \\ & \delta_8 \cdot DIV_{it} + Fixed\ effects\,(\text{firm,industry,and year}) + \varepsilon_{it} \qquad (6.1)\end{aligned}$$

where ln(*Cash*) is the natural log of cash and cash equivalents over total assets; *CF* is

[39] Ceteris paribus, managers prefer to hold as much cash as they can, because this entrenches them by enhancing job security or reducing capital market scrutiny due to less reliance on external financing. Holding excess cash also reduces the pressures on managers to operate efficiently by minimizing costs, improving margins, closely monitoring employees and operations, and engaging in other profit enhancing measures.

[40] This implicitly assumes that when deciding how to use cash savings from tax avoidance, managers trade off current misuse versus the private benefit option offered by reserving tax savings, and they put some weight on the latter. This is a plausible assumption, because self-interested managers have incentives to increase the amount of assets under their control, which suggests that tax savings are retained instead of spending immediately.

[41] From the perspective of maximizing shareholders' wealth, the optimal level of tax avoidance is that just enough cash savings are saved to meet firm's normal need and no excess cash left, given that holding excess cash exacerbates agency problems and investing in cash produces little return.

operating income minus interest and tax expenses over total assets; *NWC* is noncash net working capital over total assets; *MB* is the market-to-book ratio; *Fixed effects* include firm, industry, and year fixed effects; remaining variables are defined as in previous sections.

By using the residual of (6.1) as the dependent variable, we explore the relation between excess cash and tax avoidance with regression (6.2).

$$XCash_{it} = \lambda_0 + \lambda_1 \cdot TA_{it} + \lambda_2 \cdot TA_{it} \cdot INP_j + \lambda_3 \cdot TA_{it} \cdot TAXEF_j + \lambda_4 \cdot TA_{it} \cdot CMARD_{jt} + \lambda_5 \cdot INP_j + \lambda_6 \cdot TAXEF_j + \lambda_7 \cdot CMARD_{jt} + \lambda_8 \cdot GDP_{jt} + \varepsilon_{it} \tag{6.2}$$

where *XCash* is excess cash, which is the residual of regression (6.1). The results of estimating (6.2) are presented in Table 9.

[Insert Table 9 about here]

Table 9 shows that coefficients on *TA* are positive in all columns and they are significant in most columns, while coefficients on *TA·INP* are all significantly negative. Consistent with the misallocation argument, this result suggests that tax avoidance allows managers to hoard excess cash due to self-serving reasons, while such hoarding behavior is alleviated in countries with better investor protection.[42] This result also conforms to the conclusion of Dittmar et al. (2003) and Pinkowitz et al. (2004) that in countries with weak investor protection managers hoard as much cash as they can, and tax avoidance is one means that facilitates them to do so.

Overall, the positive relation between tax avoidance and excess cash in Table 9 implies that managers do not spend all tax savings immediately and they hoard some tax savings as cash reserves for future misuse. This is consistent with the finding in Panel B of Table 6 that current-period tax avoidance is associated with next-period overinvestment. More

[42] We recognize that managers may simply hoard tax savings to build financial flexibility. To rule out this interpretation, we have considered the effect of external financing opportunities by including *CMARD* in equation (6.2), as the extent to which firms can access to external capitals affects their incentives to build financial flexibility from hoarding tax savings (Edwards et al. 2012). Moreover, misallocation is not the only explanation for the positive relation between tax avoidance and excess cash. Another explanation is that managers hoard tax savings for legitimate purposes such as to counteract future economic downturn. External non-agency factors such as error in estimating firms' normal needs of cash or shocks to profitability may also drive this relation. However, we can rule out these confounding interpretations given that we find that strong corporate governance attenuates the relation between tax avoidance and excess cash, as corporate governance do not affect the effect of either external non-agency factors or economic downturn.

importantly, results herein indicate that in countries with poor investor protection self-serving is a possible incentive for managers to conduct tax avoidance, and such self-serving incentive is consistent with our finding that managers squander tax savings on suboptimal investment expenditures instead of spend on more value-enhancing expenditures.

5.3. *Tax avoidance and payout policy*

As a supplement test, we also investigate how tax avoidance relates to corporate payout policy. If managers hoard tax savings for self-serving reasons, then they would not want to pay tax savings out to shareholders, as payouts to shareholders will reduce the amount of cash that otherwise would be used to advance their private benefits. To test this conjecture, we follow the specification of Alzahrani and Lasfer (2012) by regressing corporate payouts on tax avoidance, the interaction between tax avoidance and investor protection, and other control variables, where payout is defined as (dividend paid on common shares + repurchases of common shares – proceeds from issuance of common shares) divided by total assets. The results are shown in Table 10.

[Insert Table 10 about here]

Table 10 shows that coefficients on *TA* are significantly negative in most columns, while coefficients on *TA·INP* are significantly positive in all column. This result is consistent with our conjecture that managers tend to be reluctant to pay tax savings out to shareholders, but this tendency is weakened in countries with better investor protection. This result also conforms to the outcome model of La Porta et al. (2000b) that with better legal protection minority shareholders can force corporate insiders to disgorge more cash to them.

5.4. *Excess cash and the valuation of tax avoidance*

In section 5.2 we have shown that tax avoidance positively relates to excess cash. Here we further examine how excess cash affects the valuation of tax avoidance. We conjecture that the presence of excess cash suggests that managers are more likely to misuse tax savings, since the further increase in cash from tax savings will bring little benefit but instead exacerbate the agency concern for holding excess cash. In this regard, the presence of excess cash will amplify the negative valuation of tax avoidance.

To test this conjecture, we estimate equation (1) by using observations with positive excess cash in previous period ($XCash_{t-1}>0$) and including this variable and its interaction with tax avoidance. We expect a negative coefficient on $TA{\cdot}XCash_{t\text{-}1}$. The estimate results are exhibited in Table 11.

[Insert Table 11 about here]

Table 11 shows coefficients on $TA{\cdot}XCash_{t\text{-}1}$ are negative for the full sample case in Panel A, and they are all significant except for in column (2). In Panel B, we use only US observations and coefficients on $TA{\cdot}XCash_{t\text{-}1}$ are significantly negative in columns (4) through (6). In Panel C we use observations for countries with low investor protection as the effect of our conjecture should be most pronounced in these countries. Consistent with our expectation, Panel C shows that coefficients on $TA{\cdot}XCash_{t\text{-}1}$ are all significantly negative and these coefficients are consistently smaller (more negative) than those in Panels A and B. Overall, results in Table 11 suggest that holding excess cash has a negative effect on the valuation of tax avoidance and this negative effect is more prominent when investor protection is weak.

6. Conclusion

Jensen (1986) argues that entrenched managers may waste free cash flows. We extend this argument to cash savings from tax avoidance. Our study proposes a new explanation for why corporate governance can affect the value of tax avoidance, which is beyond the tax-shielded rent extraction argument proposed by Desai and Dharmapala (2006, 2009) and Desai et al. (2007). Our results suggest that the main agency issue regarding tax avoidance is the misallocation of tax savings instead of managers exploiting tax avoidance to mask their rent extraction.

We find that better investor protection leads investors to place higher valuation on corporate tax avoidance. This finding is attributed to the reasoning that in countries with weak investor protection managers are more likely to squander tax savings on suboptimal investments or misallocate too much of them as cash reserves, so in these countries tax avoidance negatively impact operating performance. In contrast, these negative consequences of tax avoidance are all mitigated by better investor protection. Our international evidence suggests that the extent to which managers extract rent from tax avoidance through misallocating tax savings varies across countries with different level of investor protection.

Findings in this paper contribute to our understanding about the interaction between firm governance and tax avoidance. Although a large literature documents that better governance enhances firm value, much less is understood about how better governance works. Our study provides insight into this question by providing a direct link between governance and the value of tax savings. In this regard, we find that better governance increases firm value by improving the use of tax savings. This result sheds new light on the role of governance in the valuation of tax avoidance.

Appendix

Table A1
Empirical Definitions of Variables

Variable		Empirical Definition	Data Source
Measures of Tax Avoidance (*TA*)[1]			
BTD	=	[pretax book income – (domestic current tax expenses+ foreign current tax expenses) / top corporate statutory tax rate] / total assets.	Worldscope
RBTD	=	the residual from a firm fixed-effect regression of *BTD* on total accruals that is estimated for each country, where total accruals is calculated as (net income before extraordinary items - operating cash flow) / total assets.	Worldscope
PBTD	=	[pretax book income – (deferred tax expense + domestic current tax expenses+ foreign current tax expenses) / top corporate statutory tax rate] / total assets.	Worldscope
Measures of Legal Protection for Investor Rights (*INP*)			
LAW	=	the anti-director rights index plus 50 percent of the rule of law index	La Porta et al. 1998
CORUP	=	the corruption index	
Firm-Level Variables Used in Equations (1) to (4)			
(a) Dependent Variables			
MV	=	the sum of the market value of equity plus the book value of debt minus deferred tax expense and then divided by the book value of total asset.	Worldscope
$\Delta Cash$	=	change in cash holdings scaled by total assets	Worldscope
INVEST	=	(capital expenditures + research and development expense - proceeds from sale of fixed assets - depreciation) / the average total assets of years t and t-1	Worldscope
$INVEST^{\varepsilon}$	=	residual from regression (3.1), where positive value of $INVEST^{\varepsilon}$ represents overinvestment.	Worldscope
ROA_{t+1}	=	industry-adjusted return on assets, defined as operating income of year t+1 divided by the average total assets of t and t+1 and then adjusted with industry median value.	Worldscope

(b) Control Variables

SIZE	=	the natural log of total assets in US dollar.	Worldscope
CHS	=	the closely-held shares percentage.	Worldscope
DIV	=	dividend scaled by total assets	Worldscope
CAP	=	capital expenditures scaled by total assets	Worldscope
LEV	=	total debt scaled by total assets	Worldscope
INT	=	interest expenses scaled by total assets	Worldscope
RD	=	research and development expenses scaled by total assets	Worldscope
GROWTH	=	two-year (year t to t-1) average sales growth rate	Worldscope
TAXCR	=	income tax credit scaled by total assets	Worldscope
CashFlow	=	cash flow from operations minus dividend scaled by total assets	Worldscope
ΔNWC	=	change in noncash net working capital scaled by total assets	Worldscope
ΔSTD	=	change in short-term debt scaled by total assets	Worldscope
$LEV_{t\text{-}1}$	=	lagged book value of total debt over average total assets	Worldscope
$CASH_{t\text{-}1}$	=	lagged cash and cash equivalent over average total assets	Worldscope
$SIZE_{t\text{-}1}$	=	natural log of lagged total assets in US dollar	Worldscope
FCF	=	free cash flow, calculated as (cash from operations + research and development expense - depreciation expense) / average total assets - the predicted value of *INVEST* from regression (3.1)	Worldscope

Country-Level Control Variables

TAXEF	=	perceived strength of tax enforcement	Dyck and Zingales 2004
CMARD	=	the degree of capital market development, calculated as the sum of stock market capitalization and domestic credit provided by banking normalized by gross domestic product	World Bank Statistics
GDP	=	natural log of gross domestic product per capita in US dollar	World Bank Statistics

1. Statutory tax rates are hand-collected from a KPMG LLP online summary, PricewaterhouseCoopers LLP's online information, and Coopers & Lybrand LLP's worldwide tax summary guides.

ANTI is the anti-director rights index. *RULE* is the rule of law index. Both of these two indexes are retrieved from La Porta et al. (1998). Definitions of remaining variables are shown in Table A1 in the appendix. For each firm-level variable, the reported statistics are the means of yearly medians for specific country. For *CMARD* and *GDP*, the reported statistics is the mean over our sampling period for each country. The number of observations for each country is shown in the first column. The total of observations is161,376 and this is for *BTD* and *PBTD*. For *RBTD* we have 154,670 firm-year observations.

This table shows the results of estimating equation (1) without considering country-level variables, where the dependent variable is the Tobin's q ratio, defined as the sum of the market value of equity plus the book value of debt minus deferred tax expense and then divided by the book value of total asset. Definitions of remaining variables are shown in Table A1 in the appendix. The P-values are reported in parentheses. The estimated standard errors are adjusted by the procedure of Newey-West (1987). ***, **, and * represent statistical significant (two-tailed) at the 1%, 5% and 10% levels, respectively.

This table shows the results of estimating equation (2), where the dependent variable is $\Delta Cash$, defined as change in cash holdings scaled by total assets. Definitions of remaining variables are shown in Table A1 in the appendix. For Panels B and C in Parts I and II, countries with high (low) investor protection are deified as those with *LAW* values higher (lower) than the median of *LAW*, where the median is calculated with all our non-US sample countries. For brevity, in Part II firm-level and country-level variables are included in the estimates but their results are not presented. The P-values are reported in parentheses. The estimated standard errors are adjusted by the procedure of Newey-West (1987). ***, **, and * represent statistical significant (two-tailed) at the 1%, 5% and 10% levels, respectively.

This table shows the results of estimating equation (3.1), where the dependent variable is *INVEST*, defined as (capital expenditures + research and development expense - proceeds from sale of fixed assets - depreciation) / the average total assets of years t and t-1. Definitions of remaining variables are shown in Table A1 in the appendix. The P-values are reported in parentheses. The estimated standard errors are adjusted by the procedure of Newey-West (1987). ***, **, and * represent statistical significant (two-tailed) at the 1%, 5% and 10% levels, respectively.

This table shows the results of estimating equation (3.2). For brevity, variables *INP*, *TAXEF*, *CMARD*, *GDP*, and *FCF* are included in the estimates but their results are not presented. The dependent variable in Panel A is date *t* overinvestment $INVEST^{\varepsilon}$ defied as residual from regression (3.1), where positive value of $INVEST^{\varepsilon}$ represents overinvestment and observations used in this table are those with positive $INVEST^{\varepsilon}$. The dependent variable in Panel B is date *t*+1 overinvestment, defied as residual from regression (3.1) running with one-year ahead variables. Definitions of remaining variables are shown in Table A1 in the appendix. The P-values are reported in parentheses. The estimated standard errors are adjusted by the procedure of Newey-West (1987). ***, **, and * represent statistical significant (two-tailed) at the 1%, 5% and 10% levels, respectively.

This table shows the results of estimating equation (4). The dependent variable is industry-adjusted return on assets ROA_{t+1}, defined as operating income of year t+1 divided by the average total assets of t and t+1 and then adjusted with industry median value, where industry median is computed for each two-digit SIC industry in each country-year. Definitions of remaining variables are shown in Table A1 in the appendix. The P-values are reported in parentheses. The estimated standard errors are adjusted by the procedure of Newey-West (1987). ***, **, and * represent statistical significant (two-tailed) at the 1%, 5% and 10% levels, respectively.

This table shows the results of estimating equation (5), where the dependent variable is the Tobin's q ratio, defined as the sum of the market value of equity plus the book value of debt minus deferred tax expense and then divided by the book value of total asset. Definitions of remaining variables are shown in Table A1 in the appendix. For brevity, we only present the results relevant to our analysis and other variables are included in the estimates but their results are not presented. Data used in the estimates herein do not cover 1996 and 2012, since coverage of these two years requires data of 1995 and 2013 and this is beyond our sampling period. The P-values are reported in parentheses. The estimated standard errors are adjusted by the procedure of Newey-West (1987). ***, **, and * represent statistical significant (two-tailed) at the 1%, 5% and 10% levels, respectively.

This table shows the results of regressing payouts on tax avoidance, where payout is defined as (dividend paid on common shares + repurchases of common shares – proceeds from issuance of common shares) divided by total assets. RE/TE_{t-1} is the date t-1ratio of retained earnings over total equity. Definitions of remaining variables are shown in Table A1 in the appendix. For brevity, variables *INP*, *TAXEF*, *CMARD*, and *GDP* are included in the estimates but their results are not presented. The P-values are reported in parentheses. The estimated standard errors are adjusted by the procedure of Newey-West (1987). ***, **, and * represent statistical significant (two-tailed) at the 1%, 5% and 10% levels, respectively.

This table shows the results of estimating equation (1) by using observations with positive excess cash in previous period ($XCash_{t-1}$>0), where the dependent variable is the Tobin's q ratio, defined as the sum of the market value of equity plus the book value of debt minus deferred tax expense and then divided by the book value of total asset. Excess cash is the residual of equation (6.1). In Panel C countries with low investor protection (*INP*) are deified as those with *LAW* values lower than the median of *LAW*, where the median is calculated with all our non-US sample countries. For brevity, we only present the results relevant to our analysis and other control variables in equation (1) are included in the estimates but their results are not presented. Definitions of remaining variables are shown in Table A1 in the appendix. Data used in the estimates do not cover 1996, since coverage of 1996 has to estimate excess cash of 1995 and this is beyond our sampling period. The P-values are reported in parentheses. The estimated standard errors are adjusted by the procedure of Newey-West (1987). ***, **, and * represent statistical significant (two-tailed) at the 1%, 5% and 10% levels, respectively.

John Lee
Center for PBBEF Research
USA

The main purpose of this paper is to review and compare alternative methods for estimating implied variance. In this paper, we first review several alternative methods to estimate implied variance. Then we show how the MATLAB computer program can be used to estimate implied variance based upon the Black-Scholes model. In addition, we also discuss how the approximation method derived by Ang, Jou et al. (2013) can be used to estimate implied variance and implied stock price per share. Real world data are used to compare the estimation results using three typical alternative methods: regression method proposed by Lai, Lee et al, MATLAB computer program approach and approximation method derived by Ang, Jou et al.

1. Introduction

It is well known that implied variance estimation is important for evaluating option pricing. In this paper, we first review several alternative methods to estimate implied variance in Section B. We classify them into two different estimation routines: numerical search methods and closed-form derivation approaches. In Section C, we show how the MATLAB computer program can be used to estimate implied variance. This computer program is based upon the Black-Scholes model using Newton-Raphson method. In Section D, we discuss how the approximation method derived by Ang, Jou et al. (2013) can be used to estimate implied variance and implied stock price per share. This approximation method can also estimate implied volatility from two options with the same maturity, but different exercise prices and values. In Section E, real data from American option markets are used to compare the performances of three typical alternative methods: regression method proposed by Lai, Lee et al, MATLAB computer program approach and approximation method derived by Ang, Jou et al. The results are presented in Section E. Section F summarizes the paper.

2. Literature review

The derivation and use of the implied volatility for an option as originated by Latane and Rendleman (1976) has become a widely used methodology for variance estimation. Latane and Rendleman (1976) argued that although it is impossible to solve the B-S equation directly, one can use numerical search to closely approximate the standard deviation implied by given option price. The exact form of Black and Scholes model they used is given below.

$$C = SN(d_1) - Xe^{-rT}N(d_2) \tag{1}$$

where

$$d_1 = \frac{\ln(S/X) + (r + \frac{1}{2}s^2)T}{s\sqrt{T}}$$

$$d_2 = d_1 - s\sqrt{T}$$

S =current market price of the underlying stock;

X =exercise price;

r =continuous constant interest rate;

T =remaining life of the option.

Their procedure is to find an implied standard deviation which makes the theoretical option value, i.e. the right-hand side of Equation (1), within ± 0.001 of the observed actual call price. This is a kind of trial-and-error method.

Later researchers such as Beckers (1981), Manaster and Koehler (1982), Brenner and Subrahmanyam (1988), Lai, Lee et al. (1992), Chance (1996), Corrado and Miller (1996), Hallerbach (2004), Li (2005) and Corrado and Miller (2006), and have studied implied variance estimation in more detail.

Since the Black-Scholes' option pricing model is a nonlinear equation, an explicit analytic solution for the ISD is not available in the literature (except for at-the-money call) and numerical methods are generally used to approximate the ISD. Manaster and Koehler (1982) used the Newton-Raphson method to provide an iterative algorithm for the ISD.

They rewrote the Black-Scholes formula as in Equation (2), for given values of S, X, r and T.

$$C = f(S, X, r, T, \sigma) = f(\sigma) \tag{2}$$

For given values of S, X, r and T, f is a function of σ alone, and satisfies that:

$$\lim_{\sigma \to 0^+} f(\sigma) = \max(0, S - Xe^{-rT})$$

$$\lim_{\sigma \to \infty} f(\sigma) = S$$

Equation (2) will have a positive solution of implied standard deviation σ^*, if and only if the option is rationally priced that $\max(0, S - Xe^{-rT}) < C < S$. This is because function $f(\cdot)$ is strictly monotone increasing in σ over $(0, \infty)$ [1], and the monotonicity and continuity of $f(\cdot)$ guarantees there is a unique solution.

Newton-Raphson method is a common used method to solve nonlinear systems of equation. In this case for Equation (2), the method is stated as:

$$\sigma_{n+1} = \sigma_n - \frac{f(\sigma_n) - C}{f'(\sigma_n)} \tag{3}$$

where σ_n is the n-th estimate of σ^*, and $f'(\sigma_n)$ is the first derivative of $f(\sigma)$ when $\sigma = \sigma_n$.

Mean-Value Theorem. *Let f be a continuous function on the closed interval $[a, b]$, and can be differentiable on the open interval (a, b), where $a < b$. There exists some $c \in (a, b)$ such that:*

$$f'(c) = \frac{f(b) - f(a)}{b - a} \tag{4}$$

---

[1] Here we will briefly prove that the function $f(\cdot)$ is strictly monotone increasing in σ.

$$\begin{aligned}
f'(\sigma) &= \frac{\partial C}{\partial \sigma} = S\frac{\partial N(d_1)}{\partial \sigma} - Xe^{-rT}\frac{\partial N(d_2)}{\partial \sigma} \\
&= S\frac{\partial N(d_1)}{\partial d_1}\frac{\partial d_1}{\partial \sigma} - Xe^{-rT}\frac{\partial N(d_2)}{\partial d_2}\frac{\partial d_2}{\partial \sigma} \\
&= S\frac{1}{\sqrt{2\pi}}e^{-\frac{d_1^2}{2}}\left(\frac{\sigma^2 T^{\frac{3}{2}} - [\ln(\frac{S}{X}) + (r + \frac{1}{2}\sigma^2)T]\sqrt{T}}{\sigma^2 T}\right) - Xe^{-rT}\left(\frac{1}{\sqrt{2\pi}}e^{-\frac{d_1^2}{2}}\frac{S}{X}e^{rT}\right)\left(\frac{-[\ln(\frac{S}{X}) + (r + \frac{1}{2}\sigma^2)T]\sqrt{T}}{\sigma^2 T}\right) \\
&= S\frac{1}{\sqrt{2\pi}}e^{-\frac{d_1^2}{2}}\left(\frac{\sigma^2 T^{\frac{3}{2}}}{\sigma^2 T}\right) \\
&= S\sqrt{T}\frac{1}{\sqrt{2\pi}}e^{-\frac{d_1^2}{2}} \\
&= S\sqrt{T}N'(d_1)
\end{aligned}$$

See Chapter 20 of Lee, C.-F., J. Finnerty, et al. (2013) for more details if interested in derivation of partial derivatives.

Since $f'(\sigma) > 0$ when S, X, r and $T > 0$, and $\sigma > 0$, we have that $f(\cdot)$ is strictly monotone increasing in σ.

Under this case, mean-value theorem is stated as:

$$f'(\lambda \sigma_n + (1-\lambda)\sigma^*) = \frac{f(\sigma_n) - f(\sigma^*)}{\sigma_n - \sigma^*} = \frac{f(\sigma_n) - C}{\sigma_n - \sigma^*}, \text{ for some } \lambda \in (0,1) \tag{5}$$

Combining the above equation and Equation (3) in the main text, we can easily get:

$$\frac{\left|\sigma_{n+1} - \sigma^*\right|}{\left|\sigma_n - \sigma^*\right|} = \left|1 - \frac{f(\sigma_n) - C}{f'(\sigma_n)(\sigma_n - \sigma^*)}\right| = \left|1 - \frac{f'(\lambda \sigma^* + (1-\lambda)\sigma_n)}{f'(\sigma_n)}\right| \tag{6}$$

This motivates to choose σ_1 as σ that maximizes $f'(\sigma)$ so that σ_2 will be closer to σ^* than σ_1. From footnote 1, we know that to maximize $f'(\sigma)$ is to maximize $N'(d_1)$, where $N'(\cdot)$ is the standard normal density function. $N'(d_1) = \frac{1}{\sqrt{2\pi}}\exp(-\frac{d_1^2}{2})$. For simplicity of presentation, we denote $N'(d_1) = g(d_1)$. First order conditions for maximizing $N'(d_1)$, i.e $g(d_1)$, is: $\frac{\partial g(d_1)}{\partial \sigma} = 0$.

We then have:

$$\begin{aligned}
\frac{\partial g(d_1)}{\partial \sigma} &= \frac{1}{\sqrt{2\pi}} e^{-\frac{d_1^2}{2}} \cdot (-d_1) \cdot (\frac{\partial d_1}{\partial \sigma}) \\
&= \frac{1}{\sqrt{2\pi}} e^{-\frac{d_1^2}{2}} \cdot (-d_1) \cdot (-\frac{\ln(S/X) + rT}{\sigma^2 \sqrt{T}} + \frac{\sqrt{T}}{2}) \\
&= \frac{1}{\sqrt{2\pi}} e^{-\frac{d_1^2}{2}} \cdot (d_1) \cdot (\frac{1}{\sigma})(\frac{\ln(S/X) + rT}{\sigma\sqrt{T}} - \frac{\sigma\sqrt{T}}{2}) \\
&= \frac{1}{\sqrt{2\pi}} e^{-\frac{d_1^2}{2}} d_1 d_2 / \sigma \\
&= g(d_1) d_1 d_2 / \sigma \\
&= 0
\end{aligned}$$

Therefore, first order condition is simplified to: $d_1 d_2 = 0$. This happens if either $d_1 = 0$ in which case $\sigma^2 = \frac{-2(\ln(S/X) + rT)}{T}$ or $d_2 = 0$ in which case $\sigma^2 = \frac{2(\ln(S/X) + rT)}{T}$. Now we are checking second order conditions under both the two cases.

$$\begin{aligned}
\frac{\partial^2 g(d_1)}{\partial \sigma^2} &= \frac{\partial g'(d_1)}{\partial \sigma} \\
&= g'(d_1)\frac{\partial d_1}{\partial \sigma}\frac{d_1 d_2}{\sigma} + g(d_1)(\frac{d_1 d_2}{\sigma})' \\
&= g(d_1)(\frac{d_1 d_2}{\sigma})^2 - g(d_1)\frac{d_1^2 + d_2^2 + d_1 d_2}{\sigma^2} \\
&= g(d_1)\frac{d_1^2 d_2^2 - d_1^2 - d_2^2 - d_1 d_2}{\sigma^2}
\end{aligned}$$

First order condition give that either $d_1 = 0$ or $d_2 = 0$. When $d_1 = 0$, $\frac{\partial^2 g(d_1)}{\partial \sigma^2} = g(d_1)\frac{-d_2^2}{\sigma^2} < 0$. Similarly, when $d_2 = 0$, $\frac{\partial^2 g(d_1)}{\partial \sigma^2} = g(d_1)\frac{-d_1^2}{\sigma^2} < 0$. $\frac{\partial^2 g(d_1)}{\partial \sigma^2} < 0$ holds under both cases, therefore, $g(d_1)$ and $f'(\sigma)$ are simultaneously maximized.

From the above discussion, we know that the starting point σ_1 should be chosen by maximizing the partial derivative of call option respective to volatility $f'(\sigma)$, as given in Equation (7).

$$\sigma_1^2 = \left| \ln\left(\frac{S}{X}\right) + rT \right| \frac{2}{T} \tag{7}$$

Manaster and Koehler (1982) claimed that by starting with the above σ_1, implied variance estimate converges monotonically quadratically.

Brenner and Subrahmanyam (1988) applied Taylor series expansion to the cumulative normal function at zero up to the first order in the Black-Scholes option pricing model.

For at-the-money options, they set the underlying asset price S equal to the present value of exercise price Xe^{-rT}, i.e $S = Xe^{-rT}$, then d_1 and d_2 in Equation (1) are:

$$d_1 = \frac{1}{2}\sigma\sqrt{T}$$

$$d_2 = -\frac{1}{2}\sigma\sqrt{T} \tag{8}$$

Taylor series expansion is applied to the cumulative normal function at zero, while ignoring all the remaining terms beyond d_1.

$$N(d_1) = N(0) + N'(0)d_1 + \cdots = \frac{1}{2} + \frac{1}{\sqrt{2\pi}}d_1 + o(d_1) \tag{9}$$

Therefore, we have:

$$N(d_1) \approx \frac{1}{2} + \frac{1}{\sqrt{2\pi}}d_1 = \frac{1}{2} + \frac{1}{2\sqrt{2\pi}}\sigma\sqrt{T} \tag{10}$$

$$N(d_2) \approx 1 - N(d_1) = \frac{1}{2} - \frac{1}{2\sqrt{2\pi}}\sigma\sqrt{T} \tag{11}$$

Substituting Equations (10) and (11) into call option pricing equation demonstrated in Equation (1), we get:

$$C = \frac{S\sigma\sqrt{T}}{\sqrt{2\pi}} \tag{12}$$

Implied standard deviation then can be solved from Equation (13), shown below:

$$\sigma = \frac{C\sqrt{2\pi}}{S\sqrt{T}} \tag{13}$$

Note that Brenner and Subramanyam's method can only be used to estimate implied standard deviation from at-the-money or at least not too far in- or out-of-the-money options.

Lai, Lee et al. (1992) derived a closed form solution for the ISD in terms of the delta $\frac{\partial C}{\partial S}$, $\frac{\partial C}{\partial X}$, and other observable variables.

From Equation (1), ceteris paribus, the effects of a change in stock price S and exercise price X on the call price are determined by Smith Jr (1976), as following equations respectively:

$$\frac{\partial C}{\partial S} = N(d_1) \qquad (14)$$ [2]

$$\frac{\partial C}{\partial X} = -e^{-rT}N(d_2) \qquad (15)$$ [3]

Equations (14) and (15) can be rearranged as Equations (16) and (17) respectively:

---

[2] The derivation of $\frac{\partial C}{\partial S}$ is as follows.

$$\begin{aligned}
\frac{\partial C}{\partial S} &= N(d_1) + S\frac{\partial N(d_1)}{\partial S} - Xe^{-rT}\frac{\partial N(d_2)}{\partial S} \\
&= N(d_1) + S\frac{\partial N(d_1)}{\partial d_1}\frac{\partial d_1}{\partial S} - Xe^{-rT}\frac{\partial N(d_2)}{\partial d_2}\frac{\partial d_2}{\partial S} \\
&= N(d_1) + S\frac{1}{\sqrt{2\pi}}e^{-\frac{d_1^2}{2}} \cdot \frac{1}{S\sigma\sqrt{T}} - Xe^{-rT}\frac{1}{\sqrt{2\pi}}e^{-\frac{d_1^2}{2}}\frac{S}{X}e^{rT} \cdot \frac{1}{S\sigma\sqrt{T}} \\
&= N(d_1) + S\frac{1}{S\sigma\sqrt{2\pi T}}e^{-\frac{d_1^2}{2}} - S\frac{1}{S\sigma\sqrt{2\pi T}}e^{-\frac{d_1^2}{2}} \\
&= N(d_1)
\end{aligned}$$

Please note that:

$$\begin{aligned}
\frac{\partial N(d_2)}{\partial d_2} &= \frac{1}{\sqrt{2\pi}}e^{-\frac{d_2^2}{2}} = \frac{1}{\sqrt{2\pi}}e^{-\frac{(d_1-\sigma\sqrt{T})^2}{2}} \\
&= \frac{1}{\sqrt{2\pi}}e^{-\frac{d_1^2}{2}} \cdot e^{d_1\sigma\sqrt{T}} \cdot e^{-\frac{\sigma^2 T}{2}} \\
&= \frac{1}{\sqrt{2\pi}}e^{-\frac{d_1^2}{2}} \cdot e^{\ln(\frac{S}{X})+(r+\frac{\sigma^2}{2})T} \cdot e^{-\frac{\sigma^2 T}{2}} \\
&= \frac{1}{\sqrt{2\pi}}e^{-\frac{d_1^2}{2}} \cdot \frac{S}{X} \cdot e^{rT}
\end{aligned}$$

See Chapter 20 of Lee, C.-F., J. Finnerty, et al. (2013) for details if interested.

[3] The derivation of $\frac{\partial C}{\partial X}$ is as follows.

$$\begin{aligned}
\frac{\partial C}{\partial X} &= S\frac{\partial N(d_1)}{\partial X} - e^{-rT}N(d_2) - Xe^{-rT}\frac{\partial N(d_2)}{\partial X} \\
&= S\frac{\partial N(d_1)}{\partial d_1}\frac{\partial d_1}{\partial X} - e^{-rT}N(d_2) - Xe^{-rT}\frac{\partial N(d_2)}{\partial d_2}\frac{\partial d_2}{\partial X} \\
&= S\frac{1}{\sqrt{2\pi}}e^{-\frac{d_1^2}{2}}\frac{1}{\sigma\sqrt{T}}\frac{X}{S}(-\frac{S}{X^2}) - e^{-rT}N(d_2) - Xe^{-rT}(\frac{1}{\sqrt{2\pi}}e^{-\frac{d_1^2}{2}}\frac{S}{X}e^{rT})\frac{1}{\sigma\sqrt{T}}\frac{X}{S}(-\frac{S}{X^2}) \\
&= -e^{-rT}N(d_2)
\end{aligned}$$

See Chapter 20 of Lee, C.-F., J. Finnerty, et al. (2013) for details if interested.

$$d_1 = N^{-1}[(\frac{\partial C}{\partial S})] \tag{16}$$

$$d_2 = d_1 - \sigma\sqrt{T} = N^{-1}[e^{rT}(-\frac{\partial C}{\partial X})] \tag{17}$$

Combining Equations (16) and (17) yields:

$$\sigma = \{[N^{-1}(\frac{\partial C}{\partial S}) - N^{-1}[e^{rT}(-\frac{\partial C}{\partial X})]\} \Big/ \sqrt{T} \tag{18}$$

where $N^{-1}(\cdot)$ is the inverse cumulative normal distribution function.

Equation (18) shows that ISD calculation depends on two partial derivatives of the call option with respect to the stock price and exercise price, i.e. $\frac{\partial C}{\partial S}$ and $\frac{\partial C}{\partial X}$, and other two observable variables: time to maturity T and risk-free rate r.

Note that implied volatility σ should not be negative, therefore, a negative right-hand side of Equation (18) is not feasible.

Lai, Lee et al. (1992) argued that although the Black-Scholes option pricing model is a function of five variables, according to Merton (1973), the BS model exhibits homogeneity of degree one in the stock price and exercise price, which is shown in Equation (19).

$$C = (\frac{\partial C}{\partial S})S + (\frac{\partial C}{\partial X})X = \beta_S S + \beta_X X \tag{19}$$

where $\beta_S = \frac{\partial C}{\partial S}$ and $\beta_X = \frac{\partial C}{\partial X}$.

The two partial derivatives can be estimated by running the following linear multiple regression:

$$C_{it} = \alpha + \beta_S S_t + \beta'_X e^{-rT} X_{it} + \varepsilon_{it} \tag{20}$$

Substituting the least square estimators $\hat{\beta}_S$ and $\hat{\beta}'_X$ in Equation (20) into Equation (18), the implied variance can be estimated as:

$$\sigma = [N^{-1}(\hat{\beta}_S) - N^{-1}(-\hat{\beta}'_X)] \Big/ \sqrt{T} \tag{21}$$

Instead of running linear regression to estimate the two partial derivatives $\frac{\partial C}{\partial S}$ and $\frac{\partial C}{\partial X}$, we can first find $\frac{\partial C}{\partial X}$ by simple or weighted averaging $\frac{\Delta C}{\Delta X}$ for various exercise prices (S is being held constant provided the call price quotes are simultaneous). Then the other partial derivative $\frac{\partial C}{\partial S}$ is got from Equation (19). Lai, Lee et al. (1992) mentioned that this alternative approach would work best for index options, where there are many simultaneous quotes.

It should also be noted that, following their method, there is an alternative way to estimate implied standard deviation only using one partial derivative $\frac{\partial C}{\partial S}$. From Equation (19), we have:

$$(\frac{\partial C}{\partial X})X = C - (\frac{\partial C}{\partial S})S$$

$$\Rightarrow \ (\frac{\partial C}{\partial X}) = \frac{C}{X} - \frac{S}{X}(\frac{\partial C}{\partial S}) \tag{22}$$

Substituting Equation (22) into Equation (18), we will have a new closed form solution for the ISD only depending on delta $\frac{\partial C}{\partial S}$ and other observable variables, as shown in Equation (23).

$$\sigma = \{[N^{-1}(\frac{\partial C}{\partial S}) - N^{-1}[e^{rT}(\frac{S}{X}(\frac{\partial C}{\partial S}) - \frac{C}{X})]]\} \Big/ \sqrt{T} \tag{23}$$

Brenner and Subrahmanyam (1988)'s formula for estimating implied variance is simple, but limited only to at-the-money or at least too far in- or out-of-the-money cases. On the basis of their research, Chance (1996) developed a generalized formula so that this formula can be implemented under other cases when options are in-the-money or out-of-the-money.
Recall Brenner-Subrahmanyam formula for ISD is:

$$\sigma^* = \frac{C^*\sqrt{2\pi}}{S\sqrt{T}} \tag{24}$$

where C^* is the price of the at-the-money call. We assume the call has an exercise price X^*.

Chance (1996) proposed a model that start with Equation (24), and added terms to reflect both the moneyness and sensitivity of standard deviation. The option with the unknown implied standard deviation is priced at C and has an exercise price of X. By definition, the difference between the at-the-money call and the call with unknown ISD is given as:

$$\Delta C^* = C - C^* \tag{25}$$

He argued that the difference in the prices of the two calls comes from: (1) the difference in exercise prices, i.e. $\Delta X^* = X - X^*$; (2) the difference in standard deviation, i.e. $\Delta\sigma^* = \sigma - \sigma^*$. He applied second-order Taylor series expansion on ΔC^*, which yields:

$$\Delta C^* = \frac{\partial C^*}{\partial X^*}(\Delta X^*) + \frac{1}{2}\frac{\partial^2 C^*}{\partial X^{*2}}(\Delta X^*)^2 + \frac{\partial C^*}{\partial \sigma^*}(\Delta\sigma^*) + \frac{1}{2}\frac{\partial^2 C^*}{\partial \sigma^{*2}}(\Delta\sigma^*)^2 + \frac{\partial^2 C^*}{\partial \sigma^* \partial X^*}(\Delta\sigma^*\Delta X^*) \tag{26}$$

Since these partial derivatives which appear in Equation (26) are for at-the-money calls, their formulas can be simplified using the following relationships.

$$S = X^* e^{-rT} \tag{27}$$

$$d_1^* = \frac{1}{2}\sigma^*\sqrt{T} \tag{28}$$

$$d_2^* = -\frac{1}{2}\sigma^*\sqrt{T} \tag{29}$$

Therefore, we have the following important equations for partial derivatives hold, respectively.

$$\frac{\partial C^*}{\partial X^*} = -e^{-rT} N(d_2^*) \qquad (30)^4$$

$$\frac{\partial^2 C^*}{\partial X^{*2}} = -e^{-rT}\frac{\partial N(d_2^*)}{\partial d_2^*}\frac{\partial d_2^*}{\partial X^*} = -e^{-rT}\frac{e^{-\frac{d_2^{*2}}{2}}}{\sqrt{2\pi}}\frac{1}{\sigma^*\sqrt{T}}\left(\frac{X^*}{S^*}\right)\left(-\frac{S^*}{X^{*2}}\right) = \frac{e^{-rT}e^{-\frac{d_2^{*2}}{2}}}{X^*\sigma^*\sqrt{2\pi T}} \qquad (31)$$

For an at-the-money call, Equation (31) is given as in Equation (32):

$$\frac{\partial^2 C^*}{\partial X^{*2}} = \frac{e^{-rT}e^{-\frac{d_2^{*2}}{2}}}{X^*\sigma^*\sqrt{2\pi T}} = \frac{e^{-rT}}{X^*\sigma^*\sqrt{2\pi T}}e^{-\frac{\sigma^{*2}T}{8}} \qquad (32)$$

$$\frac{\partial C^*}{\partial \sigma^*} = S\frac{\partial N(d_1^*)}{\partial \sigma^*} - X^*e^{-rT}\frac{\partial N(d_2^*)}{\partial \sigma^*} = \frac{S\sqrt{T}e^{-\frac{d_1^{*2}}{2}}}{\sqrt{2\pi}} \qquad (33)^5$$

Given the call is at the money, Equation (33) is given as in Equation (34):

$$\frac{\partial C^*}{\partial \sigma^*} = \frac{Xe^{-rT}\sqrt{T}}{\sqrt{2\pi}}e^{-\frac{\sigma^{*2}T}{8}} \qquad (34)$$

$$\frac{\partial^2 C^*}{\partial \sigma^{*2}} = \frac{S\sqrt{T}e^{-\frac{d_1^{*2}}{2}}}{\sqrt{2\pi}}(-d_1^*)\frac{\partial d_1^*}{\partial \sigma^*} = -\frac{S\sqrt{T}e^{-\frac{d_1^{*2}}{2}}}{\sqrt{2\pi}}d_1^*\left(-\frac{\ln(S/X^*) + rT}{\sigma^{*2}\sqrt{T}} + \frac{\sqrt{T}}{2}\right) = \frac{S\sqrt{T}}{\sqrt{2\pi}}e^{-\frac{d_1^{*2}}{2}}\frac{d_1^*d_2^*}{\sigma^*} \qquad (35)$$

For an at-the-money call, Equation (35) becomes:

$$\frac{\partial^2 C^*}{\partial \sigma^{*2}} = \frac{X^*e^{-rT}T^{\frac{3}{2}}\sigma^*}{4\sqrt{2\pi}}e^{-\frac{\sigma^{*2}T}{8}} \qquad (36)$$

$$\frac{\partial^2 C^*}{\partial \sigma^*\partial X^*} = -e^{-rT}\frac{\partial N(d_2^*)}{\partial d_2^*}\frac{\partial d_2}{\partial \sigma} = -e^{-rT}\left(\frac{1}{\sqrt{2\pi}}e^{-\frac{d_1^{*2}}{2}}\frac{S}{X^*}e^{rT}\right)\left(\frac{-[\ln(\frac{S}{X^*}) + (r + \frac{1}{2}\sigma^{*2})T]\sqrt{T}}{\sigma^{*2}T}\right) = \frac{Se^{-\frac{d_1^{*2}}{2}}d_1^*}{X^*\sigma^*\sqrt{2\pi}} \qquad (37)$$

Given the call is at the money, Equation (37) becomes:

$$\frac{\partial^2 C^*}{\partial \sigma^*\partial X^*} = \frac{e^{-rT}\sqrt{T}}{2\sqrt{2\pi}}e^{-\frac{\sigma^{*2}T}{8}} \qquad (38)$$

Equation (25) can be restated as:

$$C^* - C + \Delta C^* = 0 \qquad (39)$$

Substituting Equation (26) into Equation (39), Equation (39) can be viewed as a quadratic equation of $\Delta\sigma^*$, written as:

$$a(\Delta\sigma^*)^2 + b(\Delta\sigma^*) + c = 0 \qquad (40)$$

Where

$$a = \frac{1}{2}\frac{\partial^2 C^*}{\partial \sigma^{*2}}$$

---

4 The derivation of Equation (30) has been shown in Footnote 3.

5 The derivation of Equation (33) has been shown in Footnote 1.

$$b = \frac{\partial C^*}{\partial \sigma^*} + \frac{\partial^2 C^*}{\partial \sigma^* \partial X^*}(\Delta X^*)$$

$$c = C^* - C + \frac{\partial C^*}{\partial X^*}(\Delta X^*) + \frac{1}{2}\frac{\partial^2 C^*}{\partial X^{*2}}(\Delta X^*)^2$$

Therefore, the solution of the Equation (40) should be:

$$\Delta \sigma^* = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} \tag{41}$$

Experiments in Chance (1996) suggest that positive root for $\Delta \sigma^*$ of Equation (40) give the correct solution for implied variance when adding it to the value of σ^* from Brenner-Subrahmanyam formula.

One thing that needs to be noted is that in order to apply Chance's formula to compute the ISD, the standard deviation and the option price under the at-the-money case must be given. In other words, if the underlying asset price deviates from the present value of the exercise price and the call option price is not available (or unobservable) in the market, then Chance's formula for the ISD may not apply, just as the case of Brenner-Subrahmanyam formula.

To allow for the deviation between the underlying asset price and the present value of exercise price, Corrado and Miller (1996) expanded the cumulative normal function at zero to the first order term in the Black-Scholes OPM to derive a quadratic equation of the ISD.

Their approach followed the method employed by Brenner and Subramanyam, and made use of the expansion of the normal distribution function as stated in Equation (42).

$$N(z) = \frac{1}{2} + \frac{1}{\sqrt{2\pi}}(z - \frac{z^3}{6} + \cdots) \tag{42}$$

Substituting Equation (42) into the normal probabilities $N(d_1)$ and $N(d_2)$ in classic Black-Scholes model as Equation (1) states, we have Equation (43) hold when cubic and higher order terms are ignored.

$$C = S(\frac{1}{2} + \frac{d_1}{\sqrt{2\pi}}) - Xe^{-rT}(\frac{1}{2} + \frac{d_1 - \sigma\sqrt{T}}{\sqrt{2\pi}}) \tag{43}$$

K is defined as the present value of strike price X, i.e: $K = Xe^{-rT}$.

Recall the expressions for d_1 and d_2 are:

$$d_1 = \frac{\ln(S/X) + (r + \frac{1}{2}\sigma^2)T}{\sigma\sqrt{T}} = \frac{\ln(S/K) + \frac{1}{2}\sigma^2 T}{\sigma\sqrt{T}}$$

$$d_2 = d_1 - \sigma\sqrt{T}$$

Equation (43) can be restated as:

$$C = S(\frac{1}{2} + \frac{\ln(S/K) + \frac{1}{2}\sigma^2 T}{\sigma\sqrt{2\pi T}}) - K(\frac{1}{2} + \frac{\ln(S/K) - \frac{1}{2}\sigma^2 T}{\sigma\sqrt{2\pi T}}) \tag{44}$$

Equation (44) can be formulated as the quadratic equation of $\sigma\sqrt{T}$, as shown in Equation (45)

$$\sigma^2 T(S + K) - \sigma\sqrt{T}[(2\sqrt{2\pi}C - \sqrt{2\pi}(S - K)] + 2(S - K)\ln(S/K) = 0 \tag{45}$$

Corrado and Miller (1996) proved that only the largest root for Equation (45) reduced to the original Brenner-Subramanyam formula, which is shown in Equation (46).

$$\sigma\sqrt{T} = \sqrt{2\pi}\left(\frac{2C - S + K}{2(S+K)}\right) + \sqrt{\frac{\pi}{2}\left(\frac{2C - S + K}{S+K}\right)^2 - \frac{2(S-K)\ln(S/K)}{S+K}} \tag{46}$$

After solving the quadratic equation of $\sigma\sqrt{T}$, they improve the accuracy of approximation by minimizing its concavity[6]. Therefore, their final formula to compute the implied standard deviation was given as:

$$\sigma = \sqrt{\frac{2\pi}{T}}\frac{1}{S+K}\left[C - \frac{S-K}{2} + \sqrt{\left(C - \frac{S-K}{2}\right)^2 - \frac{(S-K)^2}{\pi}}\right] \tag{47}$$

Li (2005) also followed Brenner and Subramanyam and expanded the expression to the third order term and solved for the ISD with a cubic equation.

Taylor expansion as Equation (42) states was used in Li's paper. He retained the cubic order and substituted Equation (42) into the normal probabilities in the Black-Scholes model as stated in Equation (1), and this yielded:

$$C = S\left(\frac{1}{2} + \frac{d_1}{\sqrt{2\pi}} - \frac{d_1^3}{6\sqrt{2\pi}}\right) - Xe^{-rT}\left(\frac{1}{2} + \frac{d_2}{\sqrt{2\pi}} - \frac{d_2^3}{6\sqrt{2\pi}}\right) \tag{48}$$

For at-the-money calls, $d_1 = \frac{1}{2}\sigma\sqrt{T}$, $d_2 = -\frac{1}{2}\sigma\sqrt{T}$, $S = Xe^{-rT}$.

When defining $x = \frac{1}{2}\sigma\sqrt{T}$, the following equation hold for at-the-money calls:

$$\frac{\sqrt{2\pi}C}{S} \approx 2x - \frac{1}{3}x^3 \tag{49}$$

Equation (49) can be solved by using the cubic formula[7].

He went through some tedious derivations and simplifications, and finally obtained the formula to compute implied standard deviation:

---

[6] This approach included several steps.

First, logarithmic approximation was used. $\ln(S/K) \approx 2(S-K)/(S+K)$.

Secondly, they replaced the value "4" with the parameter α to restate Equation (46) as:

$$\sigma\sqrt{T} = \sqrt{2\pi}\left(\frac{2C - S + K}{2(S+K)}\right) + \sqrt{\frac{\pi}{2}\left(\frac{2C - S + K}{S+K}\right)^2 - \alpha\left(\frac{S-K}{S+K}\right)^2}$$

They chose a value for α such that the above equation is approximately linear in the stock price when the option is near the at-the-money case. When setting the second derivative of right-hand side of the above equation with respect to stock price equal to zero, they found the realistic estimated value for α was close to 2.

[7] The general cubic equation has the form $ax^3 + bx^2 + cx + d = 0$, with $a \neq 0$. If the cubic equation is in the form of $t^3 + pt + q = 0$, it is called a depressed cubic equation. Please note that any general cubic equation can be reduced to the depressed cubic equation by dividing the general equation with a and substituting variable x with $t = x - \frac{b}{3a}$.

For a depressed cubic equation $t^3 + pt + q = 0$, the roots are:

$$t_k = 2\sqrt{-\frac{p}{3}}\cos\left(\frac{1}{3}\arccos\left(\frac{3q}{2p}\sqrt{\frac{-3}{p}}\right) - k\frac{2\pi}{3}\right), k = 0, 1, 2.$$

$$\sigma = \frac{2\sqrt{2}}{\sqrt{T}} z - \frac{1}{\sqrt{T}} \sqrt{8z^2 - \frac{6\alpha}{\sqrt{2}z}} \tag{50}$$

where $\alpha = \frac{\sqrt{2\pi}C}{S}$ and $z = \cos\left[\frac{1}{3}\cos^{-1}\left(\frac{3\alpha}{\sqrt{32}}\right)\right]$

Since Li included the third order term in the Taylor expansion on the cumulative normal distribution in his derivation, Li claimed that his formula for ISD provided a consistently more accurate estimate of the true ISD than previous studies.

To sum up, the existing researches mainly follow two different routines to estimate implied volatility. Numerical search methods tried to find an approximate solution for implied volatility which makes the theoretical option value equal to or very close to market observed option price. These methods don't provide closed-form solution for estimated implied volatility, and need iterative algorithms to approximate the ISD. Other closed-form derivation approaches took use of either Taylor expansion or inverse function to calculate the analytical solutions for the ISD. First-order, second-order, and third order Taylor expansions were applied to cumulative normal distribution function respectively to estimate the implied volatility in previous studies. There were also studies using inverse function of normal distribution to derive closed-form solution of the ISD.

An important point to be noted is that some methods rely upon the existence of "at-the-money" options, or at least not too far in- or out-of-the-money options. These approaches include Brenner and Subrahmanyam (1988), Chance (1996), and Li (2005).

Table 1 classifies the existing researches of estimating implied volatility accordingly.

Table 1. classification of the ISD estimation methods

Numerical Search	**Closed-form Derivation**
Trial and error Latane and Rendleman (1976)	**Taylor Series Expansion** First-order expansion:Brenner and Subrahmanyam (1988); Corrado and Miller (1996) Second-order expansion: Chance (1996) Third-order expansion: Li (2005)
Choose an initial point, iterative algorithm Manaster and Koehler (1982)	**Inverse Function** Estimate parameters by regression: Lai, Lee et al. (1992)

3. MATLAB approach to estimate implied variance

Usually, implied variance can be obtained from a call or put option model by an optimization technique. For each individual option, the implied variance can be obtained by first choosing an initial estimate σ_0, and then Equation (51) is used to iterate towards the correct value.

$$C_{j,t}^{M} - C_{j,t}^{T}(\sigma_0) = \left[\left. \frac{\partial C_{j,t}^{T}}{\partial \sigma} \right|_{\sigma_0} \right] (\sigma - \sigma_0) + e_{j,t} \tag{51}$$

Where

$C_{j,t}^{M}$ =market price of call option j at time t;

σ =true or actual implied standard deviation;

σ_0 =initial estimate of implied standard deviation;

$C_{j,t}^{T}(\sigma_0)$ =theoretical price of call option j at time t given $\sigma = \sigma_0$;

$\left. \frac{\partial C_{j,t}^{T}}{\partial \sigma} \right|_{\sigma_0}$ =partial derivative of the call option with respect to the standard deviation σ at $\sigma = \sigma_0$;

$e_{j,t}$ =error term.

The partial derivative of the call option with respective to the standard deviation $\frac{\partial C_{j,t}^{T}}{\partial \sigma}$ from Black-Scholes model is:

$$\frac{\partial C_{t,j}^{F}}{\partial \sigma} = X e^{-r\tau} \sqrt{\tau} N'(d_1) = X e^{-r\tau} \frac{\sqrt{\tau}}{\sqrt{2\pi}} e^{-d_1^2/2} \tag{52}$$

It is also called Vega of option.

The iteration proceeds by reinitializing σ_0 to equal σ_1 at each successive stage until an acceptable tolerance level is attained. The tolerance level used is:

$$\left| \frac{\sigma_1 - \sigma_0}{\sigma_0} \right| < .001 \tag{53}$$

The MATLAB finance toolbox provides a function blsimpv to search for implied volatility. The algorithm used in the blsimpv function is Newton's method, just as the procedure described in Equation (51). This approach minimizes the difference between observed market option value and the theoretical value of B-S model, and obtain the ISD estimate until tolerance level is attained.

The complete command of the function *blsimpv* is: Volatility = *blsimpv*(Price, Strike, Rate, Time, Value, Limit, Yield, Tolerance, Class). And the command with default setting is: Volatility = *blsimpv*(Price, Strike, Rate, Time, Value).

There are nine inputs in total, while the last four of them are optional. Detailed explanations of all the inputs are as follows:

Inputs:

Price - Current price of the underlying asset.

Strike - Strike (i.e., exercise) price of the option.

Rate - Annualized continuously compounded risk-free rate of return over the life of the option, expressed as a positive decimal number.

Time - Time to expiration of the option, expressed in years.

Value - Price (i.e., value) of a European option from which the implied volatility of the underlying asset is derived.

Optional Inputs:

Limit - Positive scalar representing the upper bound of the implied volatility search interval. If empty or missing, the default is 10, or 1000% per annum.

Yield - Annualized continuously compounded yield of the underlying asset over the life of the option, expressed as a decimal number. For example, this could represent the dividend yield and foreign risk-free interest rate for options written on stock indices and currencies, respectively. If empty or missing, the default is zero.

Tolerance - Positive scalar implied volatility termination tolerance. If empty or missing, the default is 1e-6.

Class - Option class (i.e., whether a call or put) indicating the option type from which the implied volatility is derived. This may be either a logical indicator or a cell array of characters. To specify call options, set Class = true or Class = {'Call'}; to specify put options, set Class = false or Class = {'Put'}. If empty or missing, the default is a call option.

Output:

Volatility - Implied volatility of the underlying asset derived from European option prices, expressed as a decimal number. If no solution can be found, a NaN (i.e., Not-a-Number) is returned.

Example:

Consider a European call option trading at $5 with an exercise price of $95 and 3 months until expiration. Assume the underlying stock pays 5% annual dividends, which is trading at $90 at this moment, and the risk-free rate is 3% per annum. Under these conditions, the command used in Matlab will be either of the following two:

```
Volatility = blsimpv(90, 95, 0.03, 0.25, 5,[],0.05,[], { 'Call'})
Volatility = blsimpv(90, 95, 0.03, 0.25, 5,[],0.05,[], true)
```

Note that this function provided by MATLAB's toolbox can only estimate implied volatility from a single option. For more than one option, the user needs to write their own programs to estimate implied variances.

4. Approximation approach to estimate implied variance

In this section, we will discuss alternative method proposed by Ang, Jou et al. (2009) to use the call option model and put option model to estimate implied volatility. Our approximation approach can also estimate implied volatility from two options with the same maturity, but different exercise prices and values.

Recall the Black-Scholes call option pricing model (with continuous dividends), we have:

$$C = S'N(d_1) - KN(d_2) \tag{54}$$

where

$$d_1 = \frac{\ln(S/X) + (r + \frac{s^2}{2} - q)T}{s\sqrt{T}} = \frac{\ln(S'/K)}{s\sqrt{T}} + s\sqrt{T}/2$$

$d_2 = d_1 - s\sqrt{T}$;

C =call price;

S =stock price;

q =annual dividend yield;

$S' = Se^{-qT}$

X =exercise price;

r =risk-free interest rate;

$K = Xe^{-rT}$, present value of exercise price

T =time to maturity of option in years;

$N(\cdot)$ =standard normal distribution;

s =stock volatility.

We derive a formula to estimate the ISD by applying the Taylor series expansion on a single call option. We show that, following method proposed by Ang, Jou et al. (2009) and Ang, Jou et al. (2013),the formula for ISD derived by Corrado and Miller (1996) can be improved further without any replacements.

Recall the Taylor series expansion approximating complex functions from calculus(Lee, Lee et al. 2009) (Lee, Lee et al. 2009, Appendix 5.B), which can be mathematically written as follows:

$$F_n(x) = F(a) + F'(a)(x - a) + \frac{F''(a)}{2!}(x - a)^2 + \mathrm{L} + \frac{F^{(n)}(a)}{n!}(x - a)^2 \tag{55}$$

where

$F_n(x)$ is the function we are approximating;

$F'(a)$ is the first derivative of the function;

$F^{(n)}(a)$ is the n th derivative of the function;

$n!$ is the factorial value of n , i.e $n! = (n)(n - 1)\mathrm{L}\ (2)(1)$;

a is the value near which we are making the approximation to the function $F(x)$.

Let $L' = \ln(S'/K)/\sigma\sqrt{T}$. Here, we apply the Taylor series expansion to both cumulative normal distributions in the Black-Scholes formula at L'.

Then we have

$$\begin{aligned} N(L'+\sigma\sqrt{T}/2) &= N(L') + N'(L')(L'+\sigma\sqrt{T}/2 - L') + N''(L')\frac{(L'+\sigma\sqrt{T}/2 - L')^2}{2!} + \cdots \\ &= N(L') + N'(L')\sigma\sqrt{T}/2 + N''(L')(\sigma\sqrt{T}/2)^2/2 + e_1 \\ &= N(L') + N'(L')(\sigma\sqrt{T}/2)[1 - \ln(S'/K)/4] + e_1 \end{aligned} \tag{56}$$

and

$$\begin{aligned} N(L'-\sigma\sqrt{T}/2) &= N(L') + N'(L')(L'-\sigma\sqrt{T}/2 - L') + N''(L')\frac{(L'-\sigma\sqrt{T}/2 - L')^2}{2!} + \cdots \\ &= N(L') - N'(L')\sigma\sqrt{T}/2 + N''(L')(\sigma\sqrt{T}/2)^2/2 + e_2 \end{aligned}$$

$$\begin{aligned} N(L'-\sigma\sqrt{T}/2) &= N(L') - N'(L')\sigma\sqrt{T}/2 + N''(L')(\sigma\sqrt{T}/2)^2/2 + e_2 \\ &= N(L') - N'(L')(\sigma\sqrt{T}/2)[1 + \ln(S'/K)/4] + e_2 \end{aligned} \tag{57}$$

where, e_1 and e_2 are the remainder terms of Taylor's formulas.

The above equations can be obtained by the fact that $N''(x) = -N'(x)x$.

Given $N(0) = 1/2$, $N'(0) = 1/\sqrt{2\pi}$, $N'''(0) = -N'(0)$, $N''(0) = N''''(0) = 0$, we expand $N(L')$ and $N'(L')$ at 0 respectively.

$$N(L') = N(0) + N'(0)L' + N''(0)L'^2/2 + e_3 = \frac{1}{2} + L'/\sqrt{2\pi} + e_3 \tag{58}$$

$$N'(L') = N'(0) + N''(0)L' + N'''(0)L'^2/2 + e_4 = 1/\sqrt{2\pi} - L'^2/2\sqrt{2\pi} + e_4 \tag{59}$$

Substituting Equations (56) – (59) into Equation (54) , dropping all of remainder terms, Equation (54) becomes:

$$\begin{aligned} C = {} & (S'-K)/2 + (\ln(S'/K)/\sigma\sqrt{2\pi T})[(S'-K)(1 + [\ln(S'/K)/4]^2) - \ln(S'/K)(S'+K)/4] \\ & + (\sigma\sqrt{T}/2\sqrt{2\pi})[S'+K - \ln(S'/K)(S'-K)/4] \end{aligned} \tag{60}$$

Equation (60) is a quadratic equation of $\sigma\sqrt{T}$ and can be rewritten as:

$$\begin{aligned} & \sigma^2 T[8(S'+K) - 2(S'-K)\ln(S'/K)] - 8\sigma\sqrt{T}\sqrt{2\pi}(2C - S'+K) \\ & + \ln(S'/K)[(S'-K)(16 + (\ln(S'/K))^2) - 4(S'+K)\ln(S'/K)] = 0 \end{aligned} \tag{61}$$

Solving $\sigma\sqrt{T}$ from equation (61) yields

$$\sigma\sqrt{T} = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} \tag{62}$$

Where $a = 8(S'+K) - 2(S'-K)\ln(S'/K)$

$$b = -8\sqrt{2\pi}(2C - S'+K)$$

$$c = \ln(S'/K)[(S'-K)(16 + \ln(S'/K))^2] - 4(S'+K)\ln(S'/K)]$$

A merit of Equation (62) is to circumvent the ad hoc substitution present in Corrado and Miller (1996) and improve the accuracy of the ISD's estimation. Other methods to calculate the implied volatility can be found in Lai, Lee et al. (1992) and.

According to Lee, Lee et al. (2013), put-call parity can be defined in Equation (63), we can calculate implied volatility, stock price per share, and exercise price per share in terms of put option model.

$$P = C + Xe^{-rT} - Se^{-qT} \tag{63}$$

Let $Xe^{-rT} = K$ and let $Se^{-qT} = S'$, then we have following equation.

$$P = C + K - S' \tag{64}$$

Substituting Equation (60) into Equation (64), we obtain following equation:

$$\begin{aligned} P = {} & (K - S')/2 + \left(\ln(S'/K)/s\sqrt{2pT}\right)[(S' - K)(1 + [\ln(S'/K)/4]^2) - \ln(S'/K)(S' + K)/4] \\ & + (s\sqrt{T}/2\sqrt{2p})[S' + K - \ln(S'/K)(S' - K)/4] \end{aligned} \tag{65}$$

Equation (65) is also a quadratic equation of $s\sqrt{T}$ and can be rewritten as:

$$\begin{aligned} & s^2T[8(S' + K) - 2(S' - K)\ln(S'/K)] - 8s\sqrt{T}\sqrt{2p}(2P - K + S') \\ & + \ln(S'/K)[(S' - K)(16 + (\ln(S'/K))^2) - 4(S' + K)\ln(S'/K)] = 0 \end{aligned} \tag{66}$$

Solving $s\sqrt{T}$ from Equation (66) yields

$$s\sqrt{T} = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} \tag{67}$$

Where $a = 8(S' + K) - 2(S' - K)\ln(S'/K)$, $b = -8\sqrt{2p}(2P - K + S')$,

$$c = \ln(S'/K)[(S' - K)(16 + \ln(S'/K)^2)] - 4(S' + K)\ln(S'/K)]$$

We rearrange Equation (61) in terms of S', then we obtain Equation (68).

$$\begin{aligned} & [8s^2T + 8s\sqrt{2pT} + 2s^2T\ln K - 16\ln K - 4(\ln K)^2 - (\ln K)^3]S' \\ & +[2s^2TK - 16K + 8K\ln K - 3K(\ln K)^2]\ln S' + [16 - 2s^2T + 8\ln K + 3(\ln K)^2]S'\ln S' \\ & +(3K\ln K - 4K)(\ln S')^2 - (3\ln K + 4)S'(\ln S')^2 - K(\ln S')^3 + S'(\ln S')^3 \\ & = 16Cs\sqrt{2pT} + 8s\sqrt{2pT}K - 8s^2TK + 2s^2TK\ln K - 16K\ln K + 4K(\ln K)^2 - K(\ln K)^3 \end{aligned} \tag{68}$$

Equation (68) can be used to estimate S' if we have the information of the other five variables. The solution of S' can only be obtained by the trial-and-error method.

Now, consider two call options, C_1 and C_2, on the same time to the maturity with exercise prices of X_1 and X_2. q is an annual dividend yield, S is the underlying asset value, and we denote $S' = Se^{-qT}$. We also denote the present values of the exercise prices $K_1 = X_1e^{-rT}$ and $K_2 = X_2e^{-rT}$, respectively.

For C_1, we apply Taylor's expansion to Equation (54) at K_2. This yields the following equation:

$$C_1 = C_2 - N(\ln(S'/K_2)/s\sqrt{T} - s\sqrt{T}/2)(K_1 - K_2) + e_1 \tag{69}$$

Where e_1 is the remainder term of Taylor's formula.

Similarly, for C_2, we apply Taylor's expansion to Equation (54) at K_1, which yields the following equation.

$$C_2 = C_1 - N(\ln(S'/K_1)/s\sqrt{T} - s\sqrt{T}/2)(K_2 - K_1) + e_2 \tag{70}$$

Where e_2 is the remainder term of Taylor's formula.

Rearranging the equations, dividing both sides by $(K_2 - K_1)$, then applying the inverse function of cumulative normal function on both sides, we have the following two equations.

$$N^{-1}[(C_1 - C_2)/(K_2 - K_1)] = \ln(S'/K_1)/s\sqrt{T} - s\sqrt{T}/2 + h_1 \tag{71}$$

$$N^{-1}[(C_1 - C_2)/(K_2 - K_1)] = \ln(S'/K_2)/s\sqrt{T} - s\sqrt{T}/2 + h_2 \tag{72}$$

Combining the two above equations, the effect of remainder terms may be partially offset. Then we get the quadratic equation of $s\sqrt{T}$ as follows.

$$s^2T + 2N^{-1}[(C_1 - C_2)/(K_2 - K_1)](s\sqrt{T}) - \ln(S'/K_1) - \ln(S'/K_2) = 0 \tag{73}$$

Then we can solve implied volatility as:

$$s\sqrt{T} = -N^{-1}((C_1 - C_2)/(K_2 - K_1)) \pm \sqrt{[N^{-1}((C_1 - C_2)/(K_2 - K_1))]^2 + \ln(S'^2/K_1K_2)} \tag{74}$$

Similarly, we consider two put options P_1 and P_2 on the same time to the maturity with exercise prices of X_1 and X_2. q is the annual dividend yield, S is the underlying asset value, we denote $S' = Se^{-qT}$. We also denote the present values of the exercise prices $K_1 = X_1e^{-rT}$ and $K_2 = X_2e^{-rT}$, respectively.

According to put-call parity defined in Equation (64), we have the following equations.

$$P_1 = C_1 + K_1 - S' \tag{75}$$

$$P_2 = C_2 + K_2 - S' \tag{76}$$

If we substitute the above equations into Equations (69) and (70), then we have the following equations:

$$P_1 = P_2 + (K_1 - K_2) - N(\ln(S'/K_2)/s\sqrt{T} - s\sqrt{T}/2)(K_1 - K_2) + d_1 \tag{77}$$

$$P_2 = P_1 + (K_2 - K_1) - N(\ln(S'/K_2)/s\sqrt{T} - s\sqrt{T}/2)(K_2 - K_1) + d_2 \tag{78}$$

Rearranging the equations, dividing both sides by $(K_2 - K_1)$, and then applying the inverse function of cumulative normal function on both sides, we have the following two equations.

$$N^{-1}((P_1 - P_2)/(K_2 - K_1) + 1) = \ln(S'/K_2)/s\sqrt{T} - s\sqrt{T}/2 + g_1 \tag{79}$$

$$N^{-1}((P_1 - P_2)/(K_2 - K_1) + 1) = \ln(S'/K_1)/s\sqrt{T} - s\sqrt{T}/2 + g_2 \tag{80}$$

By combining the two above equations, the effect of the remaining terms may be partially offset. Then we get the quadratic equation of $s\sqrt{T}$ as follows.

$$s^2T + 2N^{-1}[(P_1 - P_2)/(K_2 - K_1) + 1](s\sqrt{T}) - \ln(S'/K_1) - \ln(S'/K_2) = 0 \tag{81}$$

Solving the equation for $s\sqrt{T}$, we obtain:

$$s\sqrt{T} = -N^{-1}((P_1 - P_2)/(K_2 - K_1) + 1) \pm \sqrt{[N^{-1}((P_1 - P_2)/(K_2 - K_1) + 1)]^2 + \ln(S'^2/K_1K_2)} \tag{82}$$

5. Some Empirical Results

We select 10 constituent companies of S&P 500 as examples to compare the implied volatility estimation methods. The selected companies have relative large market values, and are from different industries. Table 2 shows the details of our sample.

Table 2. Details of Sample Companies

Security ID	Ticker	Company Name	SIC Code	Industry
101594	AAPL	Apple Inc.	3571	Electronic Computers
104533	XOM	Exxon Mobil Corporation	2911	Petroleum Refining
121812	GOOGL	Google Inc.	7375	Information Retrieval Services
107525	MSFT	Microsoft Corporation	7372	Prepackaged Software
106566	JNJ	Johnson & Johnson	2834	Pharmaceutical Preparations
111953	WFC	Wells Fargo & Company	6022	State Commercial Banks
105169	GE	General Electric Company	3511	Steam, Gas, and Hydraulic Turbines, and Turbine Engine
111860	WMT	Wal-Mart Stores Inc.	5331	Variety Stores
102968	CVX	Chevron Corporation	2911	Petroleum Refining
109224	PG	The Procter & Gamble Company	2841	Soap and Other Detergents
102936	JPM	JPMorgan Chase & Co.	6211	Security Brokers, Dealers & Flotation Companies
111668	VZ	Verizon Communications Inc.	4812	Radiotelephone Communications
108948	PFE	Pfizer Inc.	2834	Pharmaceutical Preparations

109775	T	AT&T, Inc.	4812	Radiotelephone Communications

Sample time spans from July, 2013 to August, 2013. 10-year treasury rate is used as the risk-free rate, i.e 2.7%. We calculated the continuously compounded annual risk free interest rate accordingly: $\ln(1+2.7\%) = 2.66\%$ as the parameter r .

Empirical results(to be filled in the table)

6. Summary

The main purpose of this paper is to discuss how to use alternative methods for estimating implied variance. In this paper, we will first review alternative methods to estimate implied variance. We classify them into two different estimation routines: numerical search methods and closed-form derivation approaches, and discussed their limitations. Then, we show how the MATLAB computer program can be used to estimate implied variance. This kind of approach used Newton-Raphson method to derive the implied variance from the standard Black-Scholes model. In addition, we also discuss how the approximation method derived by Ang, Jou et al. (2013) can be used to estimate implied variance and implied stock price per share. Not only the case of single option is presented, this approximation method also estimate implied volatility from two options with the same maturity, but different exercise prices and values. At last, we select some large-cap stocks from S&P 500 as empirical examples. The performances of three typical alternative methods: regression method proposed by Lai, Lee et al, MATLAB computer program approach and approximation method derived by Ang, Jou et al are compared.

This study examines the relation between taxpayer balloting, budget levels, and standardized tests in New Jersey school districts over a ten-year period. Cost and production functions are jointly estimated, where the endogenous variables are costs per pupil and weighted test scores. From these regressions, efficiency and effectiveness scores are derived for each school district. Granger causality tests are then used to determine the direction of causality between efficiency, effectiveness, and voting outcomes.

We find a negative relation between the one-year lag of efficiency and the current year's effectiveness scores, suggesting that cutting costs has an adverse effect on test scores the following year. We also find that a defeated budget ("no vote") is negatively related to efficiency, but positively related to effectiveness, suggesting that the proposed budget signals inefficiencies that are not cured by remedial actions, but that the negative vote is instead used as an incentive to improve performance.

Keywords: Taxpayer Voting; School District Budgets; Student Achievement Scores; Efficiency in Public Schools.

1. Introduction

It has been commonly observed that while expenditure on education has been increasing, there has not been a corresponding increase in students' performance. As a result, an active debate rages over whether public schools utilize the considerable resources at their disposal in an efficient and effective manner. Many proposed reforms aimed at increasing the efficiency of public schools in the United States share a common driving force: increased parental participation. The underlying logic is that stakeholders should be better able to allocate resources in ways that lead to improvements in academic performance. Although this argument is intuitively appealing, relatively little research is available about the effectiveness of taxpayers' voting in curbing inefficiency in public school education.

The objective of this study is to evaluate the effectiveness of taxpayers as a disciplinary mechanism for budgeting in governmental institutions. We address this question by studying the effects of defeated budgets in New Jersey – one of the few states where school budgets are subject to a direct vote of approval by the electorate – over the period of 2003 to 2013. Standardized test scores are used as an outcome measure to examine the impact of defeated budgets on efficiency. For academic year 2009-2010, 315 New Jersey school district budgets were defeated out of a total of 538 budgets (i.e., 59 percent). This is a sharp increase relative to the previous year, when only 26 percent of the budgets were defeated. An interesting question arises: "Can school districts manage with decreased resources without affecting student test performance, or do budget-cutting measures in response to defeated budgets cause test performance to deteriorate?"

There are *prima facie* reasons to expect that taxpayer balloting may not be the best control mechanism. Firstly, they may not have the necessary technical expertise to understand (or to discover the potential inefficiencies in) the budgets as proposed by the institutional administrators. (Arguably, the legislature or local governing body may be more competent in this regard.) Secondly, even if taxpayers possess the expertise, political considerations (including political apathy) may influence the outcome of the voting process, thus rendering the results of the ballot an unreliable control mechanism to curb cost inefficiencies in public institutions. Third, large numbers of taxpayers may be myopic decision-makers and may vote a budget down if the marginal benefit to them is lower than the cost imposed on them through taxes.

On the other hand, taxpayer balloting as the control mechanism may be justified as the most cost-effective means of determining the preferences of a diverse electorate. If the output of the public sector institution is a public good for which differential demand exists, allowing the electorate to approve the level of output through a vote may result in the revelation of the preference of the taxpayers. Thus, a potential justification for allowing a direct ballot on the budget of public sector institutions may be to obtain a consensus from the electorate on the value placed on the provision of the public good.

This study arrives at an important time to provide evidence on the merits of New Jersey's new school election law (P.L. 2011, c. 202) that was signed by Governor Christie on January 17, 2012. This law allowed school boards or governing bodies to change the election date of school board members from the third Tuesday in April up to the date of the general election in November. For those school districts that adopted the change, the annual vote on the school district budget was eliminated, provided the districts stay within a mandatory 2% tax levy cap.

In response to the new school election law, school districts rushed to move up the school elections from April to November.[1] The following figures summarize the number of school districts with budget referenda that were put on the ballot in April prior to the budget year:

Academic Year	Number of NJ School Districts with April Budget Votes[2]
2010-2011	538
2011-2012	539
2012-2013	70
2013-2014	39

Of the 539 school districts that were required to hold budget votes in April of 2011, only 70 (13.0%) continued to hold budget referenda in April of 2012. By April of 2013, this figure had fallen to 7.2%.

The overwhelming move to November elections may save taxpayer money in state-wide election costs in April, but the new election law may have unintended consequences. Absent direct taxpayer budget voting, an important mechanism for public oversight of the school district budgets is removed. Without this disciplinary mechanism over the budget, increases in cost inefficiencies and/or decreases in outcome effectiveness (i.e., test scores) may result. Our paper has the potential to shed light on this possibility.

We use a panel analysis approach to evaluate the relative efficiency and effectiveness of the school districts in our sample from 2003 to 2012. To measure efficiency and effectiveness, a cost function is estimated simultaneously with a production function, where the two dependent variables are the comparative cost per pupil and weighted test scores, respectively. From these regressions, efficiency (EFFCY) and effectiveness (EFTV) scores are obtained for each school district. We then estimate the relationships between EFFCY, EFTV, and voting outcomes (NO_VOTE) using Granger causality tests that control for other factors and lagged values of the endogenous variables.

Some of our main results are as follows. We document a negative relation between $EFFCY_{(t-1)}$ and $EFTV_{(t)}$, suggesting that greater efficiency in one year is associated with relatively lower test score performance the following year. Thus, cost-cutting in one period may have an adverse effect on test scores in the following year. We document a similar negative relation between $EFTV_{(t-1)}$ and $EFFCY_{(t)}$, suggesting higher performing districts may subsequently become lax on efficiency in order to maintain high levels of achievement (or they do not face the same pressure as lower performing districts to increase their cost efficiency the following year). However, both EFFTV and EFFCY have positive serial correlation, indicating a tendency for school districts to maintain their relative postures

[1] FSLR, "Scores of N.J. school districts moving elections from April to November," *NJ.Com*, February 26, 2012. www.nj.com/news/index.ssf/2012/02/scores_of_nj_school_districts.html.

[2] Source: State of New Jersey Department of Education, DOE Data and Reports, School Election Results, www.state.nj.us/education/data/vote/.

through time. Moreover, in general, we find that more efficient school districts also tend to be more test outcome-effective. In regards to voting outcomes (as motivators of behavior), we find that the $NO\_VOTE_{(t)}$ (which occurs in April preceding school year t's budget year beginning in July of that same calendar year) is positively associated with $EFTV_{(t)}$ but negatively related to $EFFCY_{(t)}$. In essence, there is a positive effect stemming from the negative budget vote on the school district's test score performance, but higher cost efficiency (the primary objective of the negative budget vote) is not achieved. This suggests two things. First, the observed budget that taxpayers are voting on signals school district inefficiencies, and subsequent remedial actions taken by the school district in response to the negative vote are ineffective in curing the inefficiency. Second, school districts would prefer to appease voters by increasing test scores, rather than making reductions in the budget.

The lagged effect of $NO\_VOTE_{(t-1)}$ on $EFTV_{(t)}$ and $EFFCY_{(t)}$ is quite different. $No\_Vote_{(t-1)}$ is negatively related to $EFTV_{(t)}$ and has no significant relationship with $EFFCY_{(t)}$. Thus, the test- score enhancing effect of $NO\_VOTE_{(t)}$ (discussed above) is mitigated, since there is a partial reversal in the following year. However, further investigation reveals that the contemporaneous positive effect of the negative vote is about three times that of the subsequent reversal, so improvements in test score performance remains positive on a cumulative basis.

The remainder of this study proceeds as follows. Section II reviews the literature on inefficiencies in school district budgeting, determinants of taxpayer balloting outcomes, and alternative institutional arrangements for setting the budget. In section III we present our methodology for assessing the effectiveness of the direct vote on school district budgets, including model specification and variable selection. We present our findings and subsequent sensitivity tests in Section IV. Our conclusions follow in section V.

2. Literature review

This literature review consists of three parts. The first part looks at evidence of budgetary inefficiencies in school spending. Both direct and indirect evidence is examined. The second part focuses on voting behavior and empirically observed determinants of public voting outcomes, including reasons why proposed budget referenda fail. The third part reviews literature on alternative institutional arrangements for approving governmental expenditures, and to what extent budget referenda serve as a cost minimizer through voter participation.

Inefficiency in Educational Spending

According to data provided by the U.S. Department of Education, expenditures on public schools rose from \$75 billion in 1975 to \$681 billion in 2010.[3] Using constant-dollar figures, public schools spent, on average, \$12,743 per pupil in 2010, relative to \$6,253 per pupil in 1975, the latest year for which data are available.[4] Despite that doubling of funds, just about

[3] (U.S. Department of Education, National Center for Education Statistics, NCES 2014-015, *Digest of Education Statistics*, 2012, table 28, p. 55).

[4] U.S. Department of Education, National Center for Education Statistics, NCES 2014-015, *Digest of Education Statistics*, 2012, table 213, p. 297).

every measure of educational outcomes has remained stagnant since 1975. Notwithstanding the poor results, state lawmakers, courts and bureaucrats keep pushing for even more spending.[5]

While a modest positive correlation between per-pupil spending and educational ranking has been found, vast differences still exist between spending per pupil and quality of education. For example, the National KIDS COUNT ranks Colorado ninth nationally in quality of education,[6] even though the State spent an average of $9,305 per student in 2009, putting it among the bottom 10 states in spending the least per pupil.[7] In comparison, Alaska, ranked 41st for its education quality, but spent an average of $15,363 per student, putting it third in the country (excluding the District of Columbia).

There is a large body of literature that indicates that school budgets are using money inefficiently. Although it is difficult to know what constitutes efficiency in a situation where private market forces are fairly weak or absent, several forms of inefficiencies in education spending have been documented.

Chalos (1997) employs data envelope analysis to examine budgetary efficiency across elementary school districts in the State of Illinois. He finds that budgetary inefficiency was positively associated with: (1) the size of the budget, (2) the administrative overhead in the budget, and (3) the proportion of the budget financed by local property taxes. These findings offer a partial explanation for the weak relationship traditionally found between educational spending inputs and performance outcomes. The results are suggestive of how school districts might improve their budgetary goal setting, performance auditing and resource allocation practices.

Ruggiero and Vitaliano (1999) use data from 520 New York school districts and show that inefficiency exists in the production of "learning" in public elementary and secondary education. Based on both the results of their stochastic frontier model and DEA, they find that operating expenditure per student is 14% above the “least cost” estimate, after controlling for socioeconomic variables.

Saito and McIntosh (2003) use data envelopment analysis to examine the efficiency of public schools in Georgia. They find that Georgia school districts utilize educational budgets with reasonable efficiency, achieving an overall efficiency of 98%, with a range of 93-100%. If all school districts were 100% efficient, outputs could be expanded 2%. However, from the consumers' (voters') point of view, this result suggests that inefficiency cost Georgia a total of $226.38 million annually on average from 1994 to 1996.

Dodson and Garrett (2004) estimate scale economies for Arkansas school districts. The results suggest that districts, especially rural districts, would experience measurable cost savings from consolidation. Simulations indicate that districts could save on average 34% on variable costs. At the state level, consolidation of rural districts in Arkansas could annually

---

[5] Over the last decade, high courts in several states have ruled that public school spending in certain urban systems violates state constitutional requirements to spend enough on public schools to produce “adequate” results.

[7] U.S. Department of Education, National Center for Education Statistics, NCES 2014-015, *Digest of Education Statistics*, 2012, table 217, p. 303).

save $40 million.

Marlow (2001) tests the hypothesis that monopoly power of school districts allows bureaucratic expansion in public school budgets, spawning inefficiency and poor academic performance. Using 1992-1993 data at the county level in the State of California, he provides evidence in support of the bureaucratic expansion hypothesis from the standpoint that monopoly power is positively associated with employment of more teachers and administrators. On the other hand, he shows that employment of more administrators raises SAT scores and lowers drop-out rates, suggesting a misallocation of resources between teachers and administrators.

Lee and Plummer (2007) examine budgets for 1,034 Texas school districts over a 1995-2002 sample period, and find budget ratcheting (budget increases associated with prior year spending variances) within subcategories of both instructional and non-instructional expenditures, although it is more prevalent in the latter. They also find that budget ratcheting is more pronounced for school districts that operate in a less competitive environment and for districts that have less voter influence.

Indirect evidence of inefficiency is presented by studies that show little or no relationship between expenditures and student performance. Hanushek (1986, 1989, 1996) has summarized the reported findings from a multitude of studies that examine the school input-test score relation. In his most recent (1996) survey, he found that expenditures had a significant positive effect on student achievement in only 27 percent of 163 studies, while 7 percent reported a significant negative relation, and 76 percent had insignificant coefficients. Hanushek's (1996) survey of the literature also examined the effects of other school input variables on student achievement. The teacher-pupil ratio, teacher experience, and teacher's salaries had significant positive effects on test scores in only 15 percent, 29 percent, and 20 percent of the studies, respectively. He concludes that "Today's schools exhibit continuing inefficiency in their operations as there is no strong or consistent relationship between variations between school resources and student performance." Because of the weak or inconsistent relation between school inputs and test scores, we omit these school input variables from our test score model in section 3.2 in favor of the known driver of test scores - socio-economic variables (e.g., Jaggia and Kelly-Hawke, 1999).

Determinants of Voting Outcomes and why Budget Referenda Fail.

A number of researchers have examined how taxpayers voted on specific budget referenda and have identified empirical determinants of budget referenda outcomes. The focus has been on the characteristics of the individual voters and budget voting patterns. For the sake of brevity, we limit our discussion to studies that examine budget votes on public schools, beginning with capital investment decisions.

Bowers, Metzger, and Militello (2010) examined voting patterns on 789 school construction bonds in the state of Michigan. They find that voter turnout, amount of bond principal, and two socio-economic variables - percent student receiving free lunches and percent district population with only a high school degree - were all negative and significant factors in passing a bond issue. Although district enrollment was not significant, being in a small or rural town was a negative factor. Zimmer, Buddin, Jones, and Liu (2011) also examine voting outcomes on capital investments in Michigan, and find that there is a higher approval rate for maintenance of existing facilities than the construction of new school buildings or additions.

Wang, Duncombe, and Yinger (2011) examine the capital investment decisions in New York's school districts in response to matching state building aid programs. They find that rural districts are much more likely to take advantage of state aid in approving capital projects than are high-need urban districts. In most cases the budgetary problems of urban districts are so severe they are unwilling or unable to accept new debt, even when most of the cost will be picked up by the state government. Urban districts face additional obstacles, including higher construction prices and greater superintendent turnover than rural districts.

Silverman (2011) examines voting on New York school district budgets over the 2003–2010 period, and finds that the overwhelming majority (92%) of proposed budgets are approved by voters. Although voter turnout was low in general,[8] higher voter turnout is associated with a greater percentage of "no votes." He also finds that the percent increase in annual spending is associated with "no votes," and that the probability of a budget being approved is greater in school districts with higher enrollment.

Ehrenberg, Ehrenberg, Smith, and Zhang (2004) analyze historical data for New York State on the percentage of school budget proposals that are defeated each year. They show that once a budget is rejected by voters, there is an increased likelihood that subsequent budgets will be voted down. Changes in per-capita county income increase the likelihood that budgets will pass. They also find that districts whose school board members have longer terms have lower probabilities of having their budget proposals defeated.

A study conducted by New York State's Department Of Education (NYSDE, 2005) found that the greater the proposed increase in the local tax levy, the greater the probability of the budget being rejected by voters. Other factors associated with budget rejection were dependence on local taxes, percentage change in district spending, the local effective tax rate, and school district enrollment. School districts in Nassau or Suffolk counties in Long Island experienced a disproportionate number of budget failures, accounting for 44 percent of defeated budgets.

In order to understand district characteristics and funding trends, several authors study the relation between voting on school budgets and community demographics. Using data from telephone surveys in the State of North Carolina, Priest and Cox (2005) found that African Americans were more likely to pass school budgets irrespective of whether they had school age children living in their households. Respondents who had more confidence in public officials and the school board were more likely to approve the bond issue. In a test of the "Gray Peril" hypothesis,"[9] Lambert, Clark, Wilcox, and Park (2009) show that senior citizens

---

[8] Silverman explains that the budget process in New York does not provide much incentive to vote. When budgets are not approved by voters, a school district can adopt a contingency budget. Due to state regulations, there is usually only a marginal difference between a proposed school district budget and a default contingency budget. So there is little motivation to go to the polls and reject a budget that ultimately will be passed in a slightly revised form.

[9] Under the "Gray Peril" hypothesis, funding for education and other public services will suffer because retirees are unwilling to support services not benefiting them. Education is considered most susceptible to Gray Peril since retirees do not have school-age children, and education expenditures are often determined by local public referenda where seniors tend to vote in large numbers. Likewise, in popular retirement destinations such as the

in the State of Tennessee tend to support local spending on public schools at the same level as other citizens, even though they do not have school age children in their households.

Taken together, the results of Silverman (2011), Bowers et al. (2010), and NYSDE (2005) suggest that voters' frustration with increases in school spending or borrowing can augment turnout at the ballot box and can result in taxpayer revolt,[10] leading to a higher rate of defeated budgets and forcing schools to manage with inadequate resources. The findings from these papers present a dilemma for school board and administrators, since there are potential incentives to discourage turnout in order to increase the chance of budgets being approved.

Are Budget Referenda an Efficient Institutional Arrangement for Approving Governmental Expenditures?

This final part of our literature review examines research on alternative institutional arrangements for budgeting government expenditures. Much of this research focuses on direct voting verses budget-setting by elected or appointed officials, and whether or not holding a budget referenda results in lower expenditures. In light of the State of New Jersey's new election law, this is a relevant question for this study.

Megdal (1983) uses a principal-agent setting to investigate the importance of the budget referendum on spending in New Jersey school districts. Her model predicts no difference between observed outcomes in communities where agents in the form of elected officials set the budget on behalf of principal taxpayers and in communities where a budget referendum is held. Her results are inconclusive, neither accepting nor rejecting the null hypothesis.

Steunenberg (1992) examines the influence of different institutional arrangements in setting and approving the budget, including obligatory fiscal referendum, voter initiative, and veto power on the outcomes of budget games. Steunenberg argues that the smallest budget is found in direct voting initiative where voters determine the level of expenditure, but that the level of spending under a representative arrangement can be equivalent to that in the case of referenda. Other studies find no significant linkage between referenda and expenditures (Bails and Tieslau 2000; Santerre 1989; Sass 1991), or even a counter-intuitive positive relation between them (Farnham 1990).

However, a large majority of studies provide empirical evidence of a constraining effect of budget referenda on public expenditures and revenues in the United States. Romer, Rosenthal, and Munley (1992) examine public school budget referenda data from 544 New York SCSDs (Small City School Districts) for the 1975-1976 fiscal year, and show that spending varies according to referendum rules. In addition, large school districts appear to be more inefficient and behave more like "budget maximizers" than small districts, where proposals are more in line with "median voter" demands. Ebdon (2000) also compares expenditures in New York State school districts with and without budget referendum

south and west that contain more transients, retirees may lack direct connections to the local school system (Duncombe, Robbins, and Stonecash 2003).

[10] Taxpayer revolt implies a large voter turnout and negative votes against the budget, as a form of protest. Protest voting is of interest because it can highlight socioeconomic conditions that augment the probability of a budget defeat. See Archibald and Feldman (2006) for a more in-depth review of the taxpayer revolt.

requirements. Using an 11 year sample period (1990-2000), Ebdon shows that total spending is 5.5% higher in districts without referenda, ceteris paribus.

Nguyen-Hoang (2012) finds that budget referenda lead to a decrease in spending. Using data from New York in 1998, he offers empirical evidence that spending-inhibiting budget referenda induce district officials to cut back expenditures on instructional services and increase student- teacher ratios while preserving administrative spending. However, Nguyen-Hoang's paper does not address how reductions in total and instructional spending and an increase in student–teacher ratios may affect student performance.

This literature review provides an overview of the literature at this time. A significant vacuum in this literature is the question of whether taxpayer balloting on school district budgets is based on an accurate assessment of the relative efficiency and effectiveness of the school districts. A related research question is whether, regardless of whether the school budget vote results are based on a well-informed evaluation of relative efficiency and effectiveness, the results of the ballot serve as a signal to school district administrators and teachers. Specifically, are the subsequent actions of the administrators and teachers (in terms of achieving greater efficiency and/or effectiveness) related to the antecedent vote outcomes? These two issues are addressed in the rest of this paper.

3. Methodology

Conceptual Framework

The preceding literature review has highlighted the intended disciplinary role that taxpayer balloting can have over school district budgets. For this disciplinary mechanism to be effective, two conditions must be met: (1) taxpayers must be fully informed about the relative efficiency and effectiveness of their school districts; and (2) school district administrators must be cognizant of the fact that the taxpayers have been provided information that enables them to assess the relative efficiency and effectiveness of the school districts in the state.

In the State of New Jersey, both conditions are easily met. The State's Department of Education has posted on its website detailed historical and current records of expenditures, standardized test scores results, and other outcomes (graduation rates, etc.) for all the school districts in the state. In addition, to improve comparability, the Department also has compiled what it refers to as District Factor Groupings (DFGs) which classify school districts into eight socio-economic groupings based on the commonality of the socio-economic factors in which the districts operate. Thus, taxpayers have access to the data on which they can access both the cost efficiency and the outcome effectiveness of the school districts, and the school districts are aware of this data accessibility.

Given the fulfillment of both conditions, we posit that in a dynamic setting, there will be interactive feedback effects, with the results of the taxpayer ballot informing school district administrators whose response in turn affects the outcomes of the following year's ballot. This results in a Granger causality type setting where the lagged values of the endogenous variables affect the current values. Specifically, we postulate the following relationships:

$$EFFCY_{(t)} = \square\,[\,EFFCY_{(t\text{-}1)}, EFTV_{(t)}, EFTV_{(t\text{-}1)}, VOTE_{(t)}, VOTE_{(t\text{-}1)}, TYPE, \text{control variables (set 1)}\,] \tag{1}$$

$$EFTV_{(t)} = \square\,[\,EFFCY_{(t)}, EFFCY_{(t\text{-}1)}, EFTV_{(t\text{-}1)}, VOTE_{(t)}, VOTE_{(t\text{-}1)}, TYPE, \text{control variables (set 2)}\,] \tag{2}$$

$$VOTE_{(t)} = \square\,[\,EFFCY_{(t\text{-}1)}, EFTV_{(t\text{-}1)}, VOTE_{(t\text{-}1)}, TYPE, \text{control variables (set 3)}\,] \tag{3}$$

where

$EFFCY_{(t)}$	=	Cost efficiency of the school district relative to other school districts in year t.
$EFTV_{(t)}$	=	Test outcome effectiveness of the school district relative to other districts in year t.
$VOTE_{(t)}$	=	Result of school districts budget ballot held in April preceding the July 1 start date of school year t (coded as dummy variable with NO = 1, and YES = 0).
TYPE	=	School district type, where:

Type 1	=	Kindergarten to Grade 4;
Type 2	=	Kindergarten to Grade 8;
Type 3	=	Kindergarten to Grade 12;
Type 4	=	Grade 5 to Grade 8; and
Type 5	=	Grade 9 to Grade 12.

As described in Equations (1) to (3), EFFCY is seen as a function of EFTV for the same budget year, the values of EFFCY and EFTV from the previous year, the results of the vote on that year's budget (conducted in April preceding the July 1st – June 30th budget year), and last year's vote outcome. Similarly, EFTV is seen as a function of the concurrent EFFCY, the lagged values of EFTV and EFFCY, and the VOTE outcome for the current year as well as the prior year. Finally, the vote outcome is seen as a function of EFFCY and EFTV of the previous year,[11] and last year's vote outcome.

An issue that arises from this conceptual framework is the measurement of EFFCY and EFTV. The literature on cost and production functions has provided a wide variety of ways in which cost efficiency and output effectiveness can be estimated. In traditional neo-classical models where well-behaved functions are assumed, Shephard's Lemma can be applied to derive the equivalence of cost and production functions (Shephard, 1953). Unfortunately, in the educational context, such well-behaved functions do not exist, as noted by Costrell, Hanuschek and Loeb (2008) and others who note the lack of any relationship (or a very weak one at best) between educational outcomes and school expenditures. The absence or weak relationship between educational spending and test outcomes suggests that cost efficiency and test outcome effectiveness can be measured independently from cost and outcome functions.

Following Imazeki (2008), a system of two equations is employed to estimate simultaneously the cost and outcome functions. Joint estimation provides a statistical approach for resolving the possible simultaneous equation bias that may result from estimating the two functions independently. The variables used to estimate these models are

---

[11] Since the school district budget vote takes place in April of each year, results of the prior year's state- wide achievement tests and actual expenditures are known by this time.

discussed in the next section.

Model Specification and Variables

The jointly dependent variables used in the cost and outcome functions are CC_TOT and TPASSR_2, respectively. CC_TOT is defined as Comparative Cost per-pupil, computed by the State of Jersey. This variable includes five major categories of school costs: classroom instructional costs, administrative costs, student support costs, operating and maintenance, and extracurricular activities. It excludes transportation, facilities acquisition costs, interest, and other miscellaneous items.

The second jointly dependent variable is test scores. The three standardized tests used in the study are given in Grades 4, 7 and 12. Students sit for the NJ ASK4 (Assessment of Skills and Knowledge) test in grade 4, the GEPA (Grade Education Proficiency Analysis) test in Grade 7, and the HSPA (High School Proficiency Analysis) test in grade 12. The State of New Jersey has now moved to having students sit for NJASK tests for all grades, but since we are using panel data, we have retained the standardized tests in these three grades because they have the longest histories. It should be noted that the use of standardized test scores (including pass rates) as the sole measure of school district performance has been criticized as inadequate since public schools pursue multiple objectives (Hanushek 1979, 1986). Nevertheless, since it is a measure that is typically used by the state as well as the general public to evaluate school performance, we rely on these statistics for our analyses.

Our test score variable is based on the mean pass rates for tests taken in that school district. Thus, for a Type 2 (K-8) school district, we compute an average pass rate using test results from both the NJ ASK4 (Grade 4) and the GEPA (Grade 7). The State distinguishes "Advanced Pass" from "regular pass." To take this into account, an "Advanced Pass" is assigned twice the weight of a "Regular Pass." So our test score variable, TPASSR_2, is a weighted pass rate. The exact computation of this variable is included in the appendix. For comparative purposes, we also provide descriptive statistics on the unweighted pass rate, TRPASSR_1, also computed in the appendix.

To estimate the two functions using actual spending and test performance data, additional controls must be introduced (see Duncombe and Yinger, 2005). Many of the hypothesized determinants of comparative cost per pupil (CC_TOT) and test results (TPASSR_2) overlap. The question is what socioeconomic and other control variables are expected to be uniquely related to the cost and test outcomes. The independent variables included in our models are discussed next.

Our first predictor variable used in the cost function is the geographic cost of living index (GEOCEI), calculated by the State of New Jersey from the US Census data. Chalos (1997) found that the proportion of school district budgets financed by local property taxes was related to greater inefficiencies (greater costs). We include the variable NON_LOCAL, defined as the amount of school district revenues funded from non-local sources (local sources of funds include property tax revenues and direct payments by the local municipal government). Dopuch and Gupta (1997) found average family income to be positively related to total school district expenditures. Thus, we include two socio-economic variables in the cost function: (1) average household family income (Lg_FAMY), and (2) percentage of the population in the school district with some college education (SOM_COLL).

Because the dependent variable for school expenditures, CC_TOT, is on a per-pupil basis, we include the total number of students enrolled in the school district (Lg_ENROLL) to capture possible economies of scale in the production of teaching. However, if the number of students exceeds a threshold, then diseconomies of scale may set in. To allow for the possibility of an inflection point, the square of enroll (Lg_ENROLL*SQR) is also included in the model (Green 1980). Since special education programs can substantially increase the costs of education, we include percentage of students in the school district classified as Special Education as an independent variable (SP_ED). Finally, we include four demographic variables to capture cross- sectional differences in the costs of education. These variables are the percentage of the population that is male (TMALE_PCT), Black (TBLCK_PCT), Asian (TASIA_PCT), and Hispanics (THSPC_PCT), respectively.

Turning to the test score model, the primary driver of student achievement is socio-economic background (Jaggia and Kelly-Hawke, 1999). Thus, we include four socio-economic variables in the test scores equation. These variables are the same two variables included in the cost function (Lg_FAMY and SOM_COLL), plus (3) proportion of the population who did not graduate from high school (NO_HS); and (4) the average occupational status of the population (OCCP_ST) (Nakao and Treas 1994). It should be noted that because of the prior lack of findings on the school inputs-test score relation, our model omits some of the common school input variables (e.g., average teacher salaries), which are often a function of the NJEAs (New Jersey Education Associations) collective bargaining process.

Mensah, Schoderbek, and Sahay (2013) find that the percentage of school district revenues raised from local property taxes was positively related to test score performance. Thus the variable NON_LOCAL is included as an explanatory variable in the test scores equation. Heineson (2005) finds that students from larger school districts had a significantly higher probability of attaining a secondary education, so we include two variables (Lg_ENROLL and Lg_ENROLL*SQR) to control for possible school size effects. The variable SP_ED is included in the model due to the predicted lower test scores for special education students. Student mobility has been found to have a negative effect on test scores in prior studies (e.g., Hanushek, Kain and Rivkin 2004), while student attendance has been shown to have positive effects (Parke and Kanyongo 2012; Mensah, Schoderbek, and Werner 2009). Thus, both the student mobility rate (STUMOB) and student attendance rate (ATTDR) are included in our model. The ACT Profile report for the State of New Jersey shows significant variation in average composite ACT scores by race/ethnicity (ACT Profile – NJ, 2012). Thus our four demographic variables TMALE_PCT, TBLCK_PCT, TASIA_PCT, and THSPC_PCT, are included in the model to capture cross-sectional differences in test scores from demographics.

We have an additional socio-economic variable (Abbott) that pertains to the TYPE3 districts (Kindergarten to Grade 12) only. ABBOTT, is a dummy variable that equals one if the school district is included among the State's 31 Abbott School districts (all K-12 school districts), else zero. Abbott districts have been identified by the New Jersey Supreme Court (or later legislative processes) as school districts with "low student achievement and concentrated poverty" (Librera 2005). Due to the educational disparities in Abbott Districts, the State provides "Abbott parity aid" that puts their per-pupil expenditures on par with the wealthiest school districts in the State. Because the Abbott remedy effects total costs, ABBOTT is included in the cost function. And since the Abbott designation is based on low student achievement, this variable is also included in the test score model.

The functional form of our two regressions is specified in equations (4) and (5) below:

$$\begin{aligned} LG\_CCTOT_i = \alpha_{10} &+ (\alpha_{11} * YR03) + (\alpha_{12} * YR04) + (\alpha_{13} * YR05) + (\alpha_{14} * YR06) \\ &+ (\alpha_{15} * YR07) + (\alpha_{16} * YR08) + (\alpha_{17} * YR09) + (\alpha_{18} * YR10) \\ &+ (\alpha_{19} * YR11) + (\beta_{11} * GEOCEI_i) + (\beta_{12} * NON\_LOCAL_i) \\ &+ (\beta_{13} * Lg\_FAMY_i) + (\beta_{14} * SOM\_COLL_i) + (\omega_{11} * lg\_ENROLL_i) \\ &+ (\omega_{12} * lg\_ENROLL*SQR_i) + (\omega_{13} * SP\_ED_i) + (\gamma_{11} * TMALE\_PCT_i) \\ &+ (\gamma_{12} * TBLCK\_PCT_i) + (\gamma_{13} * TASIA\_PCT_i) + (\gamma_{14} * THSPC\_PCT_i) \\ &+ (\gamma_{15} * ABBOTT_i) + (\lambda_{11} * TPASSR\_2_i) + e_{1i} \end{aligned} \tag{4}$$

$$\begin{aligned} TPASSR\_2_i = \alpha_{20} &+ (\alpha_{21} * YR03) + (\alpha_{22} * YR04) + (\alpha_{23} * YR05) + (\alpha_{24} * YR06) \\ &+ (\alpha_{25} * YR07) + (\alpha_{26} * YR08) + (\alpha_{27} * YR09) + (\alpha_{28} * YR10) \\ &+ (\alpha_{29} * YR11) + (\beta_{22} * NON\_LOCAL_i) + (\beta_{23} * Lg\_FAMY_i) \\ &+ (\beta_{24} * SOM\_COLL_i) + (\beta_{25} * NO\_HS_i) + (\beta_{26} * OCCP\_ST_i) \\ &+ (\omega_{21} * lg\_ENROLL_i) + (\omega_{22} * lg\_ENROLL*SQR_i) + (\omega_{23} * SP\_ED_i) \\ &+ (\omega_{24} * STMOB_i) + (\omega_{25} * ATTDR_i) + (\gamma_{21} * TMALE\_PCT_i) \\ &+ (\gamma_{22} * TBLCK\_PCT_i) + (\gamma_{23} * TASIA\_PCT_i) + (\gamma_{24} * THSPC\_PCT_i) \\ &+ (\gamma_{25} * ABBOTT_i) + (\lambda_{21} * LG\_CCTOT_i) + e_{2i} \end{aligned} \tag{5}$$

These models are estimated using the deterministic frontier function approach (Greene, 1980) to derive the cost efficiency and test outcome effectiveness measures. This approach is discussed in the next section.

Empirical Models Estimated

The EFFCY scores were obtained by running the equivalent of Equation (4) for each year and type of school district. As noted by Greene (1980), the regression estimates of the coefficients are unbiased frontier estimates except for the intercepts. By displacing the intercept term in Equation (4) until one of the residuals is zero and the rest are positive, the resulting cost frontier function can be used to derive the EFFCY ratings of individual school districts by taking the ratio of the predicted frontier cost to the actual cost. The resulting values range from 100 percent (for the most cost efficient) to values below 100. Similarly, the EFTV ratings are derived from Equation (5) by shifting the intercept until one of the residuals is zero and the rest are negative. The resulting deterministic test outcome frontier function provides an estimate of the predicted outcomes based on the explanatory variables, and the ratio of actual output to predicted output thus yields the EFTV rating of the individual school districts.

Once the EFFCY and EFTV ratings are derived for each year and school district type, the final set of regressions can be undertaken as follows:

$$\begin{aligned} EFFCY_{it} = \alpha_{10} &+ (\alpha_{11} * TYPE1_i) + (\alpha_{12} * TYPE2_i) + (\alpha_{14} * TYPE4_i) + (\alpha_{15} * TYPE5_i) \\ &+ (\gamma_{12} * EFFCY_{it-1}) + (\gamma_{13} * EFTV_{it}) + (\gamma_{14} * EFTV_{it-1}) \\ &+ (\lambda_{11} * NO\_VOTE_{it}) + (\lambda_{12} * NO\_VOTE_{it-1}) + (\phi_{11} * GEOCEI_i) \\ &+ (\phi_{12} * Lg\_CCTOT_{it}) + e_{1i} \end{aligned} \quad (6)$$

$$\begin{aligned} EFTV_{it} = \alpha_{20} &+ (\alpha_{21} * TYPE1_i) + (\alpha_{22} * TYPE2_i) + (\alpha_{24} * TYPE4_i) + (\alpha_{25} * TYPE5_i) \\ &+ (\gamma_{21} * EFFCY_{it}) + (\gamma_{22} * EFFCY_{it-1}) + (\gamma_{24} * EFTV_{it-1}) \\ &+ (\lambda_{21} * NO\_VOTE_{it}) + (\lambda_{22} * NO\_VOTE_{it-1}) + (\phi_{21} * Lg\_FAMY_i) \\ &+ (\phi_{22} * SOM\_COLL_i) + (\phi_{23} * OCCP\_ST_i) + (\phi_{24} * STMOB_i) \\ &+ (\phi_{25} * ATTDR_i) + e_{2i} \end{aligned} \quad (7)$$

$$\begin{aligned} NO\_VOTE_{it} = \alpha_{30} &+ (\alpha_{31} * TYPE1_i) + (\alpha_{32} * TYPE2_i) + (\alpha_{34} * TYPE4_i) + (\alpha_{35} * TYPE5_i) \\ &+ (\gamma_{32} * EFFCY_{it-1}) + (\gamma_{34} * EFTV_{it-1}) + (\lambda_{32} * NO\_VOTE_{it-1}) \\ &+ (\phi_{31} * OCCP\_ST_i) + (\phi_{32} * Lg\_CCTOT_{it}) + (\phi_{33} * \Delta Lg\_CCTOT_{it}) \\ &+ (\phi_{34} * \Delta LOCAL_{it}) + e_{3i} \end{aligned} \quad (8)$$

where

NO_VOTE_t	=	Dummy variable denoting voting outcome on the school district's budget was negative for year t.
$\Delta LOCAL_t$	=	Change in the percentage of the school district spending from local sources.
ΔLg_CCTOT_t	=	$Lg\_CCTOT_t - Lg\_CCTOT_{t-1.}$

Equations (6) to (8) estimate the Granger causality relationships between EFCY, EFTV and NO_VOTE after controlling for other factors that are hypothesized to be related to the endogenous variables. GEOCIE is hypothesized to be related to cross-sectional differences in EFFCY partly because the index may be an imperfect measure of the systematic variation of the cost of living in the different areas. Similarly, Lg_FAMY, SOM_COLL, and OCCP_ST, although they are controlled for in the initial estimation of EFTV, are hypothesized to have some residual effects on EFTV but not on EFFCY. OCCP_ST is hypothesized to affect the likelihood of the NO_VOTE but not EFFCY. Finally, based on the findings from the literature, both the levels of spending (Lg_CCTOT) and the change in spending (ΔLg_CCTOT_{it}) are hypothesized to influence voting outcomes. In addition, the change in the level of funding from local sources has been found in the prior literature to influence voting outcomes (NYSDE, 2005), so it is included here as a control variable.

4. Results of analyses

Descriptive Statistics

The data for the study were compiled from databases posted on the Department of Education website for years 2003-2012. Because the data exhibits similarity for each year, summary statistics for 2006 are presented in Table 1 as a representative sample of the data range for each type of school district.

Insert Table 1 here

Panels A to E of Table 1 present the summary statistics for the K-4, K-8, K-12, Grades 5-12 and 9-12 school districts, respectively. A cursory look at the details shows that in terms of the average household family income (FAMY), K-8 school districts tended to be the wealthiest districts with median household income of $82,088, followed by high school districts (Grades 9-12) with median household income of $80,360. In contrast, the K-12 school districts tended to the districts with the lowest average household income (median of $67,414), although this group also contained the district with the highest average family income ($158,888).

In terms of comparative per-pupil spending, the Grades 9 to 12 school districts have the highest median (9.43 in natural log terms). The groups with the lowest (not surprisingly) spending were the K-4 and the K-8 districts (medians of 9.25 and 9.27 respectively). At the same time, the average overall unweighted pass rate (TPASSR_1) on the relevant exams ranged from 82.32 percent for the K-12 school districts (in terms of median) to 90.90 percent for the Grade 9- 12 school districts. For illustrative purposes, we also include summary statistics for percentage pass rates (both "Regular Pass" and "Advanced Pass") on the Grade 4 NJ ASK4 tests, Grade 8 GEPA tests, and Grades 11-12 HSPA tests. As discussed in section 3.2, these pass rates are used to construct our weighted pass rate variable used in the estimation of Equations (4) and (5). Summary statistics for this variable, TPASS_2, are also shown in table 1. Because an "Advanced Pass" is weighted twice a "Regular Pass", values of TPASS_2 may exceed 100.0%.

Among the control variables, a result of interest is the percentage of total operating expenditures funded by sources other than local property taxes (NON_LOCAL) whose median value ranged from 21.5 percent for K-8 school districts to 42.5 percent for Grades 5 to 12 school districts. The maximum value for NON_LOCAL was 98.0 percent for the K-12 school districts, which includes the Abbott Districts.

Results of Estimation of the Cost Function

Equations (4) and (5) were estimated with lg_CCTOT and TPASSR_2 as the jointly endogenous variables. To evaluate whether OLS would have been appropriate without the need for joint estimation, Hausman specification tests were performed comparing OLS, 2SLS, and 3SLS. The results of these Hausman tests are disclosed in Table 2 for each type of school district- Kindergarten to Grade 4 (panel A), Kindergarten to Grade 8 (Panel B), Kindergarten to Grade 12 (Panel C), Grades 5-12 (Panel D) and Grades 9-12 (Panel E). In Panels A-C, 2SLS was found to be more consistent than either OLS or 3SLS. In order to be parsimonious, only the 2SLS results are reported.

Insert Table 2 here

To deal with heteroscedasticity, the standard errors and related t-values reported are derived using White's heteroscedasticity-consistent covariance matrix. Table 3 presents the results obtained using lg_CCTOT as the dependent variable, and Table 4 presents those with TPASSR_2 as the jointly-dependent variable.

Insert Table 3 here

The results in Table 3 are presented separately for each type of school district in panels A-E, respectively - K-4 (Type 1 districts), K-8 (Type 2 districts), K-12 (Type 3 districts), Grades 5 to 12 (Type 4 districts), and High School (Grades 9 to 12 – Type 5 districts). Since interest at this point is mostly in the signs and statistical significance of the coefficients, we present below a summary of this findings:

COS0T FUNCTION COEFFICIENTS

Variables	School District Type				
	Type 1 K-4	Type 2 K-8	Type 3 K-12	Type 4 G5-8	Type 5 G9-12
GEOCIE	+	+	+	+	+
NON_LOCAL	–	–	ns	+	–
FAMY	–	+	–	ns	–
SOM_COL	+	ns	+	–	ns
ENROLL	–	–	–	–	ns
ENROLL*SQR	+	+	+	+	ns
SP_ED	–	+	+	–	+
TMALE_ PCT	ns	+	ns	ns	ns
TBLK_ PCT	ns	ns	+	–	+
TASIA_ PCT	–	ns	ns	–	–
THSPC_PCT	ns	–	+	+	ns
ABBOTT			+		
TPASSR_2	–	–	+	+	+

As shown above, the Geographic Cost of Educational Index (GEOCIE) as calculated by the state is consistently significant and positive in all the school district types. This finding supports the inference that intra-state differences in the cost of living accounts for some of the cross- sectional differences in the average spending per pupil. In contrast, NON_LOCAL (the proportion of spending from non-local sources) has a negative coefficient only for Types 1, 2, and 5.[12] It is not significant for Type 3 school districts, and has a positive coefficient for Type 4 districts. Thus, it appears that local funding is associated with higher spending for autonomous elementary, middle school, and High School districts, but has no independent effect on the more common K-12 school districts.

Two socio-economic factors that are traditionally linked to higher student test score performance show mixed results in the estimated cost functions. Lg_FAMY (natural log of family income) is positively associated with higher per-pupil spending in the Type 2 school districts, negatively associated for the Types 1, 3 and 5 school districts, and is not significant in the Type 4 school districts. These results suggest that higher family incomes are associated with higher per pupil spending only in school districts catering to the youngest public school

[12] This result is consistent with the findings from Chalos (1997), who reports a positive relation between the proportion of school district budgets financed by local property taxes and costs.

children. In contrast, in school districts focused on older kids, higher family income is associated with less per-pupil spending. Conceivably, older kids from affluent families may depend less on the resources of the school district and more on parental resources, thus reducing the need for higher relative spending by the school district. Similarly, the proportion of the population in the school district with at least some college education (SOM_COLL) is positively associated with higher per-pupil spending in Type 1 and Type 3 school districts, negatively associated for Type 4 districts, and not significantly related to per-pupil spending in Type 2 and Type 5 districts.

With regard to the existence of possible economies and diseconomies of scale, the results are much more consistent. For all school district types except Type 5, there exists a U-shaped curve (negative coefficient for lg_ENROLL and a positive coefficient for lg_ENROLL*SQR) which suggests the existence of an optimal enrollment size within the range of observed school sizes for all school types. The sole exception of the High School districts (Type 5) suggests that enrollment size does not play a role in explaining cross-sectional differences in per-pupil spending there.

The demographic characteristics of the student population of the school districts have mixed effects on differences in per-pupil spending. The percentage of Males (MALE_PCT) is not significant in any school district type except for Type 2 where the coefficient is positive. The percentage of Blacks (TBLK_PCT) is not significant for Type 1 and 2, positive for Types 3 and 5, and negative for Type 4. The percentage of Asian (TASIA_PCT) is not significant for Types 2 and 3, and negative for Types 1, 4, and 5. Finally, for the percentage of Hispanics (THSPC_PCT), the coefficient(s) are not significant for Types 1 and 5, negative for Type 2, and positive for Types 3 and 4. Overall, the inconsistent signs make drawing any broad inferences difficult, except for ASIA_PCT where lower spending appears to be dominant. Consistent with prior expectations, the ABBOTT districts among the Type 3 districts have higher average per- pupil spending.

Finally, with regard to the potential effect of higher test score achievement on per-pupil spending, the evidence is mixed. School districts with higher test scores spend lower on a per-pupil basis in Type 1 and Type 2 school districts, but higher amounts in Types 3, 4, and 5 districts. The best interpretation of this finding is that, for school districts focused on educating younger children, higher test score achievement does not drive higher spending, whereas for the older students, the best performing schools do spend more. Creative educational approaches can lead to superior performance which can lead to reductions in per-pupil spending at the lower grade levels. At the upper grade levels, higher achievement does lead to additional spending.

Results of Estimation of the Test Outcome Function

As noted previously, Equations (4) and (5) were estimated simultaneously in order to control for possible simultaneity bias which was confirmed by the Hausman specification tests. Since the Hausman test also indicated that the 2SLS statistical technique results in the most consistent results (compared to OLS and 3SLS), the results of estimating the test outcome function are presented in Table 3 only for the 2SLS model.

Insert Table 4 here

To facilitate the discussions which follow, and also because our primary interest is in the signs of the coefficients of the explanatory variables (and their significance) at this stage, we present below a summary:

TEST OUTCOME FUNCTION COEFFICIENTS

Variables	School District Type				
	Type 1 K-4	Type 2 K-8	Type 3 K-12	Type 4 G5-8	Type 5 G9-12
NON_LOCAL	Ns	ns	ns	ns	-
FAMY	Ns	+	+	ns	+
SOM_COL	Ns	+	+	-	+
NO_HS	Ns	ns	+	-	-
OCCP_ST	Ns	+	ns	ns	ns
ENROLL	-	+	+	ns	+
ENROLL*SQR	+	-	-	ns	-
SP_ED	-	-	-	-	ns
STMOB	-	-	-	ns	-
ATTDR	Ns	+	+	+	+
TMALE_ PCT	Ns	ns	ns	ns	ns
TBLK_ PCT	Ns	-	-	ns	-
TASIA_ PCT	Ns	+	+	ns	+
THSPC_PCT	Ns	-	-	ns	-
ABBOTT			-		
CC_TOT	Ns	ns	ns	ns	-

To analyze the observed results, we focus on identifying the factors that explain the observed cross-sectional differences in test score performance by school district type. For Type 1 school districts, the only significant explanatory variables are the returns to scale (lg_ENROLL and lg_ENROLL*SQR), Special Education (SP_ED), and student mobility (STU_MOB).

Somewhat surprisingly, the returns to scale function observed here is U-shaped, implying that test scores of the smallest districts decline initially as the school district size increases, but subsequently rise as the district size increases. Not surprisingly, increases in SP_ED students exact a toll on average test score performance, as does increases in student mobility (STU_MOB).

For Type 2 school districts, Lg_FAMY, SOM_COL, occupational status (OCCP_ST), and attendance rates (ATTDR) are all positive influences on test score performance. On the other hand, STU_MOB and SP_ED are both negative influences on performance. Among the student demographic characteristics, BLK_PCT and HSPC_PCT are negative factors in explaining performance while ASIA_PCT has a positive effect. The effect of enrollment size on performance is the opposite of what was observed for the Type 1 school districts. Here, lg_ENROLL has a positive sign while its square has a negative sign, implying an inverted U-shape. Thus, the best performance in terms of test scores is observed among the medium–sized school districts and not at either extreme. It may be that as school enrollments increase, test scores for the smallest schools increase as schools take advantage of economies of scale in the production of education; but then test scores decrease after an inflection point on enrollments occurs. Per-pupil spending has no effect on test score performance in this type of school district or any other besides Type 5.

The results for the Type 3 school districts are very similar to those found in the Type 2 districts. The main differences are that OCCP_ST is not significant, and NO_HS (the percentage of households with no high school education) is now significant (but with an unexpected positive sign). The additional socio-economic variable, ABBOTT, is significant with its predicted negative sign.

Summarizing the Type 4 and Type 5 results, the variable NO_HS is now significant with its predicted negative sign in both regressions. In the Type 5 districts (Grades 9-12), Lg_ENROLL and Lg_ENROLL*SQR exhibit the same pattern as in the Type 2 and Type 3 districts, but neither variable is significant in the Type 4 districts. Likewise, three of the demographic variables (TBLK_ PCT, TASIA_ PCT and THSPC_PCT) are significant in the Type 5 districts and show the same signs as in the Type 2 and Type 3 districts, but are not significant in the Type 4 districts.

The Type 5 districts also show some results not found in the other districts. First, the variable NON_LOCAL (Proportion of school district funding from non-local sources) is significant with a negative sign, suggesting that as funding from nonlocal sources increase, achievement decreases. Also, the jointly dependent variable Lg_CCTOT is also negative, which is indicative of the mixed findings in the literature on the spending-test outcome relation.

Across all the school district types, the variables that show the most consistent positive signs are Lg_FAMY, SOM_COL, ENROLL, ATTDR, and ASIA_PCT. At the opposite end, the variables with predominantly negative coefficients are ENROLL*SQR, SP_ED, STMOB, BLK_PCT, and HSPC_PCT. All the other variables are either inconsistent across different school district types, or are predominantly not statistically significant.

Overview of Cost Efficiency and Test Outcome Effectiveness Measures

The results of applying the deterministic frontier estimation technique on a year-by-year basis to Equations (4) and (5) using the 2SLS approach are presented in Table 5A for the cost function, and 5B for the test outcome function.

Insert Tables 5A and 5B here

To facilitate the discussion, a summary of the means across the 11 years of the estimated minimum, median and maximum efficiencies by school district type are presented below:

COST EFFICIENCY MEASURES

School District Type	Min	Median	Max
Type 1: K- Grade 4	47.5%	70.4%	100.0%
Type 2: K- Grade 8	55.6%	73.7%	100.0%
Type 3: K- Grade 12	52.1%	77.4%	100.0%
Type 4: Grades 5-8	80.9%	90.2%	100.0%
Type 5: Grades 9-12	75.7%	85.9%	100.0%

OUTCOME EFFECTIVENESS MEASURES

School District Type	Min	Median	Max
Type 1: K- Grade 4	52.4%	75.7%	100.0%
Type 2: K- Grade 8	56.8%	80.4%	100.0%
Type 3: K- Grade 12	52.9%	83.0%	100.0%
Type 4: Grades 5-8	91.0%	95.1%	100.0%
Type 5: Grades 9-12	84.3%	92.6%	100.0%

As can be seen in this summary, with respect to the cost efficiency (EFFCY) measures, Type 4 school districts show the least amount of dispersion, with the minimum at 80.9 percent and the median at 90.2 percent. Note that the maximum is 100 percent by construction. At the other extreme, Type 1 school districts show the widest dispersion, with the range from a minimum of 47.5 percent and the median at 70.4 percent. This is followed by the Type 3 school districts (the most common type of school district – the K-12 districts) with a range from a minimum of 52.1 percent and a median of 77.4 percent.

A similar result is observed for the test outcome effectiveness measures. The Type 4 districts show the narrowest range from 91.0 percent minimum to a median of 95.1 percent and the maximum of 100 percent. Types 1 and 3 districts are at the other extreme, with respective minimums of 52.4 and 52.9 percent, and respective medians of 75.7 and 83.0 percent. Type 5 districts are closer to the Type 4 districts, with the average minimum effectiveness ratings of 84.3 percent and median of 92.6 percent. Type 2 school districts are intermediate between the Type 1 and Type 3 school districts in average effectiveness dispersion, with the minimum at 52.9 percent and the median at 80.4 percent.

The consistency in the relative rankings of the school district types with respect to cost efficiency measures and test outcome effectiveness measures might suggest some degree of correlation between the two measures. However, the simultaneous derivation of the two measures allow for their separate effects to be isolated, so it is not self-evident that they are necessarily highly correlated. To evaluate this empirically, the Pearson rank order correlations between the two measures by district type were computed. Below are the results:

School District Type	ρ (EFTV, EFFCY)
Type 1: K- Grade 4	-0.1777
Type 2: K- Grade 8	-0.3375
Type 3: K- Grade 12	0.0468
Type 4: Grades 5-8	-0.1261
Type 5: Grades 9-12	0.0150

The results above show a surprising degree of variations by school district type. The negative (and statistically significant) correlations between EFFCY and EFTV observed for Type 1, Type 2, and Type 4 school districts are in stark contrast to the positive but statistically insignificant correlations for the Type 3 and Type 5 districts. These results clearly do not support the presumption that school districts can be both efficient and effective. Clearly, some trade-off between these measures is the norm. The difficulty in defining the most effective actions that district administrators can take to improve both simultaneously is demonstrated by the fact that it appears that few if any school districts can achieve both.

Granger Causality Test of Relationships between EFFCY, EFTV, and Voting Results

Equations (6) to (8) were estimated using a Granger causality test approach to determine the direction of presumed causality between EFFCY, EFTV, and the voting results (measured as NO-VOTE). In order to determine the most appropriate estimation technique, the Hausman test was conducted to choose between OLS, 2SLS, and 3SLS. As disclosed in Panel B of Table 6, the results support the 2SLS technique as being most consistent. For comparability, the results of the OLS and 2SLS are reported in full, along with those obtained using the Generalized Method of Moments (GMM). The results of estimating the three equations are reported in Tables 6, 7, and 8.

Insert Tables 6, 7, and 8 here

2SLS Estimation Summary Results			
Current Year & Lagged Jointly Endogenous Variables	Current Year Variables		
	$EFFCY_{(t)}$	$EFTV_{(t)}$	$No\_Vote_{(t)}$
$EFFCY_{(t)}$	n/a	+	n/a
$EFFCY_{(t-1)}$	+	–	ns
$EFTV_{(t)}$	ns	n/a	n/a
$EFTV_{(t-1)}$	–	+	ns
$No\_Vote_{(t)}$	–	+	n/a
$No\_Vote_{(t-1)}$	ns	–	+

Key: + = Significant positive relationship.
– = Significant negative relationship.
ns = not significant.
n/a = not applicable.

Because Granger Causality tests rely on the relationships between the lagged variables of the jointly endogenous variables with their current counterparts, the results in these three tables are best evaluated by examining the summary findings below extracted from the three tables.

The 2SLS results in table 6 show that the lagged effectiveness rating ($EFTV_{(t-1)}$) is significantly related to the current year's efficiency rating ($EFFCY_{(t)}$). Likewise, table 7 shows that the lagged efficiency rating ($EFFCY_{(t-1)}$) is significantly related to the current year's effectiveness rating ($EFTV_{(t)}$). Both relationships have negative signs, suggesting a negative feedback loop where higher test scores in one period are followed in the subsequent year by more spending, and cost-cutting in one year has an adverse effect on test scores in the following year.

However, in terms of the contemporaneous relationship, $EFTV_{(t)}$ is not significantly related to $EFFCY_{(t)}$ when other factors are controlled for. In contrast, $EFFCY_{(t)}$ is a positive explanatory variable for $EFTV_{(t)}$, thus suggesting that the direction of influence or causality is from greater efficiency to greater effectiveness. In other words, more cost-efficient school districts also tend to be more test outcome-effective.

The relationship between $EFFCY_{(t)}$ and $No\_Vote_{(t)}$ is rather more complicated. Since the voting takes place in April and the budget for the school district takes effect from July of that calendar year, $EFFCY_{(t)}$ is observed well after the $No\_Vote_{(t)}$**.** Thus, while $No\_Vote_{(t)}$ can be a predictor of $EFFCY_{(t)}$, the converse is not valid. But taxpayers may condition their vote in April on the observed school district budget for which school ballot takes place (denoted here as $EFFCY_{(t-1)}$). The results thus show that $No\_Vote_{(t)}$ is significantly related to $EFFCY_{(t)}$, whereas the vote results from the previous year have no effect on $EFFCY_{(t)}$. At the same time, the observed cost efficiency in the school year in which the vote takes place ($year_{(t-1)}$) has no statistically significant effect on the voting outcome. Thus, taxpayers are not influenced in their voting by the contemporarily-observed relative cost efficiency of the school district. On the other hand, negative voting outcomes are based on the anticipated cost inefficiency included in the observed budget. Unfortunately, the corrective actions taken are not effective in curing the anticipated cost inefficiency.

Finally, the relationship between $EFTV_{(t)}$ and $No\_Vote_{(t)}$ is examined. $No\_Vote_{(t)}$ is positively related to $EFTV_{(t)}$ while $No\_Vote_{(t-1)}$ has a negative coefficient relative to $EFTV_{(t)}$. At the same time, $EFTV_{(t-1)}$ has no statistically significant relationship to $No\_Vote_{(t)}$. Taken together, these results suggest an interesting interplay where the current period's No_Vote (taken in April) appears able to motivate the school districts to improve test score performance in the year starting in July and ending in June of the following calendar year. However, the curative effect of the No_Vote appears to be short-lived since there is a partial reversal of the improvement in the test outcome effectiveness in the school year commending in the following calendar year (as noted from the negative coefficient for $No\_Vote_{(t-1)}$). In Table 7 (under 2SLS), the coefficients for $No\_Vote_{(t)}$ is 0.124 and that for $No\_Vote_{(t-1)}$ is -0.036. Thus, the contemporaneous positive effect of the negative vote is about three times that of the subsequent reversal that occurs the following calendar year. These results indicate that the improvements in test score performance remain positive on a cumulative basis.

5. Summary and conclusions

We set out in this study to examine whether balloting on school district budgets serve a useful social function. Presumably, negative votes may signal taxpayers' unhappiness with the proposed budget or dissatisfaction with expected student performance relative to proposed spending. Alternatively, it could be argued that the low voter turnout in school budget elections signals lack of interest on the part of taxpayers, and that those who vote are not fully informed about the potential benefits of the proposed budget.

Our results shows that, contrary to what may be a widespread impression, taxpayer balloting has a very salutary effect on school districts. Negative ballot outcomes have a net positive effect on improving test outcome effectiveness. The effect on cost efficiency is more limited. While taxpayers vote down a budget due to perceived cost inefficiencies, remedial action on the part of administrators is ineffective in curing these inefficiencies. Overall, the results show that actions or proposals to remove taxpayer oversight of local school district budgets are misguided because they will remove an important element of public accountability.

TABLE 2
Estimating the Cost and Production Function as a System of Simultaneous Equations: Hausman's Specification Test Results [1,2]

Panel A: Kindergarten to Grade 4 School Districts

Efficient under HO	Consistent under H1	DF	m-statistic	P < Chi-Square
OLS	2SLS	45	14.6	1.0000
OLS	3SLS	47	133.2	0.0001
3SLS	2SLS	47	-153.0	.

Interpretation: 2SLS is the preferred model

Panel B: Kindergarten to Grade 8 School Districts

Efficient under HO	Consistent under H1	DF	m-statistic	P < Chi-Square
OLS	2SLS	45	17.6	0.9999
OLS	3SLS	47	182.0	0.0001
3SLS	2SLS	47	-253.0	.

Interpretation: 2SLS is the preferred model

Panel C: Kindergarten to Grade 12 School Districts

Efficient under HO	Consistent under H1	DF	m-statistic	P < Chi-Square
OLS	2SLS	43	17.15	0.9999
OLS	3SLS	47	-37.2	.
3SLS	2SLS	49	-154.0	.

Interpretation: 2SLS is the preferred model

Panel D: Grades 5-12 School Districts

Efficient under HO	Consistent under H1	DF	m-statistic	P < Chi-Square
OLS	2SLS	44	-131.0	.
OLS	3SLS	46	256.3	0.0001
3SLS	2SLS	46	37.7	0.8033

Interpretation: 3SLS is the preferred model

Panel E: Grades 9-12 School Districts

Efficient under HO	Consistent under H1	DF	m-statistic	P < Chi-Square
OLS	2SLS	46	16.91	1.0000
OLS	3SLS	47	75.09	0.0057
3SLS	2SLS	47	2865	0.0001

Interpretation: 3SLS is the preferred model

[1] Table 2 reports the results of Hausman specification tests comparing OLS, 2SLS, and 3SLS in the joint estimation of Equations
(4) and (5), by each type of school district, with lg_CCTOT and TPASSR_2 as the jointly endogenous variables.
[2] All variables are defined in the Appendix.

APPENDIX
List of Variables Used in the Study

Variable		Definition
Lg_CCTOT	=	Comparative cost per pupil (expressed in natural logarithm).
ΔLg_CCTOT$_t$	=	Lg_CCTOT$_t$ - Lg_CCTOT$_{t-1.}$
TPASSR_1	=	Total unweighted pass rate, computed as follows: [Σ [TEST_P$_k$ + TEST_AP$_k$)]] /[Σ NTEST$_k$], where k = Grades 4, 7, and 12 standardized tests.
TPASSR_2	=	Weighted total pass rate, computed as follows: [Σ [TEST_P$_k$ + (2.0 * TEST_AP$_k$)]] /[Σ NTEST$_k$], where k = Grades 4, 7, and 12 standardized tests.
TEST_P$_k$	=	"Regular" pass rate on TEST$_k$ weighted by number of students who took the test.
TEST_AP$_k$	=	"Advanced Pass" rate on TEST$_k$ weighted by number of students who took the test.
NTEST$_k$	=	Number of students who took TEST k.
GEOCEI	=	Geographic cost of education index.
NON_LOCAL	=	Proportion of school district funding from non-local sources.
ΔLOCAL$_t$	=	Change in the percentage of the school district spending from local sources.
Lg_ENROLL	=	Total student enrollment (expressed in natural logarithm).
Lg_ENROLL*SQR	=	Square of the natural logarithm of student enrollment.
STMOB	=	Student mobility rate.
ATTDR	=	Student attendance rate.
SP_ED	=	Proportion of the students classified as "special education."
Lg_FAMY	=	Average household family income (expressed in natural logarithm).
SOM_COLL	=	Proportion of the school district's population with some college education.
NO_HS	=	Proportion of the school district's population without a high school degree.
OCCP_ST	=	Average occupancy status of the school district.
TMALE_PCT	=	Total proportion of Male students taking the tests.
TBLCK_PCT	=	Total proportion of Black students taking the tests.
TASIA_PCT	=	Total proportion of Asian students taking the tests.
THSPC_PCT	=	Total proportion of Hispanic students taking the tests.
EPASS_1	=	Percentage of students with "Regular Pass" on the Grade 4 NJ ASK4 tests.
EPASS_2	=	Percentage of students with "Advanced Pass" on the Grade 4 NJ ASK4 tests.
GPASS_1	=	Percentage of students with "Regular Pass" on the Grade 8 GEPA tests.
GPASS_2	=	Percentage of students with "Advanced Pass" on the Grade 8 GEPA tests.
HPASS_1	=	Percentage of students with "Regular Pass" on the Grades 11-12 HSPA tests.
HPASS_2	=	Percentage of students with "Advanced Pass" on the Grades 11-12 HSPA tests.
ABBOTT	=	Dummy variable for K-12 school districts classified as "ABBOTT" districts.
EFFCY	=	Cost Efficiency score derived from estimation of Equation (4).
EFTV	=	Test outcome effectiveness score derived from estimation of Equation (5).
NO_VOTE	=	Dummy variable that equals one if the voting outcome on the school district's budget was negative, else zero.

The 23rd Annual Conference on Pacific Basin Finance, Economics, Accounting, and Management (2015)

□ □ □ □ □ □ Characteristics of Conflicts of Interest in Stock Recommendations

This paper studies characteristics of conflicts of interest in stock recommendations, and finds that analyst recommendations have an impact on recommended stocks, and that this phenomenon occurs for both traditional and revise recommendations. Moreover, the negative recommendations have a much greater impact than positive recommendations on stock returns. Findings suggest that high performance analysts are more concerned with enhancing their reputations and tend to not expose themselves to conflicts of interest when making upgrade recommendations. Furthermore, the results also suggest that concentrated ownership of individual stocks corresponds with a reduction in conflicts of interest.

Keywords: Conflict of interest; recommendation; concentrated ownership; event study.

1. Introduction

The sell-side security analyst plays the important role as a stock market information intermediary. A review of the relevant literature shows that analyst recommendations have short-term investment value (Womack, 1996; Barber et al. 2001; Jegadeesh et al. 2004). While the impact of security analyst skill and recommendations investment value is widely understood, such analysts, along with their reports and employers are subject to conflicts of interest.

Conflicts of interest exist because security analysts are dependent on investment banks or brokerage houses, which will seek to increase their revenue through accessing sensitive analysis information prior to public release.[1] For instance, Irvine et al. (2007) argue that analysts are incentivized to provide such information because their firms place a high value on their relationships with institutional clients, who will then act on this information to earn outsize profits. Shen and Chih (2009) demonstrated that analysts frequently allow their investment banking colleagues to buy shares ahead of the release of recommendations, and then sell for profit after the recommendations push up the share price.

Irvine et al. (2007) and Shen and Chih (2009) both focus on trading behavior in traditional recommendations, while Loh and Stulz (2011) argue that a recommendation change event has a more significant impact on stock price than traditional recommendation events. Therefore, this study examines the trading behavior of investment banks around the release of both traditional and revision recommendations. Furthermore, this paper measures the conflicts of interest for investment banks and individual stocks based on the index provided by Shen and Chih (2009). The study seeks to extend empirical research that directly links analyst recommendations and proprietary trading.[2]

This paper also examines the characteristics of conflicts of interest for investment banks. Previous studies have shown that conflicts of interest are influenced by characteristics of investment banks. However, Ljungqvist et al. (2007) argues that the analyst is often under pressure to help generate brokerage revenue. Other studies, however, also show that analyst characteristics have a differential impact on stock prices (e.g., Stickel 1992; Mikhail et al. 1997; Fang and Yasuda 2009; and Loh and Stulz 2011). Therefore, conflicts of interest for investment banks are expected to be affected not only by firm characteristics but also by analyst characteristics. This study further examines whether analyst characteristics influence conflicts of interest for investment banks.

Finally, we focus on conflicts of interest for individual stocks. Shen and Chih (2009) document conflicts of interest for individual stocks as affected by the characteristics of individual firms. Fan and Wong (2002) report that concentrated ownership may result in low earnings informativeness, implying information ambiguity on the part of the analyst, thus decreasing the likelihood of conflicts of interest on recommendations.

---

[1] Michaely and Womack (1999) document several sources of revenue for investment banks, such as raising bank loans, M&A consulting, investment advice and proprietary trading.

[2] Irvine (2004) demonstrates that sell-side analysts have greater economic incentives to bias their recommendations than their earnings forecasts.

The results show that both traditional and revise analyst recommendations have an impact on recommended stocks. Moreover, negative recommendations have a much greater impact than positive recommendations on stock returns. Investment banks are found to have conflicts of interest in upgrade events, suggesting that high-performance analysts are more concerned with enhancing their reputations and tend not to engage in conflicts of interest when making upgrade recommendation. The results also suggest that conflicts of interest can be reduced by concentrated ownership of individual stocks.

The rest of this paper is structured as follows. Section 2 presents a literature review and proposes hypotheses. Section 3 reviews the data, discusses data constructs, defines the measures used and outlines the methodology. Section 4 presents empirical results. Conclusions are presented in Section 5.

2. Literature review and hypotheses

Many recent studies have highlighted potential conflicts of interest among sell-side security analysts and investment banks. On the one hand, sell-side analyst reports tend to be overly optimistic or pessimistic for stocks with specific characteristics. For instance, Dugar and Nathan (1995) showed that analysts tend to be overly optimistic for companies that are customers of the analyst's firm.[3] Ljungqvist et al. (2007) argues that investors are not the analyst's only constituency, but also consider the interests of the firm being assessed because the analyst is often under pressure to assist in the production of brokerage revenue. On the other hand, investment banks are concerned with maintaining their client relationships. Mehran and Stulz (2007) argue that a conflict of interest could arise if a financial institution were to obtain a direct advantage, such as additional underwriting fees. Bolton et al. (2007) showed that a specialist financial institution can differentiate itself and acquire market share by providing credible information.

Recent studies have found that conflicts of interest occur in investment banks not only because of the need to service clients but also due to proprietary trading activity. Juergens and Lindsey (2009) and Shen and Chih (2009) showed direct links between analyst recommendations and proprietary trading behavior. Juergens and Lindsey (2009) show that market makers employed by the analysts' firms engage in increased trading activity prior to recommendation revisions. Shen and Chih (2009) similarly found that the analyst's firm frequently buys the same recommended stocks through its broker-dealer before the release of the recommendation and sells it after.

However, Loh and Stulz (2011) argue that recommendation change events have a more significant impact than traditional recommendation events. Dugar and Nathan (1995) argue that analysts often produce overly optimistic stock recommendations, and will only issue sell or downgrade recommendations as a result of specifically credible information. That is, negative recommendations are usually based on more substantial information content than positive recommendations. Therefore, this study expects that negative recommendations should have a stronger stock price impact than positive recommendations.

[3] Eastwood and Nutt (1999) also finds that analysts both underreact to negative information and overreact to positive information.

Hypothesis 1: *Negative recommendations have a stronger stock price impact than positive recommendations.*

The second research question is based on characteristics of conflicts of interest for investment banks. The literature shows that conflicts of interest for investment banks may be dependent on common characteristics. For instance, Shen and Chih (2009) show that the conflicts of interest of investment banks exhibit common characteristics such as the size and age of the investment bank, and the frequency with which recommendations are issued. However, this explanation focuses on the characteristics of the investment bank. Ljungqvist et al. (2007) argue that analysts are often under pressure to push brokerage revenue. Also, prior work shows that analyst characteristics lead to differential impact of stock recommendation changes. For example, Stickel (1992), Fang and Yasuda (2009) and Loh and Stulz (2011) report that recommendation changes made by star analysts have more impact and profitable. Mikhail et al. (1997) show that analysts improve the accuracy of their earnings forecasts as they accumulate experience. Thus, it is assumed here that conflicts of interest for investment banks are affected by analyst characteristics.

Hypothesis 2: *The conflicts of interest for investment banks are affected by analyst performance or experience.*

The last research question deals with characteristics of conflicts of interest for individual stocks. Previous studies show that the magnitude of conflicts of interest for individual stocks is affected by firm characteristics (Shen and Chih, 2009), such as trading volume, firm size, number of peer firms in the same industry, systematic risk and the number of shares held by insiders. However, Fan and Wong (2002) argue that the concentrated ownership is associated with low earnings informativeness as ownership concentration prevents leakage of proprietary information. The low earnings informativeness implies that analysts obtain ambiguous information from the firm, thus reducing the likelihood of conflicts of interest in the recommendations. Gomes (2000) reports that a high ownership concentration can also serve as a credible indication that the controlling owner is interested in establishing a reputation for protecting minority shareholders. Gul et al. (2010) argues ownership concentration and foreign shareholding affected information quality. It is thus expected that high ownership concentrations decrease the likelihood of conflicts of interest in analyst recommendations, and thus for individual stocks.

Hypothesis 3: *Concentrated ownership will reduce the likelihood of conflicts of interests for individual stocks.*

3. Data and methodology

3.1. *Sample construction*

Analyst recommendation data was obtained from the Institutional Brokers' Estimate System (I/B/E/S) Recommendations Detail International files from April 1995 to

October 2013. Only recommendations related to the Taiwan market were collected by sorting for Country ID, Exchange ID, Currency, and Home Market Code.

Next, trading information and other financial variables for companies making recommendations were obtained from the Taiwan Economic Journal (TEJ) database. Our sample included investment bank recommendations, but the two databases (I/B/E/S and TEJ) use different identifiers for investment banks. A Google search provided the respective identifiers, allowing for the investment bank data from the two databases to be integrated. The final sample contained a total of 631 recommended stocks and 11 investment banks trading those stocks. Each of the investment banks can evaluate a given stock one or more times, so the total number of analyst recommendations in the sample was 10,709.[4]

3.2. *Variable definitions and measures*

To examine the conflicts of interest, this study makes use of two measures proposed by Shen and Chih (2009). The first identifies the conflicts of interest for investment banks by computing the investment bank's net buy (sell) position for the recommended stocks eight weeks prior and eight weeks following the release of the recommendation. Net traded shares of the upgrade (buy) recommendation are defined as the buy shares minus the sell shares, divided by the mean daily trading volumes of the upgrade (buy) recommendation across the sample period to eliminate the scale problem. In contrast, the net traded shares of the downgrade (sell) recommendation are calculated as the sell shares minus the buy shares, divided by the mean daily trading volumes of the downgrade (sell) recommendation across the sample period to eliminate the scale problem. The following equation is applied:

$$NTS_{i,\tau} = \frac{\sum_{j=1}^{M_i} Buy\_Shares_{i,\tau}^{j} - \sum_{j=1}^{M_i} Sell\_Shares_{i,\tau}^{j}}{M_i} \tag{1}$$

where i represents the i th investment bank issuing the recommendation, τ is the τ th week before or after the release of the report, j denotes the j th recommendation report issued by the i th investment bank, and M_i represents the total number of recommendations published by the i th recommending investment bank.

The investment banks' conflicts of interest are calculated using the net traded shares of all recommended stock recommended by the i th making issued investment bank during the period $-t$ to t weeks around the release of the analyst's recommendation.

$$CI\_IB_{i,t} = \left(\sum_{\tau=-t}^{-1} NTS_{i,\tau} - \sum_{\tau=1}^{t} NTS_{i,\tau} \right) \tag{2}$$

Equation (2) calculates the sum of the net traded shares of the i th making issued. investment bank from eight weeks preceding the release of the analyst report and the sum of the

[4] See Table A.1 in the Appendix for more detail.

net traded shares in the eight weeks following the release.

The second part denotes the conflicts of interest for individual stocks, which are computed based on the net traded shares of the k th recommended stock for all investment banks. Similar to Eq. (1), Eq. (3) is therefore as follows:

$$NTS_{k,\tau} = \frac{\sum_{l=1}^{N_k} Buy\_Shares_{i,\tau}^{l} - \sum_{l=1}^{N_k} Sell\_Shares_{i,\tau}^{l}}{N_k} \tag{3}$$

where k represents the k th recommended stock, τ is the τ th week before or after the release of the report, l denotes the l th recommendation report, and N_k represents the total number of recommendations issued regarding the k th stock by all recommending investment banks.

The conflicts of interest for individual stocks are difference between the net traded shares of k th stock by all investment banks that recommend the k th stock. Equation (4) is therefore as follows:

$$CI\_IS_{k,t} = \left(\sum_{\tau=-t}^{-1} NTS_{k,\tau} - \sum_{\tau=1}^{t} NTS_{k,\tau} \right) \tag{4}$$

Equation (4) calculates the sum of the total number of traded shares of the k th recommended stock eight weeks prior to the release of the analyst report and the sum of the net traded shares eight weeks following the release.

This study also examines the profit made by investment banks when trading the recommended stocks. Abnormal returns and cumulative abnormal returns are both calculated based on the standard event study method, which uses the market model of ordinary least squares (OLS) regressions for 250 trading days. The abnormal returns and cumulative abnormal returns can then be calculated over 40 trading days around the buy, sell, upgrade and downgrade recommendations.

4. Empirical results

4.1. *Recommendations for net traded shares*

Table 1 presents net traded shares of the recommended stocks by buy and sell around recommendations. Price share statistics are provided for the 11 investment banks and 10,709 recommendations, include mean, cumulative mean, standard deviation, maximum, and minimum across all stocks for each week for a period spanning eight weeks before and after the release of the recommendations. The cumulative mean is calculated beginning in the 8^{th} week preceding the release of the recommendations.

Panel A of Table 1 shows the mean net traded shares by the recommending investment bank around the zero before the release of the buy recommendations, and remains the status until one week after recommendation. The cumulative mean covers the eight weeks prior to the release of the report, and indicates there is no significant evidence of conflicts of interest for investment banks in buy recommendations.

In Panel B of Table 1, the mean net traded shares by the recommending investment bank takes place seven weeks before the sell recommendations, and peaks two weeks before the release of the report. The cumulative mean covers the eight weeks preceding the release of the report. However, the mean net traded shares become positive immediately following the publishing of the report, and this remains true until the 5th week following the release of the report. This result shows that the recommending investment banks become net sellers of the recommended stocks before the publication of their sell recommendations. Moreover, investment banks making a sell recommendation will buy those stocks back later. Normally, when an investment bank issues a sell recommendation, it should mean the bank considers the share price to be unjustified in terms of risk or that it is aware of news that will adversely affect the share price. The question is why would an investment bank issue sell recommendations to investors but buyback later? Such behavior may indicate potential conflicts of interest.

Insert Table 1 about here.

Panel A of Table 2 shows the mean net traded shares by the recommending investment bank before and after the upgrade recommendation, and result is similar to that of a buy recommendation. The mean net traded shares indicate the eight weeks preceding the release of the upgrade recommendation. The results for the cumulative mean are consistent with those for the mean, indicating upgrade recommendations present no significant evidence to suggest the existence of conflicts of interest for investment banks.

In Panel B of Table 2, the mean net traded shares by the recommending investment bank from seven weeks preceding the downgrade recommendation, and peaks one week prior to the release of the report. The cumulative mean covers the seven weeks prior to the release of the downgrade recommendation. Interestingly, the mean net traded shares become positive immediately following the publication of the downgrade recommendation, and remains positive for four weeks. This result suggests that the recommending investment bank was a net seller of the recommended stock prior to the publication of the downgrade recommendation. Furthermore, the investment banks which issued the downgrade recommendations later begin to buy these ‘underperforming’ stocks, again suggesting a conflict of interest on the part of the investment banks.

Insert Table 2 about here.

4.2. *Benefits of recommendations*

This section explores whether analyst recommendations produce benefits. Table 3 reports the results of ARs and CARs of the recommended stocks over 40 trading days around the buy recommendations. The ARs are positive at 2 trading days before the release of the buy recommendation until at 3 trading days after the recommendation, and become negative after 5 trading days following the recommendation. The highest and lowest returns respectively occur 1 trading day (0.19%) and 12 trading days (-0.21%) after the buy recommendation. Most CARs are significant beginning 1 trading day and ending 7 trading days after the recommendation, and CAR is -0.70% 20 trading days after. Graphs A and B of Fig. 1 plot the ARs and CARs around the buy recommendation. The ARs of Graph A are significant and positive from trading day -4 to +1. From trading day +5, the ARs are negative to the end of the event window. The CARs exhibit a stable trend from days -20 to -4, but change significantly from trading day -3 to +20. The results show that the buy recommendation had an impact on the recommended stock.[5]

Insert Table 3 and Figure 1 about here.

Table 4 presents the results of the ARs and CARs for the recommended stocks over 40 trading days around the sell recommendations. The ARs are negative starting at trading day -19, and the lowest AR is -0.74% at trading day +2. In Fig. 2, Graphs A and B respectively plot the ARs and CARs. The ARs of Graph A are significant and negative from trading days -2 to +3. In particular, the ARs are still negative and significant at trading day +18 even though recommendation is over three weeks old. The CARs are stable reduction on event windows, and CAR is -5.19% and significant at trading day +20. The results show that negative recommendations have a greater impact than positive recommendations on the recommended stock, which is consistent with hypothesis 1 and the findings of Dugar and Nathan (1995).

Insert Table 4 and Figure 2 about here.

Table 5 lists the ARs and CARs of the recommended stocks over 40 trading days around the upgrade recommendations. Most ARs are significant from trading day -2 to +3, and become negative and significant at trading day +10. The highest and lowest returns respectively occur on trading days +1 (0.28%) and +16 (-0.26%). In addition, significant CAR clusters are found from trading days -2 to +17, and CAR is 0.57% at trading day +20. Graphs A and B of Fig. 3 plot the ARs and CARs around the upgrade events. The CARs exhibit a growth trend from trading days -14 to +6, but the CARs significance falls from trading day +7 to +20. These results and trends are similar to those for buy recommendations.

Insert Table 5 and Figure 3 about here.

Table 6 presents the ARs and CARs of the recommended stocks over a period of 40 trading days around the downgrade recommendations. Most ARs are significant from trading day -5 to +3, and all ARs are negative in the downgrade event window. The highest and lowest returns respectively occur at trading days -3 (-0.09%) and +1 (-0.53%). In particular, significant CAR clusters are found from trading days -19 to +20, and CAR is -5.26% at trading day +20. Graphs A and B of Fig. 4 respectively plot the

[5] The Wilcoxon sign and Wilcoxon sign rank tests are used because Kothari and Warner (1997) found that abnormal returns around firm-specific events are severely misspecified. The rejection frequencies using parametric tests sometimes exceed 30% when the significance level of the test is 5%. Nonparametric tests are likely to reduce misspecification.

ARs and CARs from downgrade events. The CARs exhibit a descending trend in the downgrade event windows. These results and trends are similar to those of the sell recommendations. The experimental results are consistent with hypothesis 1 that negative recommendations should have a stronger impact on stock prices than positive recommendations.

Insert Table 6 and Figure 4 about here.

4.3. *Determinants of conflicts of interest for investment banks*

Six variables are considered in determining conflicts of interest: the investment bank's size (*BrokSize*) and age (*Duration*), the frequency with which the investment bank issues recommendations (*Times*), the analyst's prior-year performance (*Prior_Perf*), the average analyst's experience (*Experience*) and the investment bank's monthly sales figure (*Sale*).

BrokSize measured as the number of analysts employed by analyst's brokerage firm in the year prior to issuing the revised recommendation. *Duration* is computed as the number of years the investment bank has been in business. Shen and Chih (2009) note that *BrokSize* and *Duration* should be negative coefficients because larger or older investment banks are more concerned about their reputations. *Times* is computed as the frequency with which the investment bank issues recommendations. The coefficients should be positive, because high frequency issuing of recommendations provides an increased opportunity for conflicts of interest to develop in their trading strategy.

Following by Mikhail et al. (2004), *Prior_Perf* is the average quintile ranking of the analyst's prior performance (ranging from 0, worst, to 4, best), based on the prior-year return to the analyst's equal-weight portfolio of recommendation revisions over the event window of t= -2 to +60, where t=0 is the recommendation date. *Experience* is average analyst's experience measured in quarters (Lol and Stulz, 2011). The impacts of *Prior_Perf* and *Experience* are uncertain. An increase in the analyst's prior performance or experience should increase the impact on the recommended stock (Stickel, 1992; Kim and Verrecchia, 1994; Mikhail et al. 1997), and could provide increased incentive to include conflicts of interest in their trading strategy. On the other hand, increased prior performance or experience may leave the analyst increasingly concerned about maintaining his reputation, thus leaving the analyst reluctant to engage in conflicts of interest. The final variable is *Sale,* which is computed as the investment bank's monthly sales, and is expected to be positively correlated to the extent of conflicts of interest in the firm's trading strategy.

Table 7 reports the cross-sectional regressions of the conflict of interest indices for investment banks for positive (i.e., buy and upgrade) recommendations. In Panel A of Table 7, the dependent variables are $CI\_IB_{i,1}$ *to* $CI\_IB_{i,4}$, which denotes a period of 1 week before to 4 weeks after the analyst recommendation. To capture more information and characteristics of the conflicts of interest indices, $CI\_IB_{i,8}$ is also shown. *Duration* is found to be significantly negative for $CI\_IB_{i,1}$ in buy recommendations, suggesting that longer IB periods are more concerned with reputation and tend not to engage in conflicts of interest when making recommendations.

In Panel B of Table 7, when $CI\_IB_{i,1}$ is the dependent variable, the coefficients for *Duration* and *Prior_Perf* are significantly negative (at the 10% and 5% level, respectively) in upgrade events. When $CI\_IB_{i,2}$ is the dependent variable, the coefficients for *Size*, *Duration* and *Prior_Perf* are significantly negative (at the 5%, 10% and 10% level, respectively). When $CI\_IB_{i,3}$ is the dependent variable, the coefficients for *Size* and *Duration* are significantly negative (at the 5% and 10% level, respectively). If we observe $CI\_IB_{i,4}$ or $CI\_IB_{i,8}$ for longer windows, the coefficients for *Size* or *Duration* are significantly negative (at the 5% and 10% level, respectively). The result of conflicts of interest indices in upgrade events, suggesting that larger and older investment banks are more concerned with reputation and tend not to engage in conflicts of interest when making upgrade recommendations.

Insert Table 7 about here.

Table 8 presents the coefficient estimates for the conflicts of interest indices for investment banks for negative (i.e., sell and downgrade) recommendations. Panel A gives result for the sell recommendations. The coefficient of most interest is that for *Prior_Perf*, which is positive and statistically significant 4 weeks before and after the sell recommendation ($CI\_IB_{i,4}$). The positive coefficient implies that senior analysts tend to have conflicts of interest on sell recommendations. Panel B gives the result for the downgrade recommendations. The coefficient for *Duration* is significantly positive in $CI\_IB_{i,4}$ and $CI\_IB_{i,8}$ (both at the 10% level), indicating that older investment banks tend to have conflicts of interest for downgrade recommendations. The coefficient for *Times* is significantly positive in $CI\_IB_{i,1}$, $CI\_IB_{i,2}$, $CI\_IB_{i,4}$ and $CI\_IB_{i,8}$ (at the 10%, 5%, 10% and 10% level, respectively), implying that banks which frequently issue downgrade recommendations tend to have conflicts of interest. Also, for $CI\_IB_{i,8}$, the t-value of *Sale* is significantly positive at the 5% level, indicating that investment banks with higher sales volume tend to have conflicts of interest for downgrade recommendations. The experimental results are consistent with hypothesis 2 which states that conflicts of interest for investment banks are affected by analyst characteristics.

Insert Table 8 about here.

4.4. *Determinants of conflicts of interest for individual stocks*

Eight variables are adopted to examine the determinants of conflicts of interests for individual stocks: the average daily trading volume (*Volume*), the market value of the stock (*Size*), the frequency with which a particular stock is recommended by all investment banks (*FREQ*), the number of peer firms in the same industry (*Number*), the systematic risk of a recommended stock (*Beta*), the market-to-book ratio (*MB*), the percentage of shares held by directors or senior officers (*Insider*), and the percentage of shares held by foreign investors (*FIH*).

Volume is measured as the average daily trading volume of the recommended security. Bhushan (1989a) showed that a high trading volume in a particular stock may stem from liquidity traders causing high volatility. Shen and Chih (2009) argued that an investment bank may take advantage of such conditions to earn profits. Hence, *Volume* is expected to be positively related to conflicts of interest.

Size should be negative in sign, Lang and Lundholm (1996) argued that larger firms draw increased attention from investors, and Shen and Chih (2009) noted that, mindful of their reputations, investment banks are more vigilant when making recommendations for high-profile firms. Similar to *Times*, *FREQ* should be positive, while *Number* should be positive. Bhushan (1989b) and Shen and Chih (2009) reported that the cost to analysts for collecting information increases with the number of business lines a firm maintains, and high information collecting costs might reduce competition in information collecting, thus resulting in more informative recommendations and increasing the likelihood of conflicts of interest.

Beta should be negative, with a higher *Beta* value implying stock returns are more sensitive to market information, and relatively insensitive to firm-specific information. Thus, Shen and Chih (2009) noted that a higher *Beta* value makes it more difficult for investment banks to exploit firm-specific information by trading recommended stocks. *MB* should be positive, with Frankel et al. (2006) noting that a high *MB* value is often associated with younger firms with high growth potential. Such firms usually lack a financial experience, providing increased likelihood that their operating strategies will be vulnerable to conflicts of interest. The last two variables are *Insider* and *FIH*, which are proxy variables for concentrated ownership, and are expected to be negatively related to conflicts of interest.

Table 9 presents the cross-sectional regressions of the conflict of interest indices for individual stocks for positive recommendations. Panel A of Table 9 lists the buy recommendations. When $CI\_IS_{k,3}$ and $CI\_IS_{k,4}$ serve as the dependent variables, the coefficient for *Insider* is significantly negative (at the 1% and 5% level, respectively). On the other hand, *FIH* is significantly negative for $CI\_IS_{k,2}$ and $CI\_IS_{k,8}$ (at the 10% and 5% level, respectively). These results suggest that when a relatively higher ratio of equity is held by insiders or foreign investors, individual stocks tend to be less vulnerable to lower conflicts of interest on buy recommendations. The experimental results are consistent with hypothesis 3 which states that concentrated ownership of individual stocks reduces the incidence of conflicts of interest.

Panel B of Table 9 lists the upgrade recommendations. The coefficients for *Size* are significantly negative at $CI\_IS_{k,3}$ and $CI\_IS_{k,8}$ (at the 10% and 5% level, respectively), indicating that larger firms tend to have fewer conflicts of interest on upgrade recommendations. The coefficient for *FREQ* is significantly positive at $CI\_IB_{i,8}$ (at the 10% level), implying that higher frequency of upgrade recommendations tends to correlate with higher incidence of conflicts of interest. This result indicates that investment banks have more difficulty exploiting firm-specific information if the recommended stock has higher information transparency.

Insert Table 9 about here.

Table 10 presents the cross-sectional regressions of the conflict of interest indices for individual stocks for negative recommendations, with results for sell and downgrade recommendations respectively displayed in Panels A and B. In Panel A, the conflicts of interest for sell recommendations are almost insignificant in all coefficients. In Panel B, *Number* is significant and positive in $CI\_IB_{i,1}$ (at the 5% level), implying that a greater number of peer firms in same industry tends to correlate with increased conflicts of interest. *Beta* is significant and negative from $CI\_IS_{k,1}$ to $CI\_IS_{k,8}$, (at the 1% , 5%, 5%, 5% and 10% level, respectively), suggesting that higher systematic risk makes it more difficult for investment banks build a strategy to profit from such recommendations.

Judging from the above, sell recommendations appear not to be influenced by the explanatory variables. However, this view is quite unsatisfactory, and the above results are not absolute proof that stock characteristics have no impact on conflicts of interest. One possible explanation for these results is that the majority of conflicts of interest are not affected by the explanatory variables.

Insert Table 10 about here.

5. Conclusions

This paper studies the characteristics of conflicts of interest in stock recommendations through asking three questions: Are stock prices more heavily impacted by negative recommendations than by positive recommendations? Are conflicts of interest for investment banks affected by analyst characteristics? Will concentrated ownership reduce conflicts of interest for individual stocks?

Empirical results show that individual stocks are influenced by analyst recommendations, and this holds true for both traditional (buy and sell) recommendations and revised (upgrade and downgrade) recommendations. Moreover, negative recommendations were found to have a much greater impact on recommended stocks than positive recommendations.

This paper also uses the model proposed by Shen and Chih (2009) to examine the characteristics of conflicts of interest in stock recommendations for investment banks and for individual stocks. Variables found to impact conflicts of interests for investment banks include the age and size of the investment bank, the analyst's prior-year performance, and investment bank sales volume. More specifically, the result for conflict of interest indices in upgrade events suggest that larger and older investment banks, along with high-performing analysts, are more concerned with maintaining their reputations and tend not to engage in conflicts of interest when making upgrade recommendations.

On the other hand, for individual stocks, incidence of conflict of interest is affected by firm size, frequency of recommendations, the number of peer firms in the same industry, *Beta*, insider holdings, and foreign investor holdings. These results suggest that increased insider or foreign holdings tend to reduce the incidence of conflicts of interest on buy recommendations.

Table 7. Cross-Sectional Regressions of the Conflict of Interest Indices for Investment Banks on Positive Recommendations

The table reports coefficient estimates of the following regression:

$$CI\_IB_{i,t} = \alpha + \beta_1 BrokSize + \beta_2 Duration + \beta_3 Times + \beta_4 Prior\_Perf + \beta_5 Experience + \beta_6 Sale$$

$CI\_IB_{i,t}$ is the conflict of interest indices for investment banks t trading weeks before and after the recommendation. *BrokSize* is the size of recommending investment bank, *Duration* is the age of the investment bank in years, *Times* is the frequency with which the IBs issue buy (upgrade) recommendations, *Prior_ Perf* is the analyst's prior-year performance with which the IBs issue recommendations, *Experience* is the average analyst's experience (in quarters) with which the IBs issue recommendations, and *Sale* is the IB's monthly sales volume. *t*-statistics are reported in parentheses. Significance at the 1, 5, and 10% levels is denoted by ***, **, and *, respectively.

We propose a new measure of managerial skill based on the maximum monthly returns of hedge funds over a fixed time interval and test if this new measure (MAX) is an indicator of greater managerial talent leading to superior fund performance. We find significant cross-sectional variations and persistence in MAX. Our main finding indicates that hedge funds in the highest MAX quintile generate 8.4% more annual returns compared to funds in the lowest MAX quintile. After controlling for a large set of fund characteristics, risk factors, and past performance measures, the positive relation between MAX and future returns remains highly significant. We also show that the directional and semi-directional hedge fund managers can predict and exploit changes in the market and economic conditions by increasing (decreasing) fund exposures to risk factors when market risk and/or economic uncertainty is high (low). However, mutual funds do not have market- or macro-timing ability. Thus, we find no evidence of a significant link between managerial talent of mutual fund managers and their future returns. Overall, the results indicate that the predictive power of MAX over future returns for hedge funds is driven by superior timing ability and better managerial skills of hedge funds.

Keywords: hedge funds; mutual funds; managerial skill; return predictability.

JEL Classifications: G10, G11, C13

1. Introduction

Having experienced significant growth over the past two decades, the hedge fund industry plays an important role in investment decisions of a wide variety of investors. As the hedge fund industry grows, there is increasing interest in developing criteria for selecting talented hedge fund managers. Recent studies provide evidence for the presence of professional fund managers in the marketplace that can provide value above and beyond a passively managed fund. However, proponents of passive money management believe the active management industry provides no value-added, because fund managers lack investment-picking skills. This constituency believes markets are efficient; superior performance of hedge funds is attributed to pure randomness (luck), whereas funds that underperform are considered unlucky. However, if we assume markets are perfectly efficient and active managers lack skill, we must simultaneously assume that institutional and (wealthy) individual investors investing in active hegde funds are completely irrational. Despite little evidence of timing ability previously documented for mutual funds, we show that the hedge fund industry with dynamic trading strategies does possess strong market- and macro-timing ability. Hence, we believe both the efficient market and the completely irrational investor hypotheses are farfetched.

Managerial skills are what the manager uses to assist the fund in accomplishing its goals. Specifically, a fund manager will make use of his or her own abilities, knowledge base, experiences, and perspectives to increase the productivity of those with whom they manage. In order to perform their job effectively, fund managers need strong technical, human, and conceptual skills. In this paper, we argue that the value of a talented hedge fund manager is driven by the private, unique information she brings to the investment process. Only unique investment ideas with dynamic trading strategies are likely to generate superior performance because any potential abnormal return resulting from a well-known, heavily traded strategy is likely to be arbitraged away. Therefore, identifying professional fund managers with strong managerial skills and unique investment ideas is crucial for hedge fund investors who pay high fees for superior performance.

If one thinks of hedge fund managers as skilled professionals whose job involves gathering and analyzing data, it seems reasonable to hypothesize that some fund managers may perform better than others. We examine whether superior hedge fund performance is related to characteristics of fund managers identified by strong market- and macro-timing ability and suberp knowledge of financial markets, proxied by frequent use of dynamic trading strategies with derivatives, short-selling, and leverage. In particular, we study the cross-sectional relation between future fund returns and the manager's extreme past positive performance. We introduce a new measure of managerial skill based on the maximum monthly returns of hedge funds over a fixed time interval and test if this new measure is an indicator of greater managerial talent leading to superior fund performance in the future.

We investigate whether the extremely large positive returns observed over the past six to 24 months predict future performance of individual hedge funds. First, we conduct univariate portfolio-level analysis. For each month from January 1995 to December

2014, we form quintile portfolios by sorting individual hedge funds based on their maximum monthly return (MAX) over a specified period, where quintile 1 contains the hedge funds with the lowest MAX and quintile 5 contains the hedge funds with the highest MAX. We find that the average return difference between quintiles 5 and 1 is 0.70% per month and highly statistically significant, indicating that hedge funds in the highest MAX quintile (funds with strong managerial skill) generate 8.4% more annual returns compared to funds in the lowest MAX quintile (funds with weak managerial skill). After controlling for Fama-French-Carhart's four factors of market, size, book-to-market, and momentum as well as Fung-Hsieh's five trend-following factors on currency, bond, commodity, short-term interest rate, and stock index, the return spread between the high-MAX and low- MAX funds (9-factor alpha) remains positive, 0.47% per month, and highly significant.

Next, we provide results from the bivariate portfolios of MAX and competing proxies of managerial skill. Specifically, after controlling for the past 12-month average return, standard deviation, Sharpe ratio, appraisal ratio, incentive fee, and net fund flows in bivariate sorts, MAX remains a significant predictor of future fund returns. The univariate and bivariate portfolio-level analyses clearly indicate that managerial skill is an important determinant of future fund performance and MAX is a distinct, persistent measure of managerial talent containing orthogonal information to alternative measures such as the Sharpe ratio, appraisal ratio, incentive fee, and fund flows.

In addition to these portfolio-level analyses, we run fund-level cross-sectional regressions to control for multiple effects simultaneously. In multivariate Fama-MacBeth (1973) regressions, we control for lagged returns, standard deviation, Sharpe ratio, appraisal ratio, and a large set of fund characteristics (age, size, management fee, incentive fee, redemption period, minimum investment amount, lockup and leverage structures). Even after controlling for this large set of fund characteristics, past performance, and alternative measures of managerial skill simultaneously, the significantly positive link between MAX and future fund returns remains highly significant in multivariate Fama-MacBeth regressions. We also perform subsample analyses and find that these regression results are robust across different sample periods and different states of the economy. Thus, both Fama-MacBeth regressions and portfolio-level analyses provide strong corroborating evidence for an economically and statistically significant positive relation between MAX and future hedge fund returns.

Hedge funds have various trading strategies; some willingly take direct market exposure and risk (directional strategies), while some try to minimize market risk altogether (non-directional strategies), and some try to diversify market risk by taking both long and short, diversified positions (semi-directional strategies). After classifying hedge funds into these three groups, we test whether the predictive power of MAX changes among different hedge fund investment styles. The results indicate that the predictive power of MAX gradually increases as we move from the least directional strategies to the most directional strategies. We obtain the highest predictive power of MAX for the directional strategies because the directional funds with higher MAX and stronger managerial skill employ a wide variety of dynamic trading strategies and make extensive use of derivatives, short-selling, and leverage, compared to the non-directional funds with lower MAX and weaker managerial skill.

We also investigate whether hedge funds have the ability to time fluctuations in the equity market and macroeconomic fundamentals. Henriksson-Merton (1981) pooled panel regression results show that the directional funds are willingly take direct exposure to financial and macroeconomic risk factors, relying on their market- and macro-timing ability to generate superior returns. Since these are funds with dynamic trading strategies frequently using derivatives/leverage that are highly exposed to market risk and economic uncertainty, timing the switch in economic trends is essential to their success. Hence, our main finding indicating a stronger link between MAX and future returns for the directional funds with stronger managerial skill can be attributed to the evidence of superior market- and macro-timing ability of directional hedge fund managers.

We provide an alternative explanation for the superior performance of the directional and semi- directional hedge funds by replicating our main analyses for the mutual fund industry. We first investigate whether managerial skill of mutual fund managers (proxied by the maximum monthly return of mutual funds over the past one year) predicts their future returns. Then, we analyze whether mutual funds have the ability to time fluctuations in the equity market and macroeconomic uncertainty. Since mutual funds do not use dynamic trading strategies and tend to invest primarily on the long side without extensively using other tools (e.g., derivatives, leverage, and short-selling), the results provide no evidence for a significant link between managerial talent of mutual fund managers and their future returns. We also show that while the directional and semi-directional hedge fund managers have the ability to time changes in the market and macroeconomic fundamentals by increasing (decreasing) fund exposure to risk factors when market risk and/or economic uncertainty is high (low), mutual funds, as in the case of the non-directional hedge funds, do not have significant market- or macro-timing ability.

Finally, we examine whether investors take differences in managerial skill into account and find that the ability of high-MAX funds to produce higher returns motivates those hedge fund managers to charge higher management and incentive fees to their clients, compared to the low-MAX funds with weak managerial skill. In addition, we show that the high-MAX funds are able to attract higher inflows as well. These two results suggest investors' preference for the high-MAX funds. That is, funds with high-MAX are rewarded with higher fees and also their flows, as a percentage of assets, are significantly greater. This is most probably due to the fact that investors learn about managerial skills and they are indeed willing to pay higher fees and invest more in the high-MAX funds under the expectation of receiving large positive returns in the future.

This paper proceeds as follows. Section 2 provides a literature review. Section 3 describes the data and variables. Section 4 presents the empirical results and provides a battery of robustness checks. Section 5 examines the predictive power of managerial skill for directional, semi-directional, and non-directional hedge funds and sets forth market- and macro-timing tests. Section 6 compares and contrasts hedge funds with mutual funds to provide an alternative way to explain superior performance of directional hedge funds with stronger managerial skill. Section 7 concludes the paper.

2. Literature Review

The concept of sophisticated investors has been widely investigated in empirical asset pricing and corporate finance literatures. Whether such investors with strong manageral skills exist and whether they outperform others has been the subject of debate for at least a few decades, particularly in the literature on mutual funds.[1] While a vast number of performance measures has been proposed and extensively used to identify successful mutual fund managers, several studies question whether these measures actually capture managerial skills, given existing alternative explanations, such as luck (e.g., Kosowski et al. (2006)), model misspecification (e.g., Pastor and Stambaugh (2002), Avramov and Wermers (2006)), survivorship bias (e.g., Brown, Goetzmann, Ibbotson, and Ross (1992) and Brown and Goetzmann (1995)), or weak statistical power of empirical tests undermining the source of high performance (e.g., Kothari and Warner (2001)). Different from the aforementioned literature on mutual funds, our objective is to measure the strength of managerial skill for individual hedge funds and then test whether superior hedge fund performance is related to talent of hedge fund managers.

This paper contributes to the growing literature on the cross-sectional determinants and predictors of hedge fund performance.[2] Bali, Brown, and Caglayan (2011) find a positive (negative) and significant link between default premium beta (inflation beta) and future hedge fund returns. Funds in the highest default premium beta quintile generate 5.8% higher annual returns compared to funds in the lowest default premium beta quintile. Similarly, the annual average return of funds in the lowest inflation beta quintile is 5% higher than the annual average return of funds in the highest inflation beta quintile. Titman and Tiu (2011) find that better-informed hedge funds choose to have less exposure to factor risk. Consistent with their argument, they find that hedge funds that exhibit lower R-squareds with respect to systematic factors have higher Sharpe ratios, higher information ratios, and higher alphas. Sun, Wang, and Zheng (2012) construct a measure of the distinctiveness of a fund's investment strategy (*SDI*) and find that higher *SDI* is associated with better subsequent performance of hedge funds. Bali, Brown, and Caglayan (2012) introduce a comprehensive measure of systematic risk for individual hedge funds by breaking up total risk into systematic and residual risk components. They find that systematic variance is a highly significant factor in explaining the dispersion of cross-sectional returns, while at the same time measures of residual risk and tail risk have little explanatory power. Cao, Chen, Liang, and Lo (2013) investigate how hedge funds manage their liquidity risk by responding to aggregate liquidity shocks. Their results indicate that hedge fund managers have the ability to time liquidity by increasing portfolio market exposure when equity market liquidity is high.

---

[1] See Fama and French (2010) and the references therein.

[2] A partial list includes Fung and Hsieh (1997, 2000, 2001, 2004), Ackermann, McEnally, and Ravenscraft (1999), Liang (1999, 2001), Mitchell and Pulvino (2001), Agarwal and Naik (2000, 2004), Kosowski, Naik, and Teo (2007), Bali, Gokcan, and Liang (2007), Fung et al. (2008), Patton (2009), Jagannathan, Malakhov, and Novikov (2010), Aggarwal and Jorion (2010), Brown, Gregoriou, and Pascalau (2012), and Patton and Ramadorai (2013).

This study is also related to an extensive literature on market-timing ability of mutual funds. Following the pioneering work of Treynor and Mazuy (1966), a large number of studies investigated timing ability of professional fund managers. With a few exceptions, most of the earlier work focused on the mutual fund sample and find little evidence of market-timing ability.[3] Only recently, a few studies have investigated whether individual hedge funds have the ability to time fluctuations in the equity market, aggregate market liquidity, and macroeconomic fundamentals.[4]

Motivated by existing evidence of a preference among investors for assets with lottery-like payoffs and that many investors are poorly diversified, Bali, Cakici, and Whitelaw (2011) investigate the significance of extreme positive returns in the cross-sectional pricing of individual stocks and find a significantly negative relation between the maximum daily return over the past one month and expected stock returns. The low (high) abnormal returns of stocks with high (low) market beta – known as the betting against beta (BAB) effect – is the most persistent anomaly in empirical asset pricing literature. Bali, Brown, Murray, and Tang (2015) show that the BAB phenomenon disappears after controlling for persistent lottery characteristics of the stocks, while other measures of firm characteristics and risk fail to explain the effect. When we use the term MAX in this paper, we inevitably draw a reference to Bali, Cakici, and Whitelaw (2011) and Bali, Brown, Murray, and Tang (2015). However, the term MAX used by Bali et al. (2011, 2015) is to identify demand for lottery-like stocks, whereas in this paper it is used as a proxy for managerial talent leading to superior fund performance.[5] More importantly, in this paper, we investigate the in-sample MAX of hedge funds' managed portfolios, whereas Bali et al. (2011, 2015) examine the MAX of portfolios chosen by reference to the prior MAX of their constituent assets. Specifically, we explore the cross-sectional link between managerial talent and timing ability, and their impacts on future returns of hegde funds and mutual funds. Hence, the paper makes a significant contribution to the aforementioned comprehensive literatures on managerial skill, market-timing, and the cross-sectional determinants of fund performance.

3. Data and Variables

In this section, we first describe the hedge fund database, fund characteristics, and their summary statistics. Then, we provide definitions of key variables used in the cross-sectional predictability of future fund returns. Finally, we present the standard risk factors used in the estimation of risk-adjusted returns (alphas) of MAX-sorted portfolios.

[4] Chen and Liang (2007), Cao, Chen, Liang, and Lo (2013), and Bali, Brown, and Caglayan (2014).

[5] Also note that MAX for individual stocks is defined as the maximum daily return over the past one month, whereas MAX for hedge funds' managed portfolios is defined as the maximum monthly return over the past six to 24 months.

3.1. *Hedge fund database*

This study uses monthly hedge fund data from the Lipper TASS (Trading Advisor Selection System) database. In the database, originally we have information on a total of 19,746 defunct and live hedge funds. However, among these 19,746 funds, there are many funds that are listed multiple times as these funds report returns in different currencies, such as USD, Euro, Sterling, and Swiss Franc. These funds are essentially not separate funds, but just one fund with returns reported on a currency converted basis. In addition, typically a hedge fund has an off-shore fund and an on-shore fund, following the exact same strategy. Therefore, naturally, for all these funds their returns are highly correlated. However, the TASS database assigns a separate fund reference number to each on-shore and off-shore fund, and to each of the funds reporting in different currencies, treating these funds as separate individual funds. In order to distinguish between different share classes (of the same fund) and other actual funds, and not to use any duplicated funds (and hence returns) in our analyses, we first omit all non-USD-based hedge funds from our sample. That is, we keep in our database only the hedge funds reporting their returns in USD. Next, if a hedge fund has both an off-shore fund and an on-shore fund with multiple share classes, we keep the fund with the longest return history in our database and remove all the other share classes of that particular fund from our sample. This way, we make sure that each hedge fund is represented only once in our database. After removing all non-USD-based hedge funds and hedge funds with multiple share classes, our database contains information on a total of 11,099 distinct, non-duplicated hedge funds for the period January 1994 – December 2014, where 8,684 of them are defunct funds and the remaining 2,415 of them are live funds.

The TASS database, in addition to reporting monthly returns (net of fees) and monthly assets under management, also provides information on certain fund characteristics, including management fees, incentive fees, redemption periods, minimum investment amounts, and lockup and leverage provisions.

Table 1 provides summary statistics on hedge fund numbers, returns, assets under management (AUM), and fee structures for the sample of 11,099 hedge funds. For each year, Panel A of Table 1 reports the number of funds entering the database, the number of funds dissolved, total AUM at the end of each year (in $ billion), and the mean, median, standard deviation, minimum, and maximum monthly percentage returns on the equal-weighted hedge fund portfolio. One important characteristic about TASS is that it includes no defunct funds prior to 1994. Therefore, in an effort to mitigate potential survivorship bias in the data, we select 1994 as the start of our sample period and employ our analyses on hedge fund returns for the period January 1994–December 2014.

Table 1, Panel A reports a sharp reversal in the growth of hedge funds both in numbers and in AUM since the end of 2007, the starting point of the last worldwide financial crisis. The AUM in our database increased exponentially from a small $55 billion in 1994 to $892 billion in 2007, and the number of operating hedge funds increased almost seven times to 5,275 in December 2007 from 748 in January 1994. However, both these figures reversed course beginning with 2008, the start of the worldwide financial crisis; the number of operating hedge funds fell sharply to below

2,500, while total AUM dropped by more than half, to $405 billion by the end of December 2014. In addition, the yearly attrition rates in Panel A of Table 1 (ratio of the number of dissolved funds to the total number of funds at the beginning of the year) paints a similar picture: from 1994 to 2007, on average, the annual attrition rate in the database was only 8.1%; between 2008 and 2014, however, this annual figure increased by almost 2.4 times to 19.4%. These statistics simply reflect the severity of the financial crisis of the past seven years. In 2008 and 2011 alone, for example, hedge funds on average lost 1.56% and 0.48% (return) per month, respectively.

Panel B of Table 1 reports the cross-sectional mean, median, standard deviation, minimum, and maximum values for certain hedge fund characteristics for the period January 1994–December 2014. One interesting point evident in Panel B is the short lifespan of hedge funds. The median age (number of months in existence since inception) is only 60 months, equivalent to five years. This short lifespan is mostly due to the fact that hedge fund managers must first cover all losses from previous years before getting paid in the current year. This forces hedge fund managers to dissolve quickly and form new hedge funds after a bad year, instead of trying to cover losses in subsequent years. Another remarkable observation that can be detected from this panel is the large size disparity seen among hedge funds. When we measure fund size as average monthly AUM over the life of the fund, we see that the mean hedge fund size is $85.7 million, while the median hedge fund size is only $40.0 million. This suggests that there are a few hedge funds with very large AUM in our database, which reflects true hedge fund industry conditions.

Lastly, hedge fund studies can be subject to potential data bias issues. Brown, Goetzmann, Ibbotson, and Ross (1992), Fung and Hsieh (2000), Liang (2000), and Edwards and Caglayan (2001) cover these well-known data bias problems extensively in the hedge fund literature. The first potential data bias in a hedge fund study is the survivorship bias if the database does not include the returns of non-surviving hedge funds. In our study, for the period January 1994–December 2014, we do have monthly return histories of 2,415 funds in the live funds (survivor) database and 8,684 funds in the graveyard (defunct) database. We estimate that if the returns of non-surviving hedge funds (graveyard database) had been excluded from the analyses, there would have been a survivorship bias of 2.70% in average annual hedge fund returns. This is the difference between the annualized average return of only surviving funds in the sample and the annualized average return of all surviving and non-surviving funds in the sample.[6] However, the fact that we use the returns of defunct funds in our analyses as well, removes any potential concerns about the effect of survivorship bias on our main findings.

Another important data bias in a hedge fund study is called the back-fill bias. Once a hedge fund is included into a database, that fund's previous returns are automatically added to that database as well (this process is called "back-filling"). This practice in the hedge fund industry is problematic, because it generates an incentive only for successful

[6] This finding is comparable to earlier studies of hedge funds. Liang (2000) reports an annual survivorship bias of 2.24% and Edwards and Caglayan (2001) report an annual survivorship bias of 1.85%.

hedge funds to report their initial returns to the database vendor, and as a result, it may generate an upward bias in returns of newly reporting hedge funds during their early histories. Fung and Hsieh (2000) report that the median backfill period is about 12 months based on the TASS database from 1994 to 1998. They adjust for this bias by dropping the first 12 months of returns of all individual hedge funds in their sample and report a back-fill bias estimate of 1.4% per annum (see also Malkiel and Saha (2005) and Kosowski, Naik, and Teo (2007) for previous literature on back-fill bias and how they adjust their samples to mitigate the impact of back-fill bias on their results). In order to eliminate the potential effects of back-fill bias on our main findings, in this study we eliminate the returns of all individual hedge funds prior to the date they are added to the database. In other words, in our analyses we use the returns of hedge funds only after they are added to the TASS database.[7] During our sample period January 1994–December 2014, we measure the magnitude of the back-fill bias as 3.66% per annum, calculated as the annual average return difference between the back-fill corrected sample and the back-fill not corrected sample.

The last possible data bias in a hedge fund study is called the multi-period sampling bias. Investors generally ask for a minimum of 24 months of return history before making a decision whether to invest in a hedge fund or not. Therefore, in a hedge fund study, inclusion of hedge funds with shorter return histories than 24 months would be misleading to those investors who seek past performance data to make future investment decisions. Also, a minimum 24-month return history requirement makes sense from a statistical perspective to be able to run regressions and get sensible estimates of alphas, betas, sharpe ratios, and appraisal ratios for individual hedge funds in the sample. Therefore, we require that all hedge funds in the sample to have at least 24 months of return history in our study. This 24-month minimum return history requirement, however, decreases our sample size from 10,442 to 8,010 funds (i.e., 2,432 funds in the sample have return histories less than 24 months). There is a slight chance that we might introduce a new survivorship bias into the system due to deletion of these 2,432 hedge funds from the sample (funds that had return histories less than 24 months most probably dissolved due to bad performance). In an effort to find the impact of these deleted 2,432 hedge funds on total hedge fund performance, we compare the performance of hedge funds *before* and *after* the 24-month return history requirement. We find that the annual average return of hedge funds that pass the 24-month requirement (8,010 funds) is only 0.44% higher than the annual average return of all hedge funds (10,442 funds) in the sample. This is a small insignificant percentage difference between the two samples in terms of survivorship bias considerations.[8]

[7] In the TASS database, there are 657 hedge funds for which their entry date to the database is unknown. We remove these 657 hedge funds from our sample; as a result the total sample size is reduced to 10,442 funds from 11,099 funds.

[8] This figure is similar to the estimates from earlier studies. Edwards and Caglayan (2001) also impose a 24-month return history requirement and find a small survivorship bias estimate of 0.32%. Fung and Hsieh (2000), on the other hand, impose a 36-month return history requirement and find the survivorship bias estimate to be 0.60%.

3.2. *Variable definitions*

In the literature, managerial skill of hedge funds has been proxied by traditional measures of performance such as the CAPM alpha, the Sharpe ratio and the appraisal ratio. In addition to these risk- adjusted return measures, incentive fee and fund flows can be viewed as alternative proxies for managerial skill. This paper introduces a new measure of managerial talent based on the maximum monthly returns of funds over a fixed time interval and examines if the new measure can be considered a sign of successful fund managers leading to superior performance.

MAX: We use five alternative measures of extreme hedge fund returns (MAX) to proxy for managerial skill. MAX6, MAX9, MAX12, MAX18, and MAX24 represent the maximum monthly hedge fund returns over the past 6, 9, 12, 18, and 24 months, respectively.

Control Variables: We use a large set of fund characteristics, past return, volatility, and risk-adjusted return measures to test whether the predictive power of MAX is driven by these potential cross-secitonal predictors. Specifically, we use *Size* measured as monthly assets under management in billions of dollars; *Age* measured as the number of months in existence since inception; *Flow* measured as the change in the assets under management from previous month to current month adjusted with fund returns and scaled with previous month's assets under management;[9] *IncentFee* measured as a fixed percentage fee of the fund's annual net profits above a designated hurdle rate; *MgtFee* measured as a fixed percentage fee of assets under management, typically ranging from 1% to 2%; *MinInvest* measured as the minimum initial investment amount (measured in millions of dollars in the regression) that the fund requires from its investors to invest in a fund; *Redemption* measured as the minimum number of days an investor needs to notify a hedge fund before the investor can redeem the invested amount from the fund; *DLockup* measured as the dummy variable for lockup provisions (1 if the fund requires investors not able to withdraw initial investments for a pre-specified term, usually 12 months, 0 otherwise); and *DLever* measured as the dummy variable for leverage (1 if the fund uses leverage, 0 otherwise).

In addition to these large set of fund characteristics, in our analyses, we also control for alternative performance measures, including the one-month lagged return (*LagRet*), the past 12-month average return (*AVRG*), the past 12-month standard deviation (*STDEV*), the past 12-month Sharpe ratio (*SR*) computed as the past 12-month average excess return divided by the past 12-month standard deviation, and the appraisal ratio (*AR*) obtained from the 9-factor model of Fama-French (1993), Carhart (1997), and Fung and Hsieh (2001):

$$R_{i,t} = \alpha_i + \beta_{1,i} \cdot MKT_t + \beta_{2,i} \cdot SMB_t + \beta_{3,i} \cdot HML_t + \beta_{4,i} \cdot MOM_t + \beta_{5,i} \cdot FXTF_t + \beta_{6,i} \cdot BDTF_t + \beta_{7,i} \cdot CMTF_t + \beta_{8,i} \cdot IRTF_t + \beta_{9,i} \cdot SKTF_t + \varepsilon_{i,t} \quad (1)$$

[9] Fund flow is defined as $\{Assets_t - [(1+Return_t) \cdot Assets_{t-1}]\} / Assets_{t-1}$.

where MKT_t, SMB_t, HML_t, and MOM_t are the four factors of Fama-French (1993) and Carhart (1997), and $FXTF_t$, $BDTF_t$, $CMTF$, $IRTF$, and $SKTF$ are the five trend-following factors of Fung and Hsieh (2001). The unsystematic (or fund-specific) risk of fund i is measured by the standard deviation of $\varepsilon_{i,t}$ in eq. (1) denoted by $\sigma_{\varepsilon,i}$. The appraisal ratio (AR) is used to determine the quality of a fund's investment picking ability. It compares the fund's alpha (α_i) to the portfolio's unsystematic risk: $AR_i = \alpha_i / \sigma_{\varepsilon,i}$ [10]

3.3. *Risk factors*

We rely on the widely-accepted nine factors when computing the risk-adjusted return of MAX- sorted portfolios. Specifically, we use the market, size, book-to-market, and momentum factors of Fama and French (1993) and Carhart (1997) as well as five trend-following factors of Fung and Hsieh (2001) on currency, bond, commodity, short-term interest rate, and stock index. The market factor (MKT) of Fama- French is the value-weighted NYSE/AMEX/NASDAQ (CRSP) market index return in excess of the risk-free rate (one-month T-bill rate). The size factor (SMB) is the return of a zero-cost long-short size-based portfolio that is long stocks with low market capitalization and short stocks with high market capitalization. The book-to-market factor (HML) of Fama-French is the return of a zero-cost long-short book-to-market ratio-based portfolio that is long stocks with high book-to-market ratios and short stocks with low book- to-market ratios. The momentum factor (MOM) of Carhart (1997) is the return of a portfolio that is long stocks with high momentum and short stocks with low momentum. Fung-Hsieh (2001) currency trend- following factor (FXTF) is measured as the return of PTFS (Primitive Trend Following Strayegy) Currency Lookback Straddle; bond trend-following factor (BDTF) is measured as the return of PTFS Bond Lookback Straddle; commodity trend-following factor (CMTF) is measured as the return of PTFS Commodity Lookback Straddle; short-term interest rate trend-following factor (IRTF) is measured as the return of PTFS Short Term Interest Rate Lookback Straddle; and stock index trend-following factor (SKTF) is measured as the return of PTFS Stock Index Lookback Straddle.[11]

4. Empirical Results

In this section, we investigate whether the maxium monthly return of individual hedge funds (MAX) can predict their future performance. We conduct parametric and nonparametric tests to assess the predictive power of MAX over future hedge fund

---

[10] By selecting a basket of investments, the managers of an active investment fund attempt to beat the returns of a relevant benchmark or of the overall market. The appraisal ratio measures the managers' performance by comparing the return of their security picks to the specific risk of those selections. The higher the ratio, the better the performance of the manager in question.

[11] The monthly returns on four factors of Fama-French-Carhart are obtained from Kenneth French's online data library: http://mba.tuck.dartmouth.edu/pages/faculty/ken.french/data library.html. The five trend-following factors of Fung and Hsieh (2001); FXTF, BDTF, CMTF, IRTF, SKTF are provided by David Hsieh at http://faculty.fuqua.duke.edu/~dah7/HFRFData.htm.

returns. First, we perform univariate portfolio-level analysis. Second, we examine the significance of cross-sectional persistence in MAX. Third, we provide average portfolio characteristics of MAX-sorted portfolios of invididual hedge funds. Fourth, we report results from bivariate portfolios of MAX and competing proxies of managerial skill. Fifth, we present results from univariate and multivariate cross-sectional regressions controlling for fund characteristics, past return, volatility, and liquidity measures. Sixth, we investigate whether the predictive power of MAX for future fund returns remains intact during subsample periods when significant structural breaks are observed. Finally, we examine the long-term predictive power of MAX.

4.1. *Univariate portfolio analysis of MAX*

For each month, from January 1995 to December 2014, we form quintile portfolios by sorting individual hedge funds based on their maximum monthly return over the past 6, 9, 12, 18, and 24 months (MAX6, MAX9, MAX12, MAX18, and MAX24), where quintile 1 contains the hedge funds with the lowest MAX and quintile 5 contains the hedge funds with the highest MAX. Table 2 shows the average MAX values and the next month average returns on MAX-sorted portfolios. The last two rows in Table 2 display the differences between quintile 5 and quintile 1 the average monthly returns and the 9-factor alphas.

The top panel in Table 2 presents the average magnitude of MAX6, MAX9, MAX12, MAX18, and MAX24 for the MAX-sorted portfolios. As expected, the maximum monthly return of hedge funds increases as the estimation window increases from 6 to 24 months. The first column in Table 2 shows that, for MAX6-sorted portfolios, the average maximum return of hedge funds over the past 6 months is 1.07% per month for quintile 1 and 12.67% per month for quintile 5. Comparing the first and last columns of the top panel in Table 2 shows that the corresponding average MAX values are considerably higher for MAX24-sorted portfolios; the average maximum return of hedge funds over the past 2 years is 2.24% per month for quintile 1 and 19.63% per month for quintile 5. Overall, the results in the top panel of Table 2 indicate substantial cross-sectional variations in all measures of MAX.

The bottom panel in Table 2 shows that for each MAX measure, moving from quintile 1 to quintile 5, the next month average return on the MAX-sorted portfolios increases monotonically, leading to an economically and statistically significant return spread between the high-MAX and low- MAX quintiles. Specifically, for MAX6-sorted portfolios, the average return increases from 0.10% to 0.91% per month, yielding a monthly average return difference of 0.81% between quintiles 5 and 1 with a Newey-West (1987) *t*-statistic of 3.85. This result indicates that hedge funds in the highest MAX quintile (funds with stronger managerial skill) generate about 9.72% more annual returns compared to funds in the lowest MAX quintile (funds with weaker managerial skill). Similar return spreads are obtained from other measures of MAX as well. The average return difference between quintiles 5 and 1 is 0.75% per month (*t*-stat. = 3.79) for MAX9-sorted portfolios, 0.70% per month (*t*-stat. = 3.48) for MAX12-sorted portfolios, 0.56%

per month (t-stat. = 3.08) for MAX18-sorted portfolios, and 0.53% per month (t-stat. = 2.94) for MAX24- sorted portfolios.

We also check whether the significant return spread between high-MAX and low-MAX funds is explained by Fama-French-Carhart's four factors of market, size, book-to-market, and momentum as well as Fung-Hsieh's five trend-following factors on currency, bond, commodity, short-term interest rate, and stock index. As shown in the last row of Table 2, the 9-factor alpha difference between quintiles 5 and 1 is positive and significant for all measures of MAX. Specifically, the risk-adjusted return spread between quintiles 5 and 1 is 0.55% per month (t-stat. = 2.87) for MAX6-sorted portfolios, 0.50% per month (t-stat.= 2.70) for MAX9-sorted portfolios, 0.47% per month (t-stat. = 2.44) for MAX12-sorted portfolios, 0.37% per month (t-stat. = 1.99) for MAX18-sorted portfolios, and 0.34% per month (t-stat. = 1.80) for MAX24-sorted portfolios. These results suggest that after controlling for the well-known factors, the return spread between high-MAX and low-MAX funds remains positive and significant.[12]

Next, we investigate the source of the raw and risk-adjusted return difference between the high- MAX and low-MAX portfolios: Is it due to outperformance by high-MAX funds, underperformance by low-MAX funds, or both? For this, we compare the economic and statistical significance of the average returns and the 9-factor alphas of quintile 1 vs. quintile 5. Panel A of Table 3 shows for MAX12-sorted portfolios that the average return and the 9-factor alpha of quintile 1 are 0.09% and –0.01% per month, with t-statistics of 1.08 and –0.20, respectively, indicating that the average raw and risk-adjusted returns of the low-MAX funds are economically and statistically insignificant. On the other hand, the average return and the 9-factor alpha of quintile 5 are 0.79% and 0.46% per month with t-statistics of 3.13 and 2.25, respectively, implying economically large and statistically significant positive returns for the high-MAX funds. These results provide evidence that the positive and significant return spread between the high-MAX and low-MAX funds is due to outperformance by the high-MAX funds with stronger managerial skill, but not due to underperformance by the low-MAX funds.[13]

In addition to the average raw returns and alphas, we compute the annualized Sharpe ratios and the 9-factor appraisal ratios of quintiles 1 and 5.[14] The annualized Sharpe ratio is found to be 0.33 for the low- MAX funds (quintile 1) and 0.83 for the high-MAX funds

---

[12] As expected, the predictive power of MAX does not remain significant when it is generated from long estimation windows because the maximum return observed in distant past does not capture future managerial skill that leads to higher future returns. For MAX24-sorted portfolios, the 9-factor alpha spread between quintiles 5 and 1 (0.34% per month) is economically significant, but it is only marginally significant with a t-statistic of 1.80. Consistent with our expectations, the predictive power of MAX becomes weaker when we extend the estimation window from 24 to 36 months.

[13] Instead of repeating the full set of analyses for all measures of MAX, we present the rest of our results based on MAX12 starting with Table 3 (and onwards). For notational simplicity, the maximum return over the past 12 months is from now on denoted by *MAX*.

[14] Brown, Goetzmann, Ibbotson, and Ross (1992) provide evidence that a fund that takes substantial risk and wins (thus earning a high MAX), that survives to a second year maintaining the same risk characteristics will either win or lose big. If these funds with high MAX lose, they may well die and so there could be a preponderance of winners conditioning on survival. Brown et al. (1992) point out a way to correct for this bias using the appraisal ratio rather than alpha. Hence, following Brown et al. (1992), we compute the appraisal ratio of MAX-sorted portfolios to address the look-ahead bias that may result from the necessity of funds surviving both a 12-month estimation period and a subsequent evaluation period.

(quintile 5). This indicates that the risk-adjusted return for the high-MAX funds is more than twice as large as that of the low-MAX funds. Similarly, the 9- factor appraisal ratio is estimated to be –0.02 for the low-MAX funds (quintile 1) and 0.21 for the high- MAX funds (quintile 5). This again implies that hedge funds with strong managerial skill generate higher risk-adjusted returns compared to funds with weak managerial skill, as the appraisal ratio measures the quality of a fund's investment-picking ability.

Proponents of passive money management believe that active portfolio managers do not provide significant value-added, because these fund managers lack asset-picking skills. This constituency believes markets are efficient; i.e., funds that outperform are considered lucky, funds that underperform are considered unlucky. However, our results suggest that there are certainly some professional money managers in the marketplace that can provide value above and beyond that can be obtained from a passively managed fund. Having said that, one may still wonder if investing in an index fund is the optimal decision for investors who lack the time and/or skills to identify skilled hedge fund managers. To test this hypothesis, we compute the annualized Sharpe ratio and the 8-factor appraisal ratio of the S&P500 index (passive money management) and then compare its risk-adjusted performance with the corresponding performance measures of the high-MAX and low-MAX funds.[15]

For the sample period of January 1995–December 2014, the annualized Sharpe ratio for the S&P500 index is estimated to be 0.52, which is 58% higher than the annualized Sharpe ratio for the low- MAX funds with weak managerial skill. This result suggests that investing in an index fund could be a better option for those investors who would only invest in hedge funds with weak managerial skill. More importantly, however, the annualized Sharpe ratio for the high-MAX funds is 60% higher than the annualized Sharpe ratio of the S&P 500 index, implying significant rewards for finding successful fund managers with strong investment-picking ability. Similar results are obtained from the 8-factor appraisal ratios as well; 0.07 for the low-MAX funds, 0.16 for the S&P500 index, and 0.27 for the high-MAX funds. Overall, these results provide evidence that active fund managers, by selecting a basket of investments, can indeed beat the overall market on a risk-adjusted return basis.

4.2. *Persistence of MAX*

Of course, the maximum return over the past 12 months documented in Panel A of Table 3 is for the portfolio formation month and, not for the subsequent month over which we measure average returns. Institutional investors as well as wealthy individual investors would like to pay high incentive and management fees for hedge funds that have exhibited high-MAX in the past in the expectation that this behavior will be repeated in the future. However, a natural question is whether these expectations are rational. Panel B of Table 3 investigates this issue by presenting the average month-to-month portfolio transition matrix. Specifically, Panel B presents the average probability that a

[15] When computing the 8-factor appraisal ratio for the S&P500 index, we use equation (1) without the market factor (MKT) since the S&P500 index is a proxy for the aggregate stock market and it is highly correlated with the value-weighted CRSP index.

hedge fund in quintile i (defined by the rows) in one month will be in quintile j (defined by the columns) in the subsequent 12 months. If MAX is completely random, then all the probabilities should be approximately 20%, since a high-MAX or low-MAX in one month should say nothing about the MAX in the following 12 months. Instead, all the top-left to bottom-right diagonal elements of the transition matrix exceed 30%, illustrating that the maximum return over the past 12 months is highly persistent even after putting a 12-month gap between the lagged and lead MAX variables. Of greater importance, this persistence is especially strong for the extreme MAX quintiles. Panel B of Table 3 shows that for the 12-month-ahead persistence of MAX, hedge funds in quintile 1 (quintile 5) have a 59.5% (58.2%) chance of appearing in the same quintile next year.

These results indicate that the estimated historical MAX successfully predicts future MAX and hence the maximum return observed over the past 12 months does capture the strength of future managerial talent leading to superior future performance.

A slightly different way to examine the persistence of MAX is to look at fund-level cross-sectional regressions of MAX on lagged predictor variables. Specifically, for each month in the sample we run a regression across funds of 12-month-ahead MAX on the current MAX and current fund characteristics:

$$R_{i,t+12} = \lambda_{0,t} + \lambda_{1,t} \cdot MAX_{i,t} + \lambda_{2,t} \cdot X_{i,t} + \varepsilon_{i,t+12}, \tag{2}$$

where $MAX_{i,t}$ is the maximum monthly return of fund i in month t over the past 12 months (from month t to t–12), $MAX_{i,t+12}$ is the 12-month-ahead MAX of fund i (from month t to t+12), and $X_{i,t}$ denotes past return, volatility, and other characteristics of fund i in month t. Specifically, $X_{i,t}$ includes the past 12-month average return (*AVRG*), the past 12-month standard deviation (*STDEV*), the past 1-month return (*LagRet*), and fund characteristics; *Size*, *Age*, *Flow*, *IncentFee*, *MgtFee*, *MinInvest*, *Redemption*, *DLockup*, and *Dlever*.

Table I in the online appendix reports the average cross-sectional coefficients from these regressions and the Newey-West adjusted t-statistics. In the univariate regression of 12-month-ahead MAX on current MAX, the average slope coefficient is positive, quite large, and extremely statistically significant, and the average R-squared of 28.5% indicates substantial cross-sectional predictive power. In other words, hedge funds with extreme positive returns over the past 12 months also tend to exhibit similar features in the following 12 months. This fund-level cross-sectional regression result confirms our finding from the portfolio-level transition matrix presented in Panel B of Table 3. When the aforementioned 12 control variables are added to the regression, the coefficient on lagged MAX remains large and highly significant (the last row in Table I). Besides MAX, of the remaining 12 variables, it is the standard deviation (*STDEV*), past 12-month average return (*AVRG*), past 1-month return (*Lagret*), and Incentive Fee (*IncentFee*) that contribute most to the preditive power of the regression, with univariate R-squareds of 6.7%, 5.6%, 4.6%, and 3.2%, respectively. The remaining 8 variables all have univariate R-squareds of less than 3%. Overall, the results in Table I indicate that the persistence of MAX is not captured by size, age, fee structure, risk/liquidity attibutes, and other characteristics of individual funds.

4.3. *Average portfolio characteristics*

To obtain a clearer picture of the composition of the MAX-sorted portfolios, Panel C of Table 3 presents summary statistics for the hedge funds in the quintiles. Specifically, Panel C reports the cross- sectional averages of various characteristics for the funds in each quintile averaged across the months. We report average values for the sort variable (the maximum return over the past 12 months denoted by *MAX*), the past 12-month return (*AVRG*), the past 12-month standard deviation (*STDEV*), the past 1-month return (*LagRet*), and fund characteristics; *Size*, *Age*, *Flow*, *IncentFee*, *MgtFee*, *MinInvest*, *Redemption*, *DLockup*, and *Dlever*.

Panel C of Table 3 shows that the high-MAX funds with stronger managerial skill have higher average 12-month return, higher 12-month standard deviation, higher past one-month return, higher incentive fee, higher management fee, larger fund flow, lower minimum investment amount, lower redemption period, and they have more frequent use of leverage. However, there is no clear pattern between MAX and fund size, fund age, and lockup. These average portfolio characteristics economicaly make sense because funds with stronger managerial skill (on average) outperform funds with weaker managerial skill. The ability of the high-MAX funds to produce higher returns motivates them to charge higher management and incentive fees to their clients, compared to the low-MAX funds with weak managerial skill. The high- MAX funds also attract more capital. Accodingly, their clients are indeed willing to pay higher fees and invest more in the high-MAX funds under the expectation of getting higher returns in the future. The findings in Panel C of Table 3 also suggest that the high-MAX funds have more frequent use of dynamic trading strategies with derivatives and leverage, which may enable them to possess better market-timing and macro-timing ability.[16] Hence, the monthly returns of the high-MAX funds have higher volatility than those of the low-MAX funds.

These results also indicate that the cross-sectional predictive power of the maximum return over the past 12 months (used as a proxy for managerial skill) can be driven by its correlation with AVRG, STDEV, LagRet, IncentFee, MgmtFee, Flow, MinInvest, Redemption, and/or Dlever. We address this potential concern in the following two sections by providing different ways of dealing with the potential interaction of MAX with the aforementioned fund characteristics and risk factors. Specifically, we test whether the positive relation between MAX and the cross-section of hedge fund returns still holds once we control for these variables using bivariate portfolio sorts and Fama-MacBeth (1973) regressions.

4.4. *Bivariate portfolio analysis of MAX and alternative measures of managerial skill*

In this section, we conduct a similar nonparametric portfolio analysis, but this time by accounting for the interaction between MAX and competing proxies of managerial skill. Basically, we perform a bivariate quintile portfolio test for MAX by controlling for the past 12-month average return (AVRG), the past 12-month standard deviation

---

[16] We provide a formal test of this hypothesis in Section 6.

(STDEV), the past 12-month Sharpe ratio (SR), the apprasisal ratio (9- factor AR) defined in equation (1), incentive fee, and fund flows.

To perform this test, in Table 4 quintile portfolios are formed every month from January 1995 to December 2014 by sorting hedge funds first based on each control variable (i.e., competing proxy for managerial skill; AVRG, STDEV, Sharpe ratio, Appraisal ratio, incentive fee, and fund flows). Then, within each control variable sorted portfolio, hedge funds are further sorted into sub-quintiles based on their MAX. Quintile 1 is the portfolio of hedge funds with the lowest MAX within each control variable sorted quintile portfolio and quintile 5 is the portfolio of hedge funds with the highest MAX within each control variable sorted portfolio. In each column of Table 4, the top panel reports the average MAX in each quintile and the lower panel reports those same quintiles' next month average returns. The last two rows in Table 4 show the monthly average return differences and the 9-factor alpha differences between quintile 5 (high-MAX funds) and quintile 1 (low-MAX funds).

A notable point in Table 4 is that moving from the low-MAX to high-MAX quintile, the next- month average return on MAX-sorted portfolios increases monotonically after controlling for all competing proxies of managerial skill. Specifically, the average return difference between quintiles 5 and 1 is 0.44% per month with a Newey-west *t*-static of 3.02 after controlling for the past 12-month average return, 0.69% per month (*t*-stat. = 5.71) after controlling for the past 12-month standard deviation, 0.67% per month (*t*-stat. = 3.39) after controlling for the past 12-month Sharpe ratio, 0.69% per month (*t*-stat. = 3.46) after controlling for the appraisal ratio, 0.68% per month (*t*-stat. = 3.37) after controlling for incentive fees, and 0.68% per month (*t*-stat. = 3.55) after controlling for the fund flows. We also check whether this significant return difference between the high-MAX and low-MAX portfolios from bivariate sorts can be explained by Fama-French (1993) and Carhart's (1997) four factors as well as Fung and Hsieh's (2001) five trend-following factors. As shown in the last row of Table 4, the 9-factor alpha differences between quintiles 5 and 1 are all positive, ranging from 0.29% to 0.68% per month, and all are statistically significant with Newey-West *t*-statistics well above 2.00.

These results provide strong evidence that after controlling for competing proxies of managerial skill and a large set of risk factors, the return difference between the high-MAX and low-MAX funds remains positive and highly significant. Hence, we conclude that MAX can be viewed as an indicator of graeter managerial talent leading to superior future performance.

4.5. *Fama-MacBeth cross-sectional regressions*

We have so far tested the significance of MAX as a determinant of the cross-section of hedge fund returns at the portfolio level. The portfolio-level analysis has the advantage of being nonparametric in the sense that we do not impose a functional form on the relation between MAX and future returns. The portfolio-level analysis also has two potentially significant disadvantages. First, it throws away a large amount of information in the cross-section via aggregation. Second, it is a difficult setting in which to control for multiple effects simultaneously. Consequently, we now examine the cross-sectional relation between managerial skill and future returns at the individual fund level using Fama and MacBeth (1973) regressions.

We present the time-series averages of the slope coefficients from the regressions of one-month- ahead hedge fund excess returns on the maximum return over the past 12 months (MAX) and a large set of control variables. The average slopes provide standard Fama-MacBeth tests for determining which explanatory variables, on average, have non-zero premiums. Monthly cross-sectional regressions are run for the following econometric specification and nested versions thereof:

$$R_{i,t+1} = \lambda_{0,t} + \lambda_{1,t} \cdot MAX_{i,t} + \lambda_{2,t} \cdot X_{i,t} + \varepsilon_{i,t+1}, \tag{3}$$

where $R_{i,t+1}$ is the excess return of fund *i* in month *t*+1, *MAX* is the maximum monthly return of fund *i* in month *t* over the past 12 months (from month *t* to *t*–12), and $X_{i,t}$ denotes a large set of fund characteristics such as past returns, volatility, and risk-adjusted return measures of fund *i* in month *t*. Specifically, $X_{i,t}$ includes the following fund characteristics; *Size*, *Age*, *Flow*, *IncentFee*, *MgtFee*, *MinInv*, *Redemption*, *DLockup*, and *DLever*. In addition to these characteristics, $X_{i,t}$ includes the one-month lagged fund returns (*LagRet*), the past 12-month average return (*AVRG*), the past 12-month standard deviation (*STDEV*), and the past 12-month Sharpe ratio (SR) computed as the past 12-month average excess return divided by the past 12-month standard deviation.[17]

Panel A of Table 5 presents the average intercept and slope coefficients from the Fama-MacBeth cross-sectional regressions for the full sample period January 1995 – December 2014. The Newey-West adjusted *t*-statistics are given in parentheses. We first investigate the cross-sectional relation between MAX and future fund returns without taking into account fund characteristics, lagged return, lagged volatility, and lagged risk-adjusted return (Sharpe ratio). Consistent with our earlier findings from the univariate portfolio analysis, Regression (1) in Panel A of Table 5 provides evidence for a positive and highly significant relation between MAX and future fund returns. The average slope from the monthly univariate regressions of one-month-ahead returns on MAX alone is 0.042 with a Newey-West *t*-statistic of 3.52.

To determine the economic significance of this average slope coefficient, we use the average values of MAX in the quintile portfolios. Table 3 shows that the difference in MAX values between average funds in the first and fifth quintile is 14.21% per month [14.21% = 15.88% – 1.67%]. If a fund were to move from the first to the fifth quintile of MAX, what would be the change in that fund's expected return? The average slope coefficient of 0.042 on MAX in Panel A of Table 5 represents an economically significant increase of $(0.042) \cdot (14.21\%) = 0.60\%$ per month in the average fund's expected return for moving from the first to the fifth quintile of MAX. This result is

[17] At an earlier stage of the study, we replace the Sharpe ratio with the appraisal ratio and replicate the multivariate regressions. Since the Sharpe and appraisal ratios are highly correlated in the cross-section of individual hedge funds, the regression results from the appraisal ratio turn out to be very similar to those reported in our tables.

similar to our earlier finding of a 0.70% per month return difference between the high-MAX and low-MAX funds from univariate portfolio analysis reported in Table 3, Panel A.

After confirming a significantly positive link between MAX and future returns in univariate Fama- MacBeth regresions, we now control for all fund characteristics, lagged return, lagged volatility, and lagged risk-adjusted return simultaneously and test if managerial skill of hedge funds remains a strong predictor of future returns. Regression (2) in Panel A of Table 5 shows that the average slope on MAX is 0.030 with a Newey-West *t*-statistic of 3.35, implying that after controlling for a large set of fund characteristics, risk factors, and alternative proxies of managerial skill, the positive relation between MAX and future hedge fund returns remains highly significant.

As expected, the average slope for MAX in Panel B of Table 5 is somewhat smaller (0.030 in Panel B vs. 0.042 in Panel A) after accounting for the large set of control variables. However, the average slope of 0.030 still represents an economically significant increase of 0.43% per month in the average fund’s expected return for moving from the first to the fifth quintile of MAX, controlling for everything else.

A notable point in Table 5 is that the average slope coefficients on the control variables are consistent with earlier studies. Regression (2) in Panel A of Table 5 shows that the average slope on the one-month lagged fund returns (LagRet) and the past 12-month average return (AVRG) is positive and highly significant.[18] Consistent with the findings of Bali, Brown, and Caglayan (2012), the average slope on the standard deviation of fund returns (STDEV) is also positive and statistically significant. In addition, in line with the findings of Titman and Tiu (2012), the average slope on the Sharpe ratio is again positive and highly significant. Despite the fact that past return, past volatility, and past risk-adjusted return measures of individual hedge funds are found to be significant predictors, the significantly positive link between MAX and future fund returns remains highly significant, suggesting that MAX is a strong predictor of future hedge fund performance.

Another interesting observation that emerges from Table 5, Panel A is that the incentive fee variable has a positive and significant coefficient in monthly Fama-MacBeth regressions, even when other fund characteristics are added to the regression equation.[19] As in previous results, however, the significance of incentive fee does not diminish the predictive power of MAX on future hedge fund returns. One last noteworthy point from Table 5, Panel A is that the minimum investment amount, the redemption period, and the dummy for lockup variables, which are used by Aragon (2007)

---

[18] A similar result, that there is serial dependence in hedge fund returns is also found by Agarwal and Naik (2000), Getmansky, Lo, and Makarov (2004), Jagannathan, Malakhov, and Novikov (2010), and Bali, Brown, and Caglayan (2011, 2012, 2014). Jegadeesh and Titman (1993, 2001) find momentum in stock returns for 3, 6, 9, and 12-month horizons, although Jegadeesh (1990) and Lehmann (1990) provide strong evidence for the short-term reversal effect in individual stock returns for the one-week to one-month horizon. In addition to accounting for lagged returns in Fama-MacBeth regressions, we control for this phenomenon using the Carhart (1997) momentum factor in portfolio- level analyses.

[19] This suggests that incentive fee has a strong positive explanatory power for future hedge fund returns (i.e., funds that charge higher incentive fees also generate higher future returns), a finding similar to other studies (see Brown, Goetzmann, and Ibbotson (1999), Liang (1999), and Edwards and Caglayan (2001)).

to measure illiquidity of hedge fund portfolios, also have positive and significant average slope coefficients. This suggests that funds that use lockup and other share restrictions which enable them to invest in illiquid assets earn higher returns in succeeding months, an outcome that coincides with the findings in Aragon (2007). However, even the significance of these liquidity variables does not alter or reduce the predictive power of MAX over hedge fund returns.

4.6. *Subsample analyses*

The cross-sectional predictability results reported in earlier tables are based on the 20-year sample period from January 1995 to December 2014. We now investigate whether the predictive power of *MAX* for future fund returns remains intact during subsample periods. We conduct subsample anlaysis by dividing the full sample into two and then examining the significance of *MAX* for the first decade (January 1995 – December 2004) and the second decade (January 2005 – December 2014) separately. In addition to these two subsample periods, we examine the predictive power of *MAX* during high and low economic activity (i.e., good vs. bad states of the economy). We determine increases and decreases in economic activity by relying on the Chicago Fed National Activity (CFNAI) index, which is a monthly index designed to assess overall economic activity and related inflationary pressure. The CFNAI is a weighted average of 85 existing monthly indicators of national economic activity. It is constructed to have an average value of zero and a standard deviation of one. Since economic activity tends toward trend growth rate over time, a positive index reading corresponds to growth above trend and a negative index reading corresponds to growth below trend.[20]

We perform subsample analyses based on the Fama-MacBeth cross-sectional regressions. Panel B of Table 5 shows that, for the first half of our sample, the average slope on MAX is positive and highly significant both in univariate and multivariate regressions. The average slope from the monthly univariate regressions of one-month-ahead returns on MAX alone is 0.036 with a Newey-West *t*-statistic of 2.29. After controlling for a large set of fund characteristics, past return, volatility, and risk-adjusted returns, the average slope on MAX remains positive, 0.028 with a t-statistic of 2.12. These two average slopes (0.036 and 0.028) for the period 1995-2004 represent an economically significant increase of 0.60% and 0.47% per month, respectively, in the average fund's expected return for moving from the first to the fifth quintile of *MAX*.

Panel C of Table 5 shows that the predictive power of MAX is stronger for the second half of our sample. Specifically, the average slope on MAX has a larger magnitude of 0.048 in univariate regressions and higher statistical significance with a Newey-West *t*-statistic of 2.66. After controlling for the same set of variables, the average slope on MAX also remains positive and larger at 0.031 with a *t*-statistic of 2.62, compared to our

[20] The 85 economic indicators that are included in the CFNAI are drawn from four broad categories of data: production and income; employment, unemployment, and hours; personal consumption and housing; and sales, orders, and inventories. Each of these data series measures some aspect of overall macroeconomic activity. The derived index provides a single, summary measure of a factor common to these national economic data.

findings from the first decade (reported in Panel B of Table 5). We find that the economic significance of these two average slopes (0.048 and 0.031) for the period 2005-2014 corresponds to 0.56% and 0.36% per month increase, respectively, in the average fund's expected return when moving from the first to the fifth quintile of MAX. The results in Panels B and C of Table 5 indicate that successful hedge fund managers are able to produce superior returns during both subsample periods.

We now present the Fama-MacBeth regression results during the good and bad states of the economy separately. In Panel D of Table 5, monthly cross-sectional regressions are estimated only for those months when the CFNAI index is positive on a given month during the period January 1995– December 2014. Panel D shows that, for the good states of the economy (CFNAI > 0), the average slope on MAX is positive and highly significant in univariate regressions and after accounting for the control variables. The average slope from the monthly univariate regressions of one-month-ahead returns on MAX alone is 0.051 with a *t*-statistic of 4.09. After controlling for a large set of fund characteristics, past return, volatility, and risk-adjusted returns, the average slope on MAX remains positive, 0.033 with a *t*-statistic of 3.09. These two average slopes (0.051 and 0.033) for the good states of the economy represent an economically significant increase of 0.73% and 0.47% per month, respectively, in the average fund's expected return for moving from the first to the fifth quintile of MAX.

Panel E of Table 5 examines the predictive power of MAX during low economic activity for those months when the CFNAI index is negative. During the bad states of the economy (CFNAI < 0), the average slope on MAX in univariate regressions is again positive and statisitcally significant; 0.033 with a *t*-statistic of 2.21. After controlling for the same set of variables, the average slope on MAX remains significantly positive at 0.026 with a *t*-statistic of 2.34. We find that the economic significance of these two average slopes (0.033 and 0.026) during the bad states of the economy corresponds to 0.46% and 0.37% per month increase, respectively, in the average fund's expected return when moving from the first to the fifth quintile of MAX. Overall, the results in Panels D and E of Table 5 provide evidence that hedge fund managers with a strong set of skills are able to perform better than those with weak managerial skill during both good and bad states of the economy.

Despite large fluctuations observed in risk, return, and managerial characteristics of hedge funds during these four subperiods, Panels B through E of Table 5 provide evidence of a positive and significant relation between MAX and future fund returns for all subsample periods. These results clearly show that with and without controlling for a large set of variables, managerial skill is an important determinant of the cross-sectional dispersion in hedge fund returns for all states of the economy, including expansionary and contractionary periods.[21]

[21] We test the predictive power of MAX over future hedge fund returns with two alternative multivariate Fama- MacBeth specifications as well. Table II in the online appendix reports that, both for the full sample period and the subsample periods, the average slope coefficient on MAX is always positive and highly significant with Newey-west *t*-statistics well above 2.00, suggesting that our results are robust to alternative specifications of cross-sectional regressions.

4.7. *Long-term predictive power of MAX*

In this section, we investigate the long-term predictive power of MAX. Our empirical analyses have thus far focused on one-month-ahead return predictability. However, from a practical standpoint it would make sense to investigate the predictive power of MAX for longer investment horizons, since some investors and hedge fund portfolio managers may prefer portfolio holding periods or investment horizons longer than one month. We examine the long-term predictive power of MAX based on the univariate quintile portfolios. Table III in the online appendix reports the next 3-, 6-, 9-, and 12-month average returns for each of the five quintiles of MAX. The average return difference between quintiles 5 and 1 is 0.60% per month (*t*-stat. = 3.42) for 3-month ahead predictability, 0.49% per month (*t*-stat. = 3.13) for 6-month ahead predictability, 0.41% per month (*t*-stat. = 2.68) for 9-month ahead predictability, and 0.37% per month (*t*-stat. = 2.47) for 12-month ahead predictability. These results indicate that the positive relation between MAX and future fund returns is not just a one-month affair. Based on the average return spreads, the maximum return over the past 12 months predicts cross-sectional variation in hedge fund returns 12 months into the future.

The last row of Table III of the online appendix shows that the 9-factor alpha spread between quintiles 5 and 1 is 0.39% per month (*t*-stat. = 2.29) for 3-month ahead predictability, 0.33% per month (*t*-stat. = 2.11) for 6-month ahead predictability, 0.30% per month (*t*-stat. = 2.04) for 9-month ahead predictability, and 0.25% per month (*t*-stat. = 1.60) for 12-month ahead predictability. The 9-factor alpha spreads show that funds with higher MAX (stronger managerial skill) outperform funds with lower MAX (weaker managerial skill) not just for one-month-ahead, but nine months into the future.

5. Managerial Skill and Hedge Fund Performance by Investment Style

In this section, we first classify hedge funds into three groups (directional, semi-directional, and non-directional) and examine the strength of managerial skill and its link to derivatives use for each investment style. Then, we test if the predictive power of MAX changes among different hedge fund strategies. Second, we investigate whether hedge funds have the ability to time fluctuations in the equity market and macroeconomic fundamentals. Finally, we test whether investors take differences in managerial skill into account and are willing to pay higher fees and invest more in the high-MAX funds.

5.1. *Predictive power of MAX by hedge fund investment style*

We now test whether our main findings change if our analysis is applied to homogeneous groups of hedge funds, i.e., hedge fund investment strategies. Hedge funds have various trading strategies; some willingly take direct market exposure and risk (directional strategies, such as managed futures, global macro, and emerging market funds), while some try to minimize market risk altogether (non-directional strategies, such as equity market neutral, fixed income arbitrage, and convertible arbitrage funds), and some try to diversify market risk by taking both long and short, diversified positions (semi-directional strategies, such as fund of funds, long-short equity hedge, event-driven, and multi-strategy funds).

Table 6 provides some information and statistics on directional, semi-directional, and non- directional hedge fund categories. The first row in Table 6 presents the number of funds existing in each of the three broad investment categories. The second row in Table 6 reports for the same three broad categories the percentage of hedge funds in total sample. As shown in Table 6, we have a total of 7,645 hedge funds in our TASS database that claim a specific investment strategy, of which 9.4% follows non-directional strategies, 20.2% follows directional strategies, and the remaining 70.4% follows semi- directional strategies.

Given these three broad hedge fund investment strategies, it is not surprising to see varying strength of managerial skill and varying degrees of market/macro-timing ability by different investment strategy groups. Even within the same investment style group, one can observe varying degrees of exposures to different financial and macroeconomic risk factors over time, as hedge fund managers adjust their exposures dynamically in response to changing market conditions.

To understand the strength and variation in managerial skill among different investment strategies, we first analyze average MAX, standard deviation of MAX, and the spread between maximum and minimum values of MAX for these aforementioned three broad categories of hedge fund investment strategies separately. The third row in Table 6 presents the cross-sectional average of individual funds' MAX within each category during the full sample period. The fourth row presents the cross-sectional average of the individual funds' time-series standard deviation of MAX within each category during the sample period. The fifth row reports the cross-sectional average of the spread between the maximum and minium values of MAX within each category. As can be noticed by reading from left to right in Table 6, the directional funds have noticeably larger MAX, higher standard deviation of MAX, and greater Max– Min spread of MAX compared to non-directional and semi-directional funds. In addition, the non- directional strategies' MAX, standard deviation of MAX, and Max–Min spread of MAX are considerably smaller compared to the other strategies. Lastly, the semi-directional funds have average MAX, standard deviation of MAX, and Max–Min spread of MAX that are very similar to the all hedge fund group. We believe that directional funds' large standard deviation and large Max–Min spread of MAX might be due to superior market-timing ability of these funds' managers. In particular, when the opportunity comes (or predicted by fund managers), directional funds adjust their portfolios in such a way that they can generate large positive returns, causing their MAX to be more volatile and Max–Min spread to be larger.

Although not reported in Table 6, we test whether the average MAX of directional funds is significantly higher than the average MAX of non-directional funds, semi-directional, and all hedge funds in our sample. We find that the difference between the average MAX of directional and non-directional funds is economically very large, 5.56% (9.61% – 4.05%) per month, and highly significant with a Newey- West *t*-statistic of 22.04. Similar results are obtained when we compare the average magnitude of MAX for directional funds vs. semi-directional and all hedge funds. Specifically, the difference between the average MAX of directional and semi-directional funds is again economically large, 3.63% (9.61% – 5.98%) per month with a Newey-West *t*-statistics of 17.62; and the difference between average MAX of directional and all hedge funds is again economically large, 3.05% (9.61% – 6.56%) per month, and again highly significant with Newey-West *t*-statistics of 20.01. Overall, these results indicate that, for directional funds, the average MAX (proxy for managerial skill) is significantly greater than that of non-directional and semi-directional funds.

The last two rows in Table 6 report, for each of the three broad investment categories separately, the percentages of funds that utilize futures and other derivatives in their investment strategies. Table 6 clearly shows that the percentage of funds using futures and other derivatives increases monotonically as we move from the non-directional to the directional strategy group. Specifically, the percentage of funds using futures is 13.9% for the non-directional funds, 14% for the semi-directional funds, and 41% for the directional funds. Similarly, the percentage of funds using other derivatives is 17.5% for the non-directional funds, 18.5% for the semi-directional funds, and 24.1% for the directional funds. Overall, these results indicate that the directional funds with higher MAX and stronger managerial skill employ a wide variety of dynamic trading strategies and make extensive use of derivatives, short-selling, and leverage, compared to the semi-directional and non-directional funds with lower MAX and weaker managerial skill.

Based on this new set of results on varying strength of managerial skill among hedge fund investment strategies, we expect our main finding — a significantly positive link between MAX and future returns obtained for the overall hedge fund category — to be strongest for the directional funds with higher MAX and stronger managerial skill, and relatively weaker for the non-directional funds with lower MAX and weaker managerial skill. We now investigate the predictive power of MAX over future hedge fund returns for the three aforementioned investment strategies separately, and check whether indeed a larger MAX and dynamic trading strategies with more frequent use of futures and other derivatives are associated with stronger predictive power. We perform this test in Table 7 by forming univariate quintile portfolios of MAX for each investment style separately and by analyzing the next-month return and alpha differences between the high-MAX and low-MAX quintiles.

A notable point in Table 7 is that the average return and 9-factor alpha spreads between the high- MAX and low-MAX quintiles increase monotonically as we move from the non-directional to the directional funds. Specifically, the average return difference between quintiles 5 and 1 is 0.50% per month (*t*-stat. = 3.11) for the non-directional funds, 0.69% per month (*t*-stat. = 3.00) for the semi-directional funds, and 0.88% per month (*t*-stat. = 3.71) for the directional funds. The 9-factor alpha spreads follow a similar pattern among the three investment strategies; 0.30% per month (*t*-stat. = 2.11) for the non-directional funds, 0.40% per month (*t*-stat. = 2.43) for the semi-directional funds, and 0.76% per month (*t*-stat. = 2.71) for the directional funds.

Combining these new sets of results with the results obtained earlier on the strength of managerial skill (proxied by the magnitude of MAX) and the frequency of derivatives use across different investment styles, we observe an economically and statistically stronger relation between MAX and future returns for funds with higher MAX and more frequent use of futures and other derivatives. Another possible explanation for the stronger performance of funds with higher MAX and more frequent use of derivatives could be the market- and macro-timing ability of hedge fund managers. In the next section, we provide a formal test of the market- and macro-timing ability of the directional, semi-directional, and non-directional hedge funds.

5.2. *Market- and macro-timing ability of hedge funds*

While the results from the above analysis suggest the existence of a possible market-timing and/or macro-timing ability by fund managers in directional and semi-directional hedge funds, the analysis conducted thus far is not a direct test for market- or macro-timing. In this section, we rely on the market- timing test of Henriksson and Merton (1981) and the macro-timing test of Bali, Brown, and Caglayan (2014). We implement the same methodology to each of the three broad categories of hedge fund styles separately and determine whether funds' ability to time market and macroeconomic changes is specific to a group of hedge funds.

We investigate market-timing ability of hedge funds using pooled panel regressions based on the Henriksson and Merton model:[22]

$$R_{i,t} = \alpha + \beta_1 \cdot MKT_t + \beta_2 \cdot MKT_t^{high} + \varepsilon_{i,t}, \tag{4}$$

where $R_{i,t}$ is excess return of fund i in month t, MKT_t is the excess market return in month t, and MKT_t^{high} is the excess market return implying market-timing ability:

$$MKT_t^{high} = \begin{cases} MKT_t & \text{if } MKT_t \text{ is higher than its time-series median} \\ 0 & \text{otherwise} \end{cases}$$

In equation (4), regression parameters α, β_1, and β_2 are the intercept, the market beta, and the parameter for market-timing ability, respectively. Market timing indicates an increase (decrease) in market exposure prior to a market rise (fall), which results in a convex relation between fund returns and market returns. In this regression specification, a positive and significant estimate of β_2 implies superior market-timing ability of individual hedge funds.

Following Bali, Brown, and Caglayan (2014), we also investigate macro-timing ability of hedge funds using pooled panel regressions based on a modified model of Henriksson and Merton (1981):

$$R_{i,t} = \alpha + \beta_1 \cdot UNC_t + \beta_2 \cdot UNC_t^{high} + \varepsilon_{i,t}, \tag{5}$$

[22] Similar methodology is also used in a different context by Jagannathan and Korajczyk (1986), Chen and Liang (2007), Cao, Chen, Liang, and Lo (2013), and Caglayan and Ulutas (2013).

Where $R_{i,t}$ is excess return of fund i in month t, UNC_t is the economic uncertainty index of Bali et al. (2014) in month t, and UNC_t^{high} is the economic uncertainty index implying macro-timing ability:

$$UNC_t^{high} = \begin{cases} UNC_t & \text{if } UNC_t \text{ is higher than its time-series median} \\ 0 & \text{otherwise} \end{cases}$$

In equation (5), regression parameters α, β_1, and β_2 are the intercept, the uncertainty beta, and the parameter for macro-timing ability, respectively. In this regression specification, a positive and significant estimate of β_2 implies superior macro-timing ability of individual hedge funds.

Table 8 presents the estimated values of β_2 and the corresponding t-statistics from the pooled panel regression specifications in eqs. (4) and (5) for the sample period January 1995–December 2014. Equations (4) and (5) are estimated separately for each of the three hedge fund categories (non-directional, semi- directional, and directional). The t-statistics reported in parentheses are estimated using clustered robust standard errors, accounting for two dimensions of cluster correlation (fund and year). This approach allows for correlations among different funds in the same year as well as correlations among different years in the same fund (see Petersen (2009) for estimation of clustered robust standard errors).

As reported in the first row of Table 8, for market-timing tests, β_2 is estimated to be positive, 0.277, and highly significant with a t-statistic of 2.62 for the directional hedge funds. β_2 is also positive, 0.169, and significant with a t-statistic of 2.07 for the semi-directional hedge funds. However, the statistical and economic significance of β_2 is higher for the directional funds compared to the semi-directional funds. This indicates that directional hedge fund managers have higher capability to time fluctuations in the equity market. Consistent with our expectation, Table 8 shows that β_2 is economically and statistically insignificant for the non-directional funds, providing no evidence of market-timing ability for the non- directional hedge fund managers.

Similar results are obtained from the macro-timing tests. As presented in the last row of Table 8, β_2 is estimated to be positive, 0.894, and highly significant with a t-statistic of 2.58 for the directional hedge funds. Similar to our earlier findings from the market-timing tests, β_2 is positive, 0.494, and significant with a t-statistic of 2.32 for the semi-directional hedge funds. Consistent with the findings of Bali, Brown, and Caglayan (2014), the statistical and economic significance of β_2 is higher for the directional funds compared to the semi-directional funds, implying that the directional hedge fund managers have higher capability to time fluctuations in macroeconomic changes. As expected, β_2 is again economically and statistically insignificant for the non-directional funds, providing no evidence of macro-timing ability for the non-directional hedge fund managers.

Overall, these results make sense in the real world setting of hedge funds, as directional funds willingly take direct exposure to financial and macroeconomic risk factors, relying on their market-timing and macro-timing ability to generate superior returns. Since these are funds with dynamic trading strategies frequently using derivatives/leverage that are highly exposed to market and macroeconomic risk, timing the switch in economic trends is essential to their success. Hence, our previous results, which show a stronger link between *MAX* and future returns for the directional funds with stronger managerial skill (proxied by higher *MAX*), can be attributed to the evidence of superior market- and macro-timing ability of directional hedge fund managers.

5.3. *Do investors prefer high-MAX funds?*

Our results indicate that hedge fund portfolio managers with better managerial skill and better market- and macro-timing ability will employ an investment strategy that generates larger positive returns (high-MAX). Thus, sophisticated investors should consider past MAX as an indicator of managerial talent. To examine whether investors take differences in managerial skill into account, we test if investors are indeed willing to pay higher fees for funds with high-MAX.

As shown in Panel C of Table 3, the average management and incentive fees of individual funds increase monotonically when moving from quintile 1 to 5 in the univariate MAX-sorted portfolios. Specifically, the average management fee increases monotonically from 1.34% for the low-MAX funds to 1.58% for the high-MAX funds. Similarly, the average incentive fee increases monotonically from 12.9% for the low-MAX funds to 17.9% for the high-MAX funds.[23]

In addition to these portfolio-level analysis presenting a strong positive relation between MAX and fees, we run multivariate Fama-MacBeth regressions to check if this strong relation remains intact after controlling for individual fund characteristics, past performance, and risk/liquidity attributes. Table IV in the online appendix reports the average intercept and slope coefficients from the Fama-MacBeth regressions of management/incentive fees on MAX with and without control variables for the sample period January 1995 – December 2014. The univariate regression results (line (1) in Panel A and Panel B of Table IV) confirm the portfolio-level results presented in Panel C of Table 3. The multivariate regressions reported in line (2) of Panels A and B of Table IV produce consistently positive and highly significant average slope coefficients on MAX, indicating a strong positive link between MAX and hedge fund fees after controlling for past fund performance and other fund-specific characteristics.

To test the hypothesis that the high-MAX funds also attract more capital flows, we examine the cross-sectional relation between MAX and the one-month-ahead net flows into the fund. Specifically, we sort individual hedge funds into quintile portfolios based on their MAX and then calculate the average one- month-ahead net flows of funds in each quintile. The results indicate that the average net monthly flow, as a percentage of assets, is 52 basis points greater for the high-MAX funds than for the low-MAX funds. The

[23] The TASS database rewrites the fees if hedge funds change their management and/or incentive fee structure. The management and incentive fees used in our empirical analyses are as of December 2014. Since fees do not change much during a fund's history, one can assume that they were set at the beginning of the fund's history.

difference between the net monthly flows of high-MAX and low-MAX funds is also highly significant with a Newey-West t-statistic of 3.69.

We also run multivariate Fama-MacBeth regressions to check if this strong predictive relation between MAX and fund flows remains intact after controlling for individual fund characteristics, past performance, and risk/liquidity attributes. Panel C of Table IV in the online appendix presents the average intercept and slope coefficients from the Fama-MacBeth regressions of the one-month-ahead net fund flows on MAX with and without control variables for the sample period January 1995 – December 2014. The significantly positive average slope on MAX from the univariate regressions (average slope coefficient of 0.020 with a t-statistics of 2.96) confirm the portfolio-level results discussed earlier. The multivariate regressions reported in Panel C of Table IV produce consistently positive and highly significant average slope coefficient on MAX (average slope coefficient of 0.026 with a t-statistics of 3.76), indicating a strong positive link between MAX and the one-month-ahead net flows into the fund after controlling for past fund performance and other fund-specific characteristics.

Overall, the results in Section 5 indicate that the high-MAX funds have more frequent use of dynamic trading strategies with derivatives and leverage, which enable them to possess better market- and macro-timing ability. The ability of the high-MAX funds to produce higher returns motivates them to charge higher management and incentive fees to their clients, compared to the low-MAX funds with weak managerial skill. In addition, the high-MAX funds attract more capital (higher net inflows) as well. The findings in Table IV of the online appendix show that funds with high-MAX are rewarded with higher fees because investors learn about managerial skills and they are indeed willing to pay higher fees and invest more in the high-MAX funds under the expectation of receiving large positive returns in the future.

6. Evidence from Mutual Funds

We think that an alternative way to explain superior performance of the directional and semi- directional hedge funds with higher MAX and stronger managerial skill is to compare and contrast hedge funds with mutual funds. Therefore, in this section, we provide evidence from mutual funds by replicating our main analyses for the mutual fund industry for the sample period January 1995–June 2013.[24] We first investigate whether managerial talent of mutual fund managers (proxied by the maximum monthly return of mutual funds over the past one year) predicts their future returns. We then analyze whether mutual funds have the ability to time fluctuations in the equity market and

[24] We use monthly returns of individual mutual funds from the CRSP Mutual Fund database. However, most of the mutual funds in the CRSP database have multiple share classes designed for different client types. That is, a mutual fund may have a retail share class, an institutional share class, or a retirement share class. All of these share classes in essence constitute the same strategy, therefore their returns are highly correlated. As discussed in Section I of the online appendix, we make sure that each mutual fund is represented with a single share class in our database. After removing multiple share classes, our database contains information on a total of 16,881 distinct, non-duplicated mutual funds, of which 7,073 are defunct funds and the remaining 9,808 are live funds. Table V of the online appendix provides summary statistics both on numbers and returns of these single-share class, non-duplicated mutual funds.

macroeconomic fundamentals. Finally, we test the economic and statistical significance of timing ability for hedge funds vs. mutual funds.

6.1. *Does managerial skill matter for mutual fund performance?*

The primary differences between hedge funds and mutual funds are summarized as follows: (i) Hedge funds employ a range of investment tools, including derivatives, leverage, and short-selling, whereas mutual funds tend to invest primarily on the long side without extensively using other tools. The majority of mutual funds are long only, while hedge funds utilize much more aggressive dynamic trading strategies; (ii) Since hedge funds rely on hedging instruments and shorting techniques, they are more likely to outperform mutual funds in a down market; (iii) Mutual funds seek relative returns, or those compared to a benchmark or index. A mutual fund's sole goal is to beat the benchmark. Therefore, if the index is down 10% but the mutual fund is down only 8%, it is considered a success. On the flip side, hedge funds seek absolute returns, not related to index or benchmark performance; (iv) Hedge fund managers receive a performance fee at the end of the year paid from investor gains. Mutual funds typically do not charge performance fees. The most common hedge fund fee structure is the 2/20 – a 2% flat management fee skimmed off the top, and a 20% fee on all profits. Most mutual funds charge less than 2% in total fees; (v) The founder of a hedge fund is the general partner and an investor in the fund. The manager of a mutual fund is seldom the owner and may not be a significant fund investor; and (vi) Hedge funds have lockup periods typically of at least one year. That is, each investment must remain in the hedge fund for at least one year (the lockup period). Withdrawals are permitted only with advance notice following the lockup period. Therefore, in difficult market periods or economic conditions, some hedge funds put up gates that restrict redemptions. On the other hand, investments in mutual funds are essentially liquid and are not impacted by lock-ups or gates.[25]

The primary similarity between hedge funds and mutual funds is that both are managed portfolios. In other words, a manager or group of managers selects investments and adds them to a single portfolio. However, hedge funds are managed in a more aggressive manner than mutual funds. From the ability to short-sell stocks to taking positions in derivatives, hedge fund managers are more aggressive, as they attempt to generate the best gains possible for clients. With such an aggressive stance, hedge funds are in a better position to earn money even when the market is falling.

From an investment style perspective, mutual funds can be viewed as highly regulated hedge funds with a larger number of investors and larger AUM. Since mutual funds do not use dynamic trading strategies with unique investment ideas, we do not expect cross-sectional differences in managerial skills of mutual fund managers to explain cross-sectional dispersion in mutual fund returns. Along the same lines, we do not expect mutual funds to have significant market- or macro-timing ability either.

[25] There are other differences between hedge funds and mutual funds that are not listed here, such as differences in their regulations, asset allocation, and performance disclosure policies.

To test these conjectures, we first estimate managerial talent of mutual funds using the maximum monthly return over the past 12 months. Then, for each month, from January 1995 to June 2013, we form quintile portfolios by sorting mutual funds based on their MAX, where quintile 1 contains the mutual funds with the lowest MAX and quintile 5 contains the mutual funds with the highest MAX. Panel A of Table 9 shows the average MAX values and the next month average returns on MAX-sorted portfolios of mutual funds. The last two rows display the differences between quintile 5 and quintile 1 the average monthly returns and the 4-factor Fama-French-Carhart alphas.

The second column of Table 9, Panel A, shows that the average return difference between quintiles 5 and 1 is 0.49% per month, but statistically insignificant with a Newey-West *t*-statistic of 1.23. As shown in the last column of Table 9, Panel A, the risk-adjusted return spread turns out to be negative albeit insignificant. Specifically, the 4-factor Fama-French-Carhart alpha difference between quintiles 5 and 1 is –0.18% per month with a *t*-statistic of –1.61. This result indicates that mutual funds in the highest MAX quintile do not generate economically or statistically higher risk-adjusted returns than mutual funds in the lowest MAX quintile. Overall, the univariate portfolio results in Table 9 provide no evidence for a significant link between MAX and future returns on mutual funds, implying that managerial skill is not an important determinant of the cross-sectional differences in mutual fund returns.

6.2. *Market- and macro-timing ability of mutual funds*

To test our second conjecture, we investigate the market- and macro-timing ability of mutual funds with the same Henriksson-Merton (1981) model that we utilize in our earlier analysis for hedge funds. Panel B of Table 9 presents the estimated values of β_2 and the corresponding *t*-statistics for mutual funds. Essentially, equations (4) and (5) are estimated with a pooled panel regression for the sample period January 1995–June 2013, this time using mutual fund excess returns as the dependent variable. The *t*-statistics reported in parenthesis are again estimated using clustered robust standard errors, accounting for two dimensions of cluster correlation (fund and year). Table 9, Panel B shows that for the equity market index, β_2 is statistically insignificant (a coefficient of –0.037 with a *t*-statistic of –0.61) for mutual funds, providing no evidence of market-timing ability for mutual fund managers. Similar results are obtained for the economic uncertainty index; β_2 is again statistically insignificant (a coefficient of 0.609 with a *t*-statistic of 1.62), providing no evidence of macro-timing ability for mutual fund managers.

Overall, the results show that directional and semi-directional hedge fund managers have the ability to actively vary their exposure to market risk and economic uncertainty up or down in a timely fashion according to the macroeconomic conditions and state of the financial markets. As a result, they can generate superior returns, and there exists a positive and stronger link between their managerial talent and future returns. On the other hand, mutual funds do not have market- or macro-timing ability. In line with this finding, there is no evidence of a significant cross-sectional link between MAX and future returns for mutual funds.

6.3. *Testing the economic and statistical significance of timing ability*

Can professional fund managers predict and exploit changes in the market and macroeconomic conditions? Starting with Treynor and Mazuy (1966), there has been an extensive literature on market- timing ability of mutual funds. Most of the earlier studies provide little evidence of timing ability for mutual funds, and some studies even find negative timing ability (concavity) which can be interpreted as systematically adjusting market exposure in a perverse way.[26]

In this paper, we explore the cross-sectional link between managerial talent, timing ability, and future fund performance. In particular, we have tested whether hedge fund and mutual fund managers can time the market and/or economic uncertainty by strategically adjusting fund exposures based on their forecasts of future market and macroeconomic conditions. If so, how much economic value does timing skill bring to fund investors? In this section, we investigate this issue by testing the economic and statistical significance of market- and macro-timing ability for the directional, semi-directional, and non-directional hedge funds versus mutual funds.

Panel C of Table 9 presents results from testing the significance of average returns and 4-factor alphas for the high-MAX directional, semi-directional, and non-directional hedge funds versus the high- MAX mutual funds. In the first row of Panel C, the average returns and alphas are compared for the high- MAX directional funds (with strong timing ability) vs. the high-MAX mutual funds (with no timing ability). In the second row, the average returns and alphas are compared for the high-MAX semi-directional funds (with semi-strong timing ability) vs. the high-MAX mutual funds (with no timing ability). In the last row, the average returns and alphas are compared for the high-MAX non-directional hedge funds vs. the high-MAX mutual funds (both groups with no timing ability).

The results reported in the first two rows in Panel C of Table 9 clearly show that the predictive power of managerial talent (proxied by MAX) for future fund performance is substantially higher for the directional and semi-directional funds as compared to mutual funds, because the differences between the average returns and alphas for the high-MAX directional and semi-directional funds vs. the high-MAX mutual funds are economically and statistically significant. The last row of Table 9, Panel C, provides evidence that, due to lack of investment-picking skills and lack of timing ability of non-directional hedge fund managers, the predictive power of managerial skill for future fund performance is not robustly, significantly greater for the high-MAX non-directional funds, as compared to the high-MAX mutual funds. Overall, the results in Table 9 suggest that market- and macro-timing ability represent managerial skill adding

[26] Bollen and Busse (2001) using daily return data and Jiang, Yao, and Yu (2007) using portfolio holding data provide supporting evidence of timing ability for mutual funds. Their findings suggest that the identification of market-timing ability may be sensitive to data frequency or data type (see Goetzmann, Ingersoll, and Ivkovich (2000)).

significant economic value to investors of the directional and semi-directional hedge funds.

7. Conclusion

Investors pay a great deal of attention to the technical, human, and conceptual skills of individuals who are managing their money because investors prefer to put money in hedge funds run by talented managers with unique investment ideas and superior investment-picking skills that generate higher risk- adjusted returns. In light of this investor behavior, a natural question to ask is whether some fund managers are indeed better than others. Since hedge funds do not disclose their trading strategies, security holdings, or asset allocation decisions, identifying managerial talent is a difficult task.

We introduce a new measure of managerial skill based on the maximum monthly returns of hedge funds over the past one year and test if this new measure (MAX) is an indicator of greater managerial talent leading to superior fund performance. We find that this is indeed the case. Specifically, the hedge funds in the highest MAX quintile (with strong managerial skill) generate 8.4% more annual returns compared to funds in the lowest MAX quintile (with weak managerial skill). After controlling for Fama-French- Carhart's four factors of market, size, book-to-market, and momentum as well as Fung-Hsieh's five trend- following factors on currency, bond, commodity, short-term interest rate, and stock index, the 9-factor alpha spread between the high-MAX and low-MAX funds remains positive and highly significant. We also run fund-level cross-sectional regressions to control for fund characteristics and alternative measures of past performance and managerial skill simultaneously. Both Fama-MacBeth regressions and portfolio-level analyses provide strong corroborating evidence for an economically and statistically significant positive relation between MAX and future returns.

Once we establish our main finding that managerial talent matters for hedge fund performance, we test if the predictive power of MAX gradually increases as we move from the least directional strategies to the most directional strategies. Consistent with our expectation, the predictive power of MAX turns out to be the highest for the directional funds because these funds with higher MAX and stronger managerial skill employ a wide variety of dynamic trading strategies and make extensive use of derivatives, short-selling, and leverage. As expected, the predictive power of MAX is found to be the lowest for the non-directional funds with lower MAX and weaker managerial skill. We also investigate whether hedge funds and mutual funds have the ability to time fluctuations in the equity market and macroeconomic fundamentals. The results indicate that the directional hedge fund managers can predict and exploit changes in the market and macroeconomic conditions by increasing (decreasing) fund exposure to risk factors when market risk and/or economic uncertainty is high (low). However, mutual funds do not have market- or macro-timing ability. Thus, we find no evidence of a significant link between managerial talent of mutual fund managers and their future returns.

These results are consistent with our managerial skill hypothesis – skilled hedge fund managers with superior market- and macro-timing ability are more likely to pursue unique investment strategies that result in superior performance, while less-skilled non-directional and mutual fund managers do not have good investiment-picking skills and they are more likely to trade on known strategies. Overall, our findings suggest that MAX is a useful indicator of managerial talent which can be effectively used by investors when selecting individual hedge funds.

Finally, we examine whether hedge fund investors take differences in managerial skill into account. For high-MAX funds, both the management and performance fees are considerably higher compared to other funds. Thus, for investors, the reward for finding talented fund managers is justified with the increased fees that these fund managers charge investors. In sum, our results suggest investors' preference for high-MAX funds; funds with high-MAX are rewarded with higher fees and, also their flows, as a percentage of assets, are significantly greater. This is due to the fact that investors learn about managerial skills and they are indeed willing to pay higher fees and invest more in the high-MAX funds under the expectation of receiving large positive returns in the future.

Table 1. Descriptive Statistics of Hedge Funds

There are total of 11,099 hedge funds that reported monthly returns to TASS for the years between 1994 and 2014 in this database, of which 8,684 are defunct funds and 2,415 are live funds. For each year from 1994 to 2014, Panel A reports the number of hedge funds, total assets under management (AUM) at the end of each year by all hedge funds (in billion $s), and the mean, median, standard deviation, minimum, and maximum monthly percentage returns on the equal-weighted hedge fund portfolio. Panel B reports for the sample period January 1994 – December 2014 the cross-sectional mean, median, standard deviation, minimum, and maximum statistics for hedge fund characteristics including returns, size, age, management fee, incentive fee, redemption period, and minimum investment amount.

Panel A. Summary Statistics Year by Year

						Equal-Weighted Hedge Fund Portfolio Monthly Returns (%)				
Year	**Year Start**	**Entries**	**Dissolved**	**Year End**	**Total AUM (billion $s)**	**Mean**	**Median**	**Std. Dev.**	**Minimum**	**Maximum**
1994	748	276	17	1,007	55.0	-0.01	0.14	0.97	–1.58	1.12
1995	1,007	304	54	1,257	66.5	1.40	1.48	1.05	–0.94	3.14
1996	1,257	354	113	1,498	89.2	1.45	1.56	1.53	–1.65	4.00
1997	1,498	389	100	1,787	133.1	1.47	1.69	2.01	–1.56	4.79

Table 1 (continued)

Panel B. Cross-Sectional Statistics of Hedge Fund Characteristics: January 1994 – December 2014

	N	Mean	Median	Std. Dev.	Minimum	Maximum
Average Monthly Return over the life of the Fund (%)	11,099	0.50	0.49	1.24	–25.14	25.47
Average Monthly AUM over the life of the Fund (million $)	11,099	85.7	40.0	233.8	0.5	7,835.1
Age of the Fund (# of months in existence)	11,099	73.4	60.0	54.0	1.0	252.0
Management Fee (%)	10,971	1.46	1.50	0.65	0.00	10.00
Incentive Fee (%)	10,847	15.40	20.00	7.79	0.00	50.00
Redemption Period (# of days)	11,099	37.1	30.0	32.9	0.0	365.0
Minimum Investment Amount (million $)	11,014	1.30	0.25	15.32	0.00	1,000.00

Table 2. Univariate Portfolios of Alternative MAX measures

Quintile portfolios are formed every month from January 1995 to December 2014 by sorting hedge funds based on their alternative MAX measures. MAX6, MAX9, MAX12, MAX18, and MAX24 represent the maximum monthly hedge fund returns over the last 6, 9, 12, 18, and 24 months, respectively. Quintile 1 is the portfolio of hedge funds with the lowest MAX measures, and quintile 5 is the portfolio of hedge funds with the highest MAX measures. In each column, the top panel reports the average MAX measures in each quintile, and the lower panel reports those same quintiles' next month average returns. The last two rows show the monthly average raw return differences and the 9-factor Alpha differences between quintile 5 (High MAX funds) and quintile 1 (low MAX funds). Average returns and Alphas are defined in monthly percentage terms. Newey-West adjusted *t*-statistics are given in parentheses. Numbers in bold denote statistical significance.

	Average Size of MAX6	Average Size of MAX9	Average Size of MAX12	Average Size of MAX18	Average Size of MAX24
Q1	1.07	1.45	1.67	1.99	2.24
Q2	2.20	2.69	3.04	3.59	4.02
Q3	3.46	4.17	4.69	5.50	6.11
Q4	5.58	6.61	7.39	8.56	9.49
Q5	12.67	14.51	15.88	17.98	19.63
	Next-month returns of MAX6 Quintiles	Next-month returns of MAX9 Quintiles	Next-month returns of MAX12 Quintiles	Next-month returns of MAX18 Quintiles	Next-month returns of MAX24 Quintiles
Q1	0.10	0.08	0.09	0.12	0.16
Q2	0.30	0.33	0.33	0.35	0.34
Q3	0.43	0.44	0.45	0.45	0.42
Q4	0.59	0.60	0.58	0.56	0.51
Q5	0.91	0.83	0.79	0.69	0.69
Q5 – Q1 Return Diff.	**0.81** **(3.85)**	**0.75** **(3.79)**	**0.70** **(3.48)**	**0.56** **(3.08)**	**0.53** **(2.94)**
Q5 – Q1 9-factor Alpha Diff.	**0.55** **(2.87)**	**0.50** **(2.70)**	**0.47** **(2.44)**	**0.37** **(1.99)**	**0.34** **(1.80)**

Table 3. Univariate Portfolios of Hedge Funds Sorted by MAX

Panel A. Average Raw and Risk-Adjusted Returns of MAX Quintile Portfolios

In Panel A of Table 3, quintile portfolios are formed every month from January 1995 to December 2014 by sorting hedge funds based on their MAX. Quintile 1 is the portfolio of hedge funds with the lowest MAX, and quintile 5 is the portfolio of hedge funds with the highest MAX. The table reports average MAX in each quintile, the next month average returns, and the 9-factor alphas for each quintile. The last row shows the average monthly raw return difference and the 9-factor alpha difference between High MAX and Low MAX quintiles. Average returns and alphas are defined in monthly percentage terms. Newey-West adjusted *t*-statistics are given in parentheses. Numbers in bold denote statistical significance of the returns and alphas.

Quintiles	Average MAX in each Quintile	Next Month Average Returns	Next Month 9-Factor Alphas
Q1	1.67	0.09	–0.01
		(1.08)	(–0.20)
Q2	3.04	**0.33**	**0.20**
		(3.20)	**(2.56)**
Q3	4.69	**0.45**	**0.29**
		(3.63)	**(3.54)**
Q4	7.39	**0.58**	**0.32**
		(3.61)	**(3.00)**
Q5	15.88	**0.79**	**0.46**
		(3.13)	**(2.25)**
Q5 – Q1		**0.70**	**0.47**
t-statistic		**(3.48)**	**(2.44)**

Table 3 (continued)

Panel B. 12-month-ahead Transition Matrix

This table reports the average month-to-month portfolio transition matrix in 12 months ahead. The table presents the average probability that a hedge fund in quintile *i* (defined by the rows) in one month will be in quintile *j* (defined by the columns) in the subsequent 12 months. If *MAX* is completely random, then all the probabilities should be approximately 20%, since a high-MAX or low-MAX in one month should say nothing about the MAX in the following 12 months. Instead, all the diagonal elements from top left to bottom right of the transition matrix exceed 20%, illustrating that the maximum return over the past 12 months is highly persistent even after putting a 12-month gap between the lagged and lead MAX variables. The sample period is January 1995–December 2014.

	Low MAX	Q2	Q3	Q4	High MAX	Total
Low MAX	59.5%	24.9%	10.0%	3.8%	1.8%	100.0%
Q2	25.8%	35.7%	23.7%	10.8%	4.0%	100.0%
Q3	10.0%	24.5%	32.5%	23.1%	10.0%	100.0%
Q4	4.4%	10.7%	23.5%	35.6%	25.8%	100.0%
High MAX	1.6%	4.1%	10.0%	26.1%	58.2%	100.0%

Table 3 (continued)

Panel C. Average Fund Characteristics of MAX Quintile Portfolios

Quintile portfolios are formed every month from January 1995 to December 2014 by sorting hedge funds based on their MAX measure. MAX is the maximum monthly hedge fund returns over the last 12 months. Quintile 1 is the portfolio of hedge funds with the lowest MAX measure, and quintile 5 is the portfolio of hedge funds with the highest MAX measure. This table reports the average fund charactersitics of hedge funds for each of the five quintiles. AVRG is the past 12-month average return, STDEV is the past 12-month standard deviation, LagRet is the one-month lagged return, Size is measured as monthly assets under management in billions of dollars, Age is measured as the number of months in existence since inception, Flow is measured as the change in the assets under management from previous month to current month adjusted with fund returns and scaled with previous month's assets under management, IncentFee is a fixed percentage fee of the fund's annual net profits above a designated hurdle rate, MgtFee is a fixed percentage fee of assets under management, typically ranging from 1% to 2%, MinInvest is the minimum initial investment amount (measured in millions of dollars in the regression) that the fund requires from its investors to invest in a fund, Redemption is the minimum number of days an investor needs to notify a hedge fund before the investor can redeem the invested amount from the fund, DLockup is the dummy variable for lockup provisions (1 if the fund requires investors not to withdraw initial investments for a pre-specified term, usually 12 months, 0 otherwise), and DLever is the dummy variable for leverage (1 if the fund uses leverage, 0 otherwise).

	MAX	AVRG	STDEV	LagRet	Size	Age	Flow	IncentFee	MgtFee	MinInvest	Redemption	DLockup	DLever
Q1	1.67	0.22	1.12	–0.05	0.14	58.8	–0.21	12.9	1.34	1.69	42.4	0.20	0.49
Q2	3.04	0.41	1.79	0.17	0.15	59.5	–0.14	13.0	1.41	1.21	40.8	0.22	0.51
Q3	4.69	0.56	2.64	0.29	0.15	58.8	–0.09	14.8	1.46	1.08	37.0	0.23	0.56
Q4	7.39	0.82	3.97	0.52	0.13	58.9	0.09	16.8	1.49	0.83	33.2	0.25	0.62
Q5	15.88	1.61	7.57	1.32	0.10	59.9	0.11	17.9	1.58	0.64	29.9	0.24	0.66

Table 4. Bivariate Portfolios of MAX after Controlling for AVRG, STDEV, Sharpe Ratio, Appraisal Ratio, Incentive Fee, and Fund Flows

Quintile portfolios are formed every month from January 1995 to December 2014 by sorting hedge funds first based on their fund characteristics (AVRG, STDEV, Sharpe Ratio, 9-Factor Appraisal Ratio, Incentive Fee, and Fund Flows) separately. Then, within each fund characteristics sorted portfolio, hedge funds are further sorted into sub-quintiles based on their MAX. Quintile 1 is the portfolio of hedge funds with the lowest MAX within each fund characteristics sorted quintile portfolio (depending on which fund characteristic's effect on MAX is controlled for) and Quintile 5 is the portfolio of hedge funds with the highest MAX within each fund characteristics sorted quintile portfolio (again depending on which fund characteristic's effect on MAX is controlled for). In each column, the top panel reports the average MAX in each quintile, and the lower panel reports those same quintiles' next month average returns. The last two rows show the monthly average raw return differences and the 9-factor Alpha differences between quintile 5 (High MAX funds) and quintile 1 (low MAX funds). Average returns and Alphas are defined in monthly percentage terms. Newey-West adjusted *t*-statistics are given in parentheses. Numbers in bold denote statistical significance.

	MAX Portfolios after controlling for AVRG	MAX Portfolios after controlling for STDEV	MAX Portfolios after controlling for SR	MAX Portfolios after controlling for 9-Factor AR	MAX Portfolios after controlling for Incentive Fee	MAX Portfolios after controlling for Fund Flows

Table 5. Fama-MacBeth Cross-sectional Regressions of Hedge Fund Returns on MAX and Control Variables

This table reports the average intercept and average slope coefficients from the Fama-MacBeth cross-sectional regressions of one-month-ahead hedge fund excess returns on MAX with and without control variables. The Fama-MacBeth regressions are run each month for the period January 1995–December 2014, and the average slope coefficients are calculated for the full sample period (in Panel A) as well as for two subsample periods (Panels B and C) and for good and bad states of the economy (Panels D and E). Newey-West *t*-statistics are reported in parentheses to determine the statistical significance of the average intercept and slope coefficients. Numbers in bold denote statistical significance of the average slope coefficients.

Table 6. MAX by Three Broad Hedge Fund Investment Categories

The first row of this table presents the number of funds existing in each of the three broad hedge fund investment style categories. The second row reports the percentage of hedge funds in total sample for each of the three hedge fund investment styles. The third row reports the cross-sectional average of individual funds' MAX within each category during the full sample period. The fourth row presents, for each investment style separately, the cross-sectional average of the individual funds' time-series standard deviation of MAX during the sample period. The fifth row reports for each investment style the cross-sectional average of the spread between Max and Min of MAX. The sixth and seventh rows report, for each of the three broad investment categories separately, the percentages of funds that utilize futures and other derivatives in their investment strategies. For comparison purposes, the same statistics across all hedge funds (irrespective of the hedge fund categories) are also reported in the last column. As can be noticed by reading from left to right, Non-directional category, which includes the Equity Market Neutral, Fixed Income Arbitrage, and Convertible Arbitrage hedge fund investment styles have noticeably lower MAX, lower standard deviation of MAX, and lower Max–Min spread of MAX compared to Directional category, which includes the Managed Futures, Global Macro, and Emerging Markets hedge fund investment styles. More importantly, Directional strategies' MAX, standard deviation of MAX, and Max–Min spread of MAX are considerably larger compared to the all hedge fund group as well. Finally, Semi-directional category, which includes the Fund of Funds, Multi Strategy, Long-short Equity Hedge, and Event Driven hedge fund investment styles have MAX, standard deviation of MAX, and Max–Min spread of MAX that are very similar to the all hedge fund group.

	Non-directional Hedge Funds	Semi-directional Hedge Funds	Directional Hedge Funds	All Hedge Funds
Number of Funds	718	5,383	1,544	7,645
% of Funds in total sample	9.4%	70.4%	20.2%	100.0%
Average MAX	4.05	5.98	9.61	6.56
Avg. Std. Dev. of MAX	1.76	2.43	3.75	2.63
Avg. Max–Min spread of MAX	5.61	7.95	12.25	8.60
% of Funds using Futures	13.9%	14.0%	41.0%	19.9%
% of Funds using other Derivatives	17.5%	18.5%	24.1%	19.6%

Table 7. Univariate Portfolios of MAX for Three Broad Hedge Fund Categories

For each of the three broad hedge fund investment style categories (Non-directional, Semi-directional, and Directional), univariate quintile portfolios are formed every month from January 1995 to December 2014 by sorting hedge funds based on their MAX. Quintile 1 (5) is the portfolio of hedge funds with the lowest (highest) MAX in each hedge fund category. In each column, the top panel reports the average MAX in each quintile, and the lower panel reports those same quintiles' next month average returns. The last two rows show the monthly average raw return differences and the 9-factor Alpha differences between quintile 5 (High MAX funds) and quintile 1 (low MAX funds). Average returns and Alphas are defined in monthly percentage terms. Newey-West adjusted *t*-statistics are given in parentheses. Numbers in bold denote statistical significance.

	Non-Directional Funds Average MAX	Semi-Directional Funds Average MAX	Directional Funds Average MAX
Q1	1.34	1.72	2.64
Q2	2.17	2.98	5.20
Q3	3.07	4.41	7.71
Q4	4.52	6.73	11.28
Q5	10.45	14.08	21.27
	Next-month returns of MAX Quintiles	Next-month returns of MAX Quintiles	Next-month returns of MAX Quintiles
Q1	0.18	0.13	0.09
Q2	0.27	0.34	0.26
Q3	0.42	0.44	0.54
Q4	0.57	0.58	0.58
Q5	0.67	0.82	0.96
Q5 – Q1 Return Diff.	**0.50** **(3.11)**	**0.69** **(3.00)**	**0.88** **(3.71)**
Q5 – Q1 9-factor Alpha Diff.	**0.30** **(2.11)**	**0.40** **(2.43)**	**0.76** **(2.71)**

Table 8. Market- and Macro-timing Tests of Individual Hedge Funds

This table investigates the market- and macro-timing ability of non-directional, semi-directional, and directional hedge funds. Market-timing ability is tested using the excess market return (*MKT*), and macro-timing ability is tested using the Economic Uncertainty Index (*UNC*) of Bali, Brown, Caglayan (2014). For each analysis, individual hedge fund excess returns are regressed on the excess market return and the economic uncertainty index separately as well as on the index implying market- and macro-timing ability using pooled panel regressions for the sample period January 1995–December 2014. Market and macro-timing ability of hedge funds is tested using a model similar to Henriksson and Merton (1981):

$$R_{i,t} = \alpha + \beta_1 \cdot Y_t + \beta_2 \cdot Y_t^{high} + \varepsilon_{i,t},$$

where $R_{i,t}$ is excess return of fund i in month t, Y_t is the excess market return in month t for the market-timing test, and the economic uncertainty index of Bali et al. in month t for the macro-timing test, and Y_t^{high} is variable implying market-timing ability for the market-timing test, and the economic uncertainty index implying macro-timing ability for the macro-timing test:

$$Y_t^{high} = \begin{Bmatrix} Y_t & \text{if } Y_t \text{ is higher than its time-series median} \\ 0 & \text{otherwise} \end{Bmatrix}$$

In this regression specification, a positive and significant value of β_2 implies superior market- and macro-timing ability of individual hedge funds. For the *t*-statistics reported in parentheses, clustered robust standard errors are estimated to account for two dimensions of cluster correlation (fund and year). This approach allows for correlations among different funds in the same year as well as correlations among different years in the same fund. Numbers in bold denote statistical significance.

	Non-Directional Hedge Funds	Semi-Directional Hedge Funds	Directional Hedge Funds
β_2 from using MKT in the market-timing estimation	–0.050 (–0.80)	**0.169** **(2.07)**	**0.277** **(2.62)**
β_2 from using UNC in the macro-timing estimation	0.101 (0.93)	**0.494** **(2.32)**	**0.894** **(2.58)**

Table 9. MAX and Mutual Fund Returns

Panel A. Average Raw and Risk-Adjusted Returns of MAX Quintile Portfolios

Quintile portfolios of mutual funds are formed every month from January 1995 to June 2013 by sorting mutual funds based on their MAX. Quintile 1 is the portfolio of mutual funds with the lowest MAX and quintile 5 is the portfolio of mutual funds with the highest MAX. Panel A reports average MAX in each quintile, the next month average returns, and the 4-factor alphas for each quintile. The last row of Panel A shows the average monthly raw return difference and the 4-factor alpha difference between High MAX and Low MAX quintiles. Average returns and alphas are defined in monthly percentage terms. Newey-West adjusted *t*-statistics are given in parentheses. Numbers in bold denote statistical significance of the returns and alphas.

Quintiles	Average MAX in each Quintile	Next Month Average Returns	Next Month 4-Factor Alphas
Q1	0.70	0.01	–0.00
		(0.26)	(–0.07)
Q2	2.73	0.21	0.03
		(1.67)	(0.28)
Q3	5.31	0.32	**–0.16**
		(1.22)	**(–1.94)**
Q4	7.59	0.47	–0.13
		(1.43)	(–1.52)
Q5	12.28	0.50	–0.18
		(1.22)	(–1.57)
Q5 – Q1		0.49	–0.18
t-statistic		(1.23)	(–1.61)

Panel B. Market- and Macro-timing Tests of Individual Mutual Funds

Panel B investigates the market- and macro-timing ability of mutual funds using pooled panel regressions of Henriksson-Merton (1981) and Bali, Brown, and Caglayan (2014) for the sample period January 1995–June 2013. A positive and significant value of β_2 implies superior market-and macro-timing ability of individual muutal funds. For the *t*-statistics reported in parentheses, clustered robust standard errors are estimated to account for two dimensions of cluster correlation (fund and year). This approach allows for correlations among different funds in the same year as well as correlations among different years in the same fund.

	Mutual Funds
β_2 from using MKT in the market-timing estimation	–0.037 (–0.61)
β_2 from using UNC in the macro-timing estimation	0.609 (1.62)

Table 9 (continued)

Panel C. Testing the significance of timing ability

Panel C tests the economic and statistical significance of market- and macro-timing ability for the high-MAX directional, semi-directional, and non-directional hedge funds versus the high-MAX mutual funds. In the first row of Panel C, the average returns and alphas are compared for the high-MAX directional funds (with strong timing ability) vs. the high-MAX mutual funds (with no timing ability). In the second row, the average returns and alphas are compared for the high-MAX semi-directional funds (with semi-strong timing ability) vs. the high-MAX mutual funds (with no timing ability). In the last row, the average returns and alphas are compared for the high-MAX non-directional hedge funds vs. the high-MAX mutual funds (both groups with no timing ability).

	Mutual Funds	
	Return Diff.	Alpha Diff.
Directional Hedge Funds	**0.50**	**0.82**
	(2.15)	**(3.38)**
Semi-directional Hedge Funds	**0.33**	**0.57**
	(1.97)	**(5.77)**
Non-directional Hedge Funds	0.23	**0.65**
	(0.89)	**(4.73)**

Managerial Talent and Hedge Fund Performance

Online Appendix

To save space in the paper, we present some of our findings in the Online Appendix. Section I describes the mutual fund database and reports the number of mutual funds, yearly attrition rates, and their summary statistics. Table I examines the persistence of MAX using fund-level Fama-MacBeth cross-sectional regressions of MAX on lagged predictor variables. Table II investigates the predictive power of MAX over future hedge fund returns with two alternative multivariate Fama-MacBeth specifications of future hedge fund returns on MAX and control variables. Table III examines the long-term predictive power of MAX and reports the next 3-, 6-, 9-, and 12-month-ahead returns of quintile portfolios sorted by MAX. Table IV tests whether investors are willing to pay higher fees and invest more in funds that generate higher MAX via separate cross-sectional regressions of hedge fund fees and one-month-ahead flows on MAX and other control variables. Table V presents summary statistics for the mutual funds database.

This Version: June 2015

I. Mutual Fund Database

This study uses monthly returns of individual mutual funds from CRSP Mutual Fund database. Originally in our database there are 48,218 funds that report monthly returns at some point during our sample period from January 1994 to June 2013. Most of the mutual funds in the CRSP database, however, have multiple share classes designed for different client types. That is, a mutual fund may have a retail share class, an institutional share class, or a retirement share class. All of these share classes in essence constitute the same strategy, therefore their returns are highly correlated. However, the CRSP Mutual Fund database assigns a separate fund id number to each share class of the same fund, treating these share classes as if they are separate funds. In order to distinguish between share classes and funds, and not to use any duplicated funds (and hence returns) in our analyses, we first remove the multiple share classes of mutual funds from our study. We do this by keeping only the share class with the smallest fund id number (within a mutual fund family) in the database, and by removing the rest of the share classes of that particular mutual fund family from our analyses. This way, we make sure that each mutual fund family is represented with a single share class in our database. After removing multiple share classes, our sample size of mutual funds drops from 48,218 funds to 16,881 funds. That is, our database contains information on a total of 16,881 distinct, non-duplicated mutual funds, of which 7,073 are defunct funds and the remaining 9,808 are live funds. Table V of this online appendix provides summary statistics both on numbers and returns of these single-share class, non-duplicated mutual funds. For each year, Table V reports the number of funds entered into database, number of funds dissolved, attrition rate (the ratio of number of dissolved funds to the total number of funds at the beginning of the year), and the mean, median, standard deviation, minimum, and maximum monthly percentage returns on the equal-weighted mutual fund portfolio.

The most notable point in Table V is a sharp increase in the yearly attrition rates of mutual funds after year 2007, the starting point of the big worldwide financial crisis. From 1994 to 2007, on average, the annual attrition rate in the database was only 4.98%; however, this annual figure jumped to 10.56% in 2008 and to 9.63% in 2009 (the two highest figures detected in our sample period), giving an indication on how harsh the financial crisis is felt in the mutual fund industry in those years. In line with this jump in attrition rates, just during 2008, for example, mutual funds on average lost 2.67% (return) per month, generating the largest losses ever for their investors since the start of our analysis in 1994.

Table I. Fama-MacBeth Cross-sectional Regressions of 12-month-ahead MAX on Current MAX and Other Fund Characteristics

This table reports the average intercept and average slope coefficients from the Fama-MacBeth cross-sectional regressions of 12-month-ahead MAX on current MAX and other fund characteristics. Fama-MacBeth regressions are run for each month, and the average slope coefficients are calculated for the period January 1995–December 2014. Newey-West *t*-statistics are reported in parentheses to determine the statistical significance of the average intercept and slope coefficients. Numbers in bold denote statistical significance.

Table II. Fama-MacBeth Cross-sectional Regressions of Hedge Fund Returns on MAX and Control Variables

This table reports the average intercept and average slope coefficients from the Fama-MacBeth cross-sectional regressions of one-month-ahead hedge fund excess returns on MAX with and without control variables. The Fama-MacBeth regressions are run each month for the period January 1995–December 2014, and the average slope coefficients are calculated for the full sample period (in Panel A) as well as for two subsample periods (Panels B and C) and for good and bad states of the economy (Panels D and E). Newey-West *t*-statistics are reported in parentheses to determine the statistical significance of the average intercept and slope coefficients. Numbers in bold denote statistical significance of the average slope coefficients.

Table III. Long-term Predictive Power of MAX

Quintile portfolios are formed each month by sorting hedge funds based on their MAX measures. Quintile 1 is the portfolio of hedge funds with the lowest MAX measure and quintile 5 is the portfolio of hedge funds with the highest MAX measure. This table reports the next 3-month, 6-month, 9-month, and 12-month average returns for each of the five quintiles. The last two rows show the monthly average raw return differences and the 9-factor Alpha differences between quintile 5 (High MAX funds) and quintile 1 (low MAX funds). Average returns and alphas are defined in monthly percentage terms. Newey-West adjusted *t*-statistics are given in parentheses. Numbers in bold denote statistical significance.

	3-month ahead returns of MAX Quintiles	6-month ahead returns of MAX Quintiles	9-month ahead returns of MAX Quintiles	12-month ahead returns of MAX Quintiles
Q1	0.12	0.14	0.15	0.16
Q2	0.35	0.34	0.31	0.31
Q3	0.45	0.44	0.40	0.38
Q4	0.55	0.48	0.46	0.44
Q5	0.72	0.64	0.56	0.53
Q5 – Q1 Return Diff.	**0.60** **(3.42)**	**0.49** **(3.13)**	**0.41** **(2.68)**	**0.37** **(2.47)**
Q5 – Q1 9-factor Alpha Diff.	**0.39** **(2.29)**	**0.33** **(2.11)**	**0.30** **(2.04)**	0.25 (1.60)

Table IV. Fama-MacBeth Cross-sectional Regressions of Hedge Fund Fees and One-month-ahead Hedge Fund Flows on MAX and Control Variables

This table reports the average intercept and average slope coefficients from the Fama-MacBeth cross-sectional regressions of Incentive Fees, Management Fees, and one-month-ahead Flows (separately) on MAX with and without control variables. The Fama-MacBeth regressions are run each month for the period January 1995–December 2014, and the average slope coefficients are calculated for the full sample period. Newey-West *t*-statistics are reported in parentheses to determine the statistical significance of the average intercept and slope coefficients. Numbers in bold denote statistical significance of the average slope coefficients.

Panel A: Cross-sectional regressions of Incentive Fee on MAX with and without control variables:

	Intercept	MAX	SR	STDEV	LagRet	Size	Age	Flow	MgtFee	MinInv	Redemption	DLockup	DLever
(1)	13.378 (142.48)	**0.283** **(20.54)**

Table V. Descriptive Statistics of Mutual Funds

There are total of 16,881 mutual funds that reported monthly returns to CRSP Mutual Fund Database for the years between 1994 and 2013 in this database, of which 7,073 are defunct funds and 9,808 are live funds. For each year from 1994 to 2013, this table reports the number of mutual funds, yearly attrition rates, and the mean, median, standard deviation, minimum, and maximum monthly percentage returns on the equal-weighted mutual fund portfolio.

						Equal-Weighted Mutual Fund Portfolio Monthly Returns (%)				
Year	**Year Start**	**Entries**	**Dissolved**	**Year End**	**Attrition Rate (%)**	**Mean**	**Median**	**Std. Dev.**	**Minimum**	**Maximum**
1994	3,108	625	132	3,601	4.25	-0.17	0.18	1.64	-3.08	2.00

This study investigates the effects of government crisis interventions on economic growth under an international prospective. We also evaluate how financial markets (banking, insurance, and stocks), financial liberalization, and monetary policy shape the effect of crisis intervention on economic growth. Our main empirical result points out first that the proxies of government interventions do have a significantly negative impact on economic growth. A higher level of banking development supports the enhanced credit crunch effect, while greater insurance and stock market developments mitigate this negative impact. Financial liberalization and monetary also helps to mitigate this negative impact under certain circumstances.

Keywords: Crisis intervention, Financial market, Economic growth, Financial liberalization, Monetary policy.

JEL Classification: E22, E52, G01, G28

1. Introduction

In recent decades, multiple countries have experienced some sort of a systemic banking crisis. In fact, the recent global financial crisis has given rise to the largest wave of banking crises seen since the Great Depression. The effects of this financial crisis are still lingering and in many cases the crisis is still ongoing. The crisis not only resulted from the collapse of financial institutions such as Lehman Brothers and American International Group (AIG) and the subsequent economic downturn, but also hit global financial markets, thus pushing governments to quickly establish safety net interventions to stabilize the financial markets.

Governments spent as much as 40-55% of GDP in the early 1980s' crises in Argentina and Chile. A substantial part of the costs of the 1997 Asian financial crisis – projected in the region of 20-55% of GDP for the three worst affected countries – ultimately fell on the government budget of the affected. Despite the fact that their economies are small, developing economies as a group have suffered cumulative fiscal costs in excess of $1 trillion from financial crisis. Among industrialized countries, Japan has spent around 20% of GDP to restructure its financial system during its long, drawn-out banking crisis (Honohan and Klingebiel, 2003). The recent 2008-2011 Icelandic financial crisis was a major economic and political event in Iceland that involved the collapse of all three of the country's major privately owned commercial banks, following their difficulties in refinancing their short-term debt and a run on deposits in the Netherlands and the United Kingdom. In terms of fiscal costs it reached at least 44% of GDP (Laeven and Valencia, 2013).

Studies analyzing crisis intervention policies usually focus on the fiscal and output costs of alternative intervention policies. Most of these studies suggest that the fiscal cost is positively related to the extent to which countries adopt accommodative policies (Honohan and Klingebiel, 2003; Kane and Klingebiel, 2004; Claessens et al., 2005). Another strand of the literature argues that government guarantees or other crisis intervention measures reduce market discipline,[1] particularly if the guarantees are perceived to be credible (Martínez-Peria and Schmukler, 2001; Demirguc-Kunt and Huizinga, 2004; Hoggarth et al., 2005; Nier and Baumann, 2006; and Hadad et al., 2011). Cubillas et al. (2012) further find that adoptions of an explicit blanket guarantee, forbearance, government recapitalization, and nationalization programs are interventions that have a weakening effect on market discipline, but Cubillas et al. do not find that the provision of liquidity support to banks has a specific negative effect on market discipline after a crisis.

Government crisis interventions are expensive, but there are potential benefits. One typical benefit of the safety net is to limit depositors' tendency to overreact by changing the incentives of bank depositors. Problems in the banking sector have large spillover effects upon other sectors, because banks provide a unique source of credit to other firms and manage the flow of payments throughout the economy. Disruptions in bank credit supply and in the smooth functioning of the payments system create potentially large social costs borne outside the banking system. Thus, banks in distress entail uniquely large social costs. Second, banks suffer a special risk in that their claimants (depositors) may "rationally overreact" to information and produce costly systemic runs (Calomiris, 1999).

Two channels of crisis intervention need explanation. One is ***the crowding effect***. Crisis intervention policies cause governments to increase their fiscal costs and crowd other sectors' fiscal expenses out, resulting in a decline of real GDP per capita. The other one is the ***credit crunch effect***. Once a crisis occurs, the government usually adopts necessary intervention

[1] Market discipline is generally analyzed by whether depositors penalize riskier banks by requiring higher interest rates.

measures, while at the same time depositors generally penalize riskier banks by requiring higher interest rates. This reduces the amount of available loans from banks. In such situations, a credit crunch is accompanied by a flight to quality by lenders and investors, affecting the flow of bank loans to those agents (households and small and medium-sized enterprises) for whom close substitutes for bank credit are unavailable. In turn, the disruption to the availability of finance for bank-dependent borrowers may stymie economic activity (Ding et al., 1998).

Rather than targeting the impacts of crisis intervention on fiscal costs, this study fills the gap in the literature by examining the impacts on economic growth. However, it is essential to consider that the relationship between crisis intervention and economic growth will change under different certain circumstances, such as financial systems.

From a theoretical point of view, the relationship between a financial system and economic growth may run in either or both directions. The 'supply-leading' and 'demand following' views as presented by Patrick (1966) postulate that economic growth (real income) can be enhanced either through growth in financial systems, or alternatively through growth in the economy, which brings about the development of financial activities. Based on the 'supply-leading' view, financial development enhances economic growth by transferring resources from traditional sectors to modern sectors and by promoting entrepreneurial responses in these modern sectors. By contrast, the 'demand-following' view indicates that a lack of financial development or institutions is due to a lack of demand for financial services. Thus, as the growth rate of real income rises, investors' and savers' demands for various new financial services materialize, hence leading to the creation of modern financial institutions, a greater supply of their financial assets and liabilities, and more related financial services.

Most studies empirically confirm the existence of a positive nexus between financial development and economic performance. King and Levine (1993), for example, show that the degree of financial development helps to explain long-run growth using data on 80 countries over the 1960-1989 period. Levine and Zervos (1998) and others support this evidence. Nevertheless, counter-evidence also exists (such as, Ram, 1999; Khan and Senhadji, 2003; Zhang, 2003; Arestis et al., 2001). However, Shen and Lee (2006) exhibit mixed evidence in which only stock market development has a positive effect on growth and that banking development has an unfavorable, if not negative, effect on growth. As for the insurance sector, Fortune (1973), Lewis (1989), Beck and Webb (2003), Li et al. (2007), and Lee et al. (2010) all ascertain that life insurance demand is positively related to income.[2]

Financial liberalization may also affect economic growth by reducing capital market imperfections, which might in turn reduce the external finance premium. Rajan and Zingales (1998) present that financially constrained industries grow faster in more financially developed countries. Laeven (2003) shows that liberalization of the banking sector reduces the imperfections firms face when dealing with financial markets. Bekaert et al. (2001) demonstrate that financial liberalization does increase economic growth. Specifically, financial liberalization leads to a 1% increase in annual real per capita GDP growth over a five-year period. Klein and Olivei (2008) also confirm that countries with an open capital account have a significantly greater increase in financial depth and stronger economic growth.

Along with financial depth and financial liberalization, monetary policy also plays a stabilizing role in influencing economic growth through a number of channels, such as the setting of interest rate and money supply levels. Since financial depth does matter for growth, it may change the relationship between crisis intervention and economic growth, but to our best

[2] Please refer to Lee et al. (2013) for a comprehensive survey.

acknowledge, previous studies do not consider this issue. In this study we evaluate how financial markets (banking, insurance, and stocks), financial liberalization, and monetary policy shape the effect of government intervention on economic growth.

Our paper hence fills some gaps in previous studies. First, we provide empirical evidence from examining the effects of government interventions on economic growth under an international prospective by using a panel data framework from 39 selected countries over the period 1984-2009. Second, we consider both the containment phase and resolution phase as proxies for crisis intervention. The containment phase includes a blanket guarantee or liquidity support, whereas the resolution phase includes government recapitalization or banks' nationalization. Third, we consider whether financial market, financial liberalization, and monetary policy change the relationship between crisis intervention and economic growth.

The rest of this paper is organized as follows. Section 2 provides a brief literature review of related works. Section 3 outlines the empirical model and the methodology. Section 4 provides a description of the data including data sources and definitions of variables. Section 5 reports and analyzes the empirical results of both the benchmark model and extended model. The final section presents the conclusions and implications.

2. Conditions Influencing the Relationship between Crisis Intervention and Economic Growth

2.1 Financial Depth

Most studies confirm the existence of a positive nexus between financial development and economic growth. King and Levine (1993), for example, show that the degree of financial development helps to explain long-run growth, using data on 80 countries over the 1960-1989 period. Levine and Zervos (1998) and others also support this evidence. Levine (1997) shows the impact of stock markets on growth, as stock markets encourage specialization as well as the acquisition and dissemination of information about firms, which may mobilize savings, thereby facilitating growth. Well-developed stock markets may enhance corporate control by mitigating the principal-agent problem.

Some studies do not agree with this positive relationship and claim that banking development may actually hinder growth. More specifically, they assert that by enhancing resource allocation and hence the returns on savings, banking development may even lower savings rates. If there are sufficiently large externalities associated with savings and investments, then banking development, they hold, slows long-run growth (Beck, and Levine, 2004). Examining 95 countries over the 1960-89 period, Ram (1999) also argues that the results pertaining to the finance-growth nexus are, at best, uncertain and ambiguous. Khan and Senhadji (2003) similarly demonstrate that certain banking development indicators become statistically insignificant when growth equations are estimated through the use of panels. By considering eight Asian economies, Zhang (2003) notes that there was a significantly negative connection between banking development and economic growth during the 1960-1999 period. Similarly, De Gregorio and Guidotti (1995) confirm this negative nexus by employing 12 Latin American countries over 1950-1985.

Arestis et al. (2001) argue that stock markets and banks are clearly substitutive sources for corporate finance. They base this on the grounds that when a firm issues new equity, its borrowing requirements from the banking system decline. From this viewpoint, it seems that the relationship between bank development and growth may therefore not be so robust.

In addition to such possible negative effects of banking development on growth, as reported by some researchers, still other studies dispute the fact that stock market development may hamper growth. Stiglitz (1985) presents that stock market liquidity does not strengthen the incentives for acquiring information about firms or for exerting corporate governance. From a similar perspective, Bhide (1993) emphasizes that excessive liquidity may hinder the costly monitoring of managers since shareholders can readily sell their stakes in a firm. Devereux and Smith (1994) indicate that greater risk sharing through stock market activities can actually reduce savings rates, hence slowing economic growth. In a similar vein, De Long et al. (1989) show that excessive stock trading can introduce "noise" into the market and be detrimental to efficient resource allocation. Mayer (1988) makes the argument that if not much corporate investment is financed through the issuance of equity, then stock markets do not play any part in economic growth. Shen and Lee (2006) exhibit mix evidence in which only stock market development has a positive effect on growth and that banking development has an unfavorable, if not negative, effect on growth.

As for the insurance sector, Fortune (1973), Lewis (1989), Beck and Webb (2003), Li et al. (2007), and Lee et al. (2010) all ascertain that life insurance demand is positively related to income. Moreover, the insurance market contributes to economic growth by improving the sound functions of financial systems, as noted in Ward and Zurbruegg (2000), Haiss and Sümegi (2008), Han et al. (2010), Lee (2013), and Lee et al. (2013). Thus, their results suggest that insurance markets and economic growth are endogenous.

2.2 Financial Liberalization

The effects of liberalization on economic growth have, of course, been widely studied, and the different spheres of liberalization are three-fold: trade, financial, and globalization. Tornell et al. (2004) find that trade liberalization enhances growth, but that financial liberalization does not necessarily lead to more rapid growth, in large part because it is associated with risky capital flow, lending booms, and crises. The latter is exemplified by Demirgüç-Kunt and Detragiache

(1998), who show that financial liberalization has a very large and statistically significant effect on the probability of a banking crisis. Others also confirm the unfavorable effects of financial liberalization (such as Loayza and Ranciere, 2006; Rousseau and Wachtel, 2007; Angkinand et al., 2010; Misati and Nyamongo, 2012; Lee and Hsieh, 2014)

Financial liberalization may also affect economic growth by reducing capital market imperfections, which might in turn reduce the external finance premium. Rajan and Zingales (1998) show that financially constrained industries grow faster in more financially developed countries. Laeven (2003) offers that liberalization of the banking sector reduces the imperfections firms face when dealing with financial markets. Bekaert et al. (2001) demonstrate that financial liberalization does lead to a 1% increase in annual real per capita GDP growth. Ito (2006) focuses on Asia over the period 1980 to 2000 and finds that trade openness is a prerequisite for successful inducement of financial development via capital account liberalization; while Klein and Olivei (2008) confirm capital account liberalization have a significantly increase in economic growth.

Dreher (2006) presents an index of globalization covering its three main dimensions: economic integration, social integration, and political integration. Using panel data for 123 countries in 1970-2000, Dreher finds that globalization promotes growth. Dreher et al. (2008) further update the index of globalization. In the literature there is general agreement that globalization implies countries are becoming more integrated into the international economy, increasing people's interactions, information exchanges, technology transformations, and convergence in cultural activities (Dreher, 2006; Lee and Chang, 2012; Lee et al., 2013). García-Herrero and Martinez Peria (2007) also note some evidence for cross-border expansion into emerging market countries in which a larger share of foreign claims is extended through the local affiliates of foreign banks, allowing local firms to enjoy more stable foreign financing. Hsieh et al. (2014) reveal that a higher degree of globalization decreases bank stability through income diversity, but stability rises through asset diversity.

2.3 Monetary Policy

The pioneer work of Friedman and Schwartz (1963) identifies the notion that monetary contraction and errors by the Federal Reserve caused the Great Depression. This is the so-called Friedman-Schwartz hypothesis in that a more accommodative monetary policy could have greatly reduced the severity of the Great Depression. The monetary transmission mechanism has been a subject of much research over a number of years (see Stiglitz and Weiss, 1981; Bernanke and Gertler, 1995; and Christiano et al., 1997), describing how policy-induced changes in monetary policy actions impact policy goals, e.g. output and inflation. A substantial body of recent literature has focused on these issues looking at the transmission mechanisms and sectoral effects of monetary policy. The most distinguishing characteristic of the monetary transmission mechanism either focuses on prices (interest rate, exchange rate, and other asset prices) or quantities (money, credit, base money, bonds, foreign assets, etc.). Taylor (1995) presents the financial market price framework for analyzing the monetary transmission mechanism - the process through which monetary policy decisions are transmitted into changes in real GDP and inflation.

3. Models

Beyond the panel data, the model that establishes the relationship between crisis intervention and economic growth remains unanswered. The basic model can be given by:

$$Growth_{i,t} = \beta_0 + \beta_1 Interv_{i,t} + \lambda' X_{i,t} + \varepsilon_{i,t} \tag{1}$$

Here, i =1, ..., N; t =1, ...,T; N refers to the country number; and T is for time. The dependent variable, $Growth_{i,t}$, is proxied by real per capita GDP growth (Cavallo and Cavallo, 2010; Shen and Lee, 2006). $Interv_{i,t}$ is the policy of government crisis intervention; $X_{i,t}$ denotes the control variables, including government consumption, education (years of secondary schooling), investment, and inflation; and $\varepsilon_{i,t}$ is the error term.

We define crisis intervention policy variables (*Interv*) using the data provided by Laeven and Valencia (2008). These are all dummy variables taking the value of 0 when the intervention policy is strict and 1 when a more accommodative approach is chosen. We differentiate between containment and resolution phases of crisis policy responses. In the containment phase, we consider two types of intervention using two variables: (1) *BLANKG* is a dummy variable that takes a value of 1 if authorities issue an explicit blanket guarantee to depositors and creditors after the initial onset of the crisis, or if market participants are implicitly protected from any losses if public banks' market share exceeds 75%; otherwise, it takes a value of 0; and (2) *LIQSUP* is a dummy variable that takes a value of 1 if authorities provide emergency liquidity support; otherwise, it takes a value of 0. The definition of "emergency" support is when claims from monetary authorities on banks' deposit money to total deposits reach at least 5% and at least twice as much as in the year before the crisis. In the resolution phase, we consider two types of intervention using different variables: (1) *RECAP* is a dummy variable that takes a value of 1 if banks are recapitalized by the government during the first 3 years of the crisis and 0 otherwise; and (2) *NATION* is a dummy that takes a value of 1 if banks are nationalized during the first 5 years of the crisis.

As for other control variables, we follow Shen and Lee (2006), Shen et al. (2010), Cavallo and Cavallo (2010), Ben Salha et al. (2012), Misati and Nyamongo (2012), Christiansen et al.

(2013), and Law et al. (2013) and include the ratio of government consumption against GDP (*GC*) for controlling government size, secondary gross enrollment rate (*ED_SEC*) as a human capital proxy, capital formation (*KF*), and inflation (*INFLA*) The higher the government consumption ratio is, the lower economic growth will be, since high government consumption by the public sector crowds out private investment in the economy. Thus, the coefficient of government consumption is expected to be negative. We further expect a higher level of human capital formation to be positive to growth. The coefficients of investment are found to be positive and significant in nearly all the existing literature. We therefore anticipate that the coefficient of capital formation should be positive. Inflation is also included in the model to test the macroeconomic stability. It is especially true if high inflation is also associated with increased price variability and reduced economy stability. The coefficient of inflation is then expected to be negative.

As discussed earlier, this study thus considers the effect of financial depth. We further look at whether financial depth influences the relation between crisis intervention and growth. Our extended model is:

$$Growth_{i,t} = \beta_0 + \beta_1 Interv_{i,t} + \beta_2 (Interv_{i,t} \times FD_{i,t}) + \lambda' X_{i,t} + \varepsilon_{i,t} \tag{2}$$

Here, *FD* refers to financial markets (bank, insurance, and stocks), financial liberalization, and monetary policy. We introduce *FD* to control financial environmental (or institutional) quality.

Referring to King and Levine (1993), Levine and Zervos (1998), Shen and Lee (2006), Chen et al. (2012) and others, the proxies of financial markets include two variables to measure the bank sector: domestic credit growth, which denotes the annual growth rate (*BCG*), and the ratio of bank private credit to GDP (*BPC*). To proxy the insurance sector, we employ life and non-life insurance densities (*ILID*, *INLID*), defined as premiums per capita, and life and non-life insurance penetrations (*ILIP*, *INLIP*), defined as the ratio of premium volume to GDP. To measure the stock market, we consider the ratio of stock market capitalization to GDP (*SMC*) and the stock turnover ratio (*STR*).

Following Rajan and Zingales (1998), Bekaert et al. (2001), Laeven (2003), and Klein and Olivei (2008), we include two types of financial liberalization. One is the degree of capital account liberalization (freedom of trade internationally, *FTI*; Chin-Ito index series, *CIT*), and the other one is globalization (economic and social globalizations). Capital account liberalization consists of removing restrictions on cross-border financial transactions[3] (Ben Salha et al., 2012).

The proxy of freedom of trade internationally (*FTI*) is published annually by the Frasher Institute and represents financial liberalization variables (Gwartney et al., 2010; Shehzad and De Haan, 2009). The freedom of trade internationally denotes a wide variety of restraints that affect international exchange of goods: tariffs, quotas, hidden administrative restraints, and controls on exchange rates and capital. A higher level of the index indicates a larger degree of economic freedom.

We also use the Kaopen indicator with the Chin-Ito index series (*CIT*) of financial openness and the progress of financial liberalization developed by Chinn and Ito (2008), updated to 2012, as the measuring degree of capital account openness at the country level during a certain period. The index has a mean of 0 and ranges from −2.66, representing full capital controls, to +2.66, representing complete liberalization. Higher values of the financial openness index reflect a country that is more open to cross-border capital transactions. The Kaopen indicator is based on the binary dummy variables reported in the IMF's Annual Report on Exchange Arrangements and Exchange Restrictions (AREAER). The popularly used Chinn-Ito index series are often referred to as the degree of financial openness (Misati and Nyamongo, 2012) and a measure of

[3] We do not take the IMF dummy indicator into account, which takes the value one in years where there are restrictions on capital account transactions and zero otherwise, due to its restriction on intensity consideration.

intensity capital controls (Ahmed, 2013). Yalta and Yalta (2012) and Ahmed and Islam (2010) employ the Chin-Ito index as an essential measure of a liberal financial environment.

The second type of financial labialization we include is the index of globalization, whereby we use the index recently developed from the KOF database of the Swiss Economic Institute ("Konjunkturforschungsstelle") as proposed by Dreher (2006) and updated in Dreher et al. (2008). The globalization index is on a yearly basis and is frequently used in the recent empirical literature.[4] The index consists of economic, social, and political dimensions of globalization. In this study we select economic and social globalizations as financial liberalization proxies from the updated 2010 KOF index of globalization, which measures globalization over the range from 1 to 100, where higher values represent higher levels of globalization.

For the proxies of monetary policy, we apply the annual real interest rate (*INT*) following Shen et al. (2010) and employ the ratio of M2 to Reserves (*M2RES*).

We are now able to construct two hypotheses - *the mitigated credit crunch effect* and *the enhanced credit crunch effect*. Doing so allows us to investigate the indirect impacts from the financial market, financial liberalization, and monetary policy on economic growth during the financial crisis periods.

This paper hypothesizes four possible outcomes in relation to the coefficients β_1 and β_2 of equation (2) as follows. We explore the four hypotheses below individually.

(1) If $\beta_1 > 0$ and $\beta_2 > 0$, then crisis intervention has a positive effect on growth, and financial depth affects the relation favorably.

(2) If $\beta_1 > 0$ and $\beta_2 < 0$, then crisis intervention has a positive effect on growth, and financial depth affects the relation adversely.

(3) If $\beta_1 < 0$ and $\beta_2 > 0$, then crisis intervention has a negative effect on growth, and financial

[4] For a detailed description and a long list of articles using the index, see http://www.kof.ethz.ch/globalization.

depth adversely impacts that negative effect.

(4) If $\beta_1 < 0$ and $\beta_2 < 0$, then crisis intervention has a negative effect on growth, and financial depth favorably impacts that negative effect.

4. Descriptions and Sources of Data

Our sample contains 39 selected countries over the period between 1984 and 2009. Data availability dictates the choice of the sample period and size. Figure 1 plots the relationship between real GDP average growth rate and the number of public interventions. The patterns are not clear, except there are two significant economic downturns: during the periods 1997-1998 and 2007-2008. Economic growth obviously declined as interventions were implemented (see Table A1 of Appendix).

[Figure 1 about here]

Table 1 provides our variables' definitions and full information on data sources in the study, whereas Table 2 presents summary statistics of all variables used as well as the descriptive statistics for the raw variables. The dependent variable, *Growth*, has a mean of 8.955 in logarithmic form. The first intervention variable, *BLAGU*, has a mean of 9.17% with 93 out of 1014 observations. The liquidity support variable, *LIQSUP*, has a mean of 2.76% with 28 observations. The other two intervention variables, *NATION* and RECAP, have a mean of 8.97% and 7.79%, respectively.

[Tables 1 and 2 about here]

5. Empirical Results

5.1 Crisis Intervention Policy and Economic Growth

Tables 3-8 shows the panel data regression results with fixed effects, with Table 3 presenting our benchmark results.[5] We find that all crisis intervention variables are significantly negative to economic growth, supporting *the credit crunch effect*. Hence, our results further supplement the two strands of related literature: one is that crisis intervention policies are positively related to fiscal costs (Honohan and Klingebiel, 2003; Kane and Klingebiel, 2004; Claessens et al., 2005); the other one is that government guarantees or other crisis intervention measures reduce market discipline, particularly if the guarantees are perceived to be credible (Martínez-Peria and Schmukler, 2001; Demirguc-Kunt and Huizinga, 2004; Hoggarth et al., 2005; Nier and Baumann, 2006; and Hadad et al., 2011).

As for the control variables, government consumption (*GC*) and inflation (*INF*) are associated with a decreased tendency towards economic growth, matching the results of Shen and Lee (2006), Shen et al. (2010), Cavallo and Cavallo (2010), Misati and Nyamongo (2012), and Christiansen et al. (2013), who all conclude that higher government consumption and higher inflation are harmful to economic growth. On the contrary, our result indicates that a higher level of investment (*KF*) helps increase economic growth, which is in line with Shen et al. (2010), Ben Salha et al. (2012), Misati and Nyamongo (2012), and Law et al. (2013).

[Table 3 about here]

5.2 Results of the Extended Model

Tables 4-7 present the empirical results for the interaction between government crisis intervention and financial depth. The concept is expressed mathematically:

$$\frac{\partial Growth_{i,t}}{\partial Interv_{i,t}} = \beta_1 + \beta_2 \times FD_{i,t} \tag{3}$$

[5] The time-fixed effects are not reported in the table to save space. The full table is available upon request.

Here, β_1 indicates the direct effect, ($\beta_2 \times FD_{i,t}$) represents the indirect effect of crisis intervention, and $(\beta_1 + \beta_2 \times FD_{i,t})$ is the total effect. In other words, the final influential effect of crisis intervention on economic growth is confirmed, although only through observing the total effect. Accordingly, in the extended model we clearly find that the sign of the marginal effect is influenced by the coefficients β_1 and β_2 and the financial depth variable *FD*. Consequently, the marginal effects of the extended model may be ambiguous.

The effect of domestic credit growth and the direct (β_1) and indirect effects (β_2) of the four crisis intervention variables on economic growth are almost significantly negative, showing that the factors of domestic credit growth (*BCG*) and bank private credit (*BPC*) may enhance the negative relation between crisis intervention and growth (Table 4). Thus, the banking sector enhances *the credit crunch effect*. This result is in accordance with theoretical studies like Bencivenga and Smith (1991), Bencivenga et al. (1995), and King and Levine (1993). These models show that financial development can hurt growth. Specifically, financial development, by enhancing resource allocation and hence the returns to saving, may lower saving rates. If there are sufficiently large externalities associated with savings and investment, then financial development slows long-run growth (Beck and Levine, 2004). Our results also clearly support existing empirical studies like Ram (1999) and Khan and Senhadji (2003) who present the finance-growth nexus is, at best, uncertain and ambiguous. We also confirm Zhang (2003) and De Gregorio and Guidotti (1995) as they find a negative nexus. However, our results partially contradict the findings of Beck and Levine (2004), who offer evidence that both bank and stock markets positively influence economic growth.

[Table 4 about here]

Table 5 presents four crisis interventions with the insurance market. When non-life density and non-life penetration are applied in the liquidity support panel (columns 6 and 8), the direct and indirect effects are both positive and both reach at least the 10% significant level. This result may confirm that the insurance market has a perfect substitute channel for banking, supporting Ward and Zurbruegg (2000), Haiss and Sümegi (2008), Han et al. (2010), Lee (2013), and Lee et al. (2013): the insurance market fosters income or growth.

[Table 5 about here]

Table 6 presents the interaction effect of crisis intervention and the stock market. The effects of interventions and the direct and indirect effects of the stock market on economic growth are significantly negative and positive, showing that the stock market turnover rate plays an essential role in mitigating the negative relation between crisis intervention and growth. Thus, the stock market mitigates *the credit crunch effect*. Such evidence also confirms some theories that provide conflicting predictions about whether stock markets and banks are substitutes, compliments, or whether one is more conducive to growth than the other (Boyd and Prescott, 1986; Stiglitz, 1985; and Bhide, 1993).

[Table 6 about here]

With respect to the impact of financial liberalization, shown in Table 7, when *FTI*, *ECOGLO*, and *SOCGLO* are adopted, we see a negative and direct relation between intervention and growth. A positive and indirect effect shows that freedom of trade internationally and economic and social globalizations mitigate *the credit crunch effect*. This result could further confirm the discussion of the existing literature. For instance, Bekaert et al. (2001) demonstrate that financial liberalization does increase economic growth. Laeven (2003) shows that liberalization of the banking sector reduces the imperfections firms face when dealing with financial markets. Ito (2006) finds that trade openness is a prerequisite for successful inducement of financial development via capital account liberalization. Klein and Olivei (2008) also confirm that countries with an open capital account have a significantly greater increase in economic growth.

[Table 7 about here]

Turning to the impact of monetary policy, shown in Table 8, the interactions of interest rates and crisis interventions are significantly negative. However, the results of *M2RES* fail to reach the same pattern. This negative finding for interest rates is consistent with the monetary transmission mechanism (Stiglitz and Weiss, 1981; Bernanke and Gertler, 1995; Taylor, 1995 and Christiano et al., 1997). Specifically, our results are mostly related with Taylor (1995) in which the financial market price plays a more important role through which monetary policy decisions are transmitted into changes in real GDP and inflation.

[Table 8 about here]

5.3 Robustness Test

This section further performs a robustness check on our main findings in the previous section. We utilize an alternative specification, the dynamic panel GMM approach,[6] to further examine the indirect effects conditional on government interventions on economic growth using the same proxies. The dynamic panel GMM approach is used to control for joint endogeneity of all explanatory variables in a dynamic formulation and eliminates potential biases arising from country-specific effects by taking the first difference of all variables. We therefore follow Cavallo and Cavallo (2010) to take the first-difference transformation (i.e., Δ) of equation (1) in order to remove the unobserved country-specific effect. To check the appropriateness of the panel GMM estimator, we employ two specification tests. One is Hansen's J test of over-identifying restrictions, which examines the overall validity of the instruments by analyzing the

[6] The dynamic GMM approach suggested by Arellano and Bover (1995) and Blundell and Bond (2000) is appropriate for dealing with the potential endogeneity, heteroskedasticity, and autocorrelation problems.

sample analog of the moment conditions used in the estimation process (Hansen, 1982). Under the null of joint validity of the full instrument set, the J test statistics are asymptotically χ^2. The second test scrutinizes the hypothesis that the error term $\varepsilon_{i,t}$ is not serially correlated. In both the difference regression and the system difference-level regression we test whether the differenced error term is second-order serially correlated. Basically, the GMM estimator is consistent if there is no second-order serial correlation between error terms of the first-difference equation and when the Hansen statistics are insignificant.

Tables 9-12 report the overall robust estimation results.[7] The four tables present estimations based on the one-step system-GMM estimator corrected for heteroscedasticity and small sample bias. We report the Hansen statistics of over-identifying restrictions and the autocorrelation tests of order 2 in all tables. We rely on the two- to four-period lags of the same variables as instruments. The *p*-value for the AR (2) tests of all models suggests that there is no autocorrelation in levels, and the Hansen test confirms that the instruments we use are exogenous.

The main finding here is that our significant results are robust to addressing our conditional proxies of financial depth. The robustness estimation results are mostly supportive of our earlier findings. For example, the direct effects of the four crisis interventions are still significantly negative. For the banking sector variables, we find that the coefficient of the interaction term with bank private credit (*BPC*) is still significantly negative, implying it still deteriorates the negative effect of government interventions on economic growth. For the insurance sector, we find that the coefficient of the interaction term of life insurance density (*ILID*) turns out a significantly positive sign, while the interaction term of non-life insurance density (*INLID*)

[7] The robustness estimation results for the year dummy are not reported to save space. We also regress economic growth on the four crisis interventions with stock market capitalization (*SMC*), freedom of trade internationally (*FTI*), and the Chin-Ito index (*CIT*). The estimation results remain unchanged and are still insignificant.

maintains a significantly positive effect on economic growth, implying that the insurance sector plays a more important role in economic growth. However, the indirect effect of the stock market turnover rate (*STR*) falls below the 10% significant level and changes to an insignificant result.

For the proxies of financial liberalization, we find that the interactions of crisis interventions with economic globalization and social globalization remain significantly positively associated with economic growth. In addition, for the monetary policy proxies, we find that the coefficient of the interaction term for the interest rate (*INT*) turns out an insignificantly positive sign, while the interaction term for the M2 to total reserve ratio (*M2RES*) is significantly positively associated with economic growth, suggesting that an expansionary monetary policy benefits economy growth.

Our main results overall remain mostly unchanged. Specifically, a higher level of banking development supports *the enhanced credit crunch effect*, while greater insurance and stock market developments mitigate this negative impact. Financial liberalization and monetary policy also help to mitigate this negative impact under certain circumstances.

[Tables 9, 10, 11, and 12 about here]

6. Conclusion and Implications

This paper provides empirical evidence from investigating the effects of government crisis interventions on economic growth under an international prospective by using a panel data framework from 39 selected countries. We also evaluate how financial markets (banking, insurance, and stocks), financial liberalization, and monetary policy shape the effect of government intervention on economic growth. We apply the fixed effects model of panel data with the Hausman test and also control for unobservable country-specific and year-fixed effects with a country-level cluster.

Our main empirical result overall points out first that the proxies of government intervention do have a significantly negative impact on economic growth. Second, a higher level of banking development supports *the enhanced credit crunch effect*, while greater insurance and stock market developments mitigate this negative impact. Third, financial liberalization and monetary policy also help to mitigate this negative impact under certain circumstances. Finally, we conduct robustness checks on our main findings with an alternative specification- dynamic panel GMM model to further examine the indirect effect conditional on government interventions on economic growth using the same proxies. We find that the direct effects of the four crisis interventions are still significantly negative and remain unchanged. The crisis interventions that interact with the insurance sector, economic globalization, and social globalization still hold the same results. Overall, the robustness results are supportive of our earlier findings.

Some important policy implications can be drawn from our analyses. First, from our findings, the negative effect of public intervention policies on economic growth indicates that crisis interventions fail to positively stimulate economic performance. Policymakers or governments should be aware that any crisis intervention policy implementation is discouraged when a financial crisis erupts, because the crisis intervention policy involves a sacrifice of economic growth by increasing government fiscal costs and crowding out other fiscal expenses, thus lowering real GDP.

Second, the financial market, financial liberalization, and monetary policy all play an important role affecting the relationship between crisis intervention policy and economic growth. Policymakers or governments should further consider other conditional environments present that can help promote economic growth during a crisis period.

Third, the study finds that the roles of non-life insurance and stock markets are positively important in explaining economic growth, while a higher level of banking development is harmful to economic growth. In order to increase economic growth through a crisis intervention policy, policymakers or governments should not only pay more attention to highlighting a strong non-life insurance sector and/or stock market, but also focus on the banking sector. For the banking market, countries with higher credit growth rates and bank private credit should further consider the possible negative impact (i.e., moral hazard effect) when implementing a crisis intervention policy. Insurers and stock market investors also may have expectations that insurance and stock markets will be targeted for support during financial crises.

Fourth, higher levels of financial liberalization and monetary policy will mitigate the negative impact of a crisis invention policy on economic growth. This finding offers implications for policymakers and governments to act upon. Any policy related to improving financial liberalization and/or expanding the monetary base (e.g., lower interest rates or increases in money supply) may be highly recommended to promote economic growth during a financial crisis as well.

Fifth and finally, in view of the constraints on our collection of data, more research needs to be done on the conditional variables in order to analyze the economic growth issue. For example, future studies may investigate government supervision, market regulations, and political institutional environments.

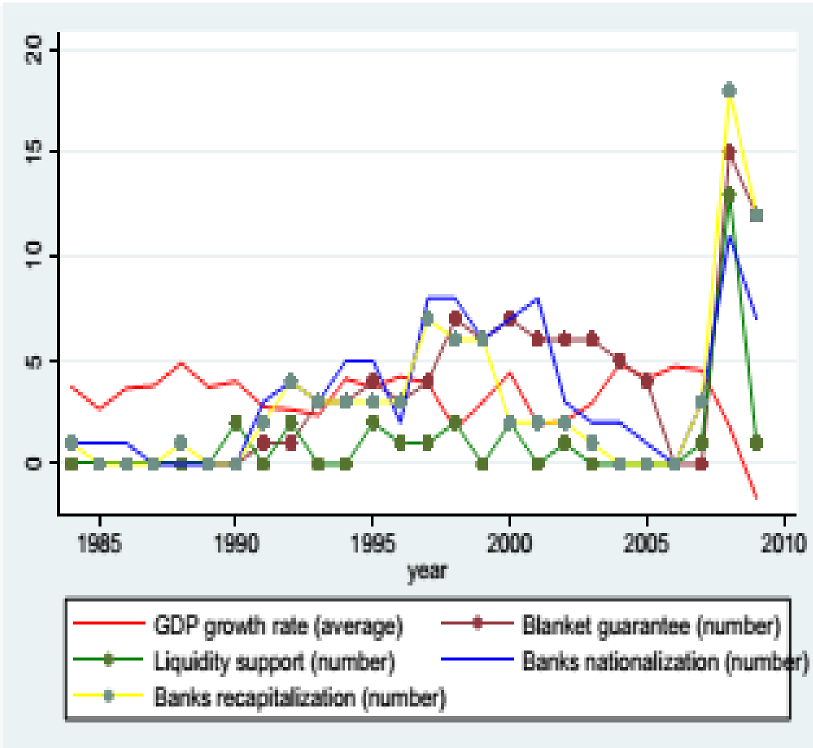

Figure 1. Plots of real GDP growth rate (average) and total number of crisis interventions 1984-2009. (Source: WDI, 2012, and Laeven and Valencia, 2008, 2013)

Table 1. Data descriptions and sources.

		Variables	Descriptions	Sources
Dependent Variables				
	Growth rate of real GDP per capita	Growth	Log difference of the ratio of real gross domestic product (constant 2000 USD)	World Development Indicator (WDI, 2012)
Independent Variables				
	Blanket guarantee	BLAGU	Dummy variable that takes a value of 1 if authorities issue an explicit blanket guarantee to depositors and creditors after the initial onset of a crisis; 0 otherwise.	Laeven and Valencia (2008, 2013)
	Liquidity support	LIQSUP	Dummy variable that takes a value of 1 if authorities provide emergency liquidity support; 0 otherwise.	
	Nationalized banks	NATION	Dummy variable that takes a value of 1 if banks are nationalized during the first 5 years of the crisis; 0 otherwise.	
	Bank recapitalized	RECAP	Dummy variable that takes a value of 1 if banks are recapitalized by the government during the first 3 years of the crisis; 0 otherwise.	
Controlled Variables				
	Inflation	INFLA	Log (1+annual change in consumer price index)	World Development Indicator (WDI, 2012)
	Government consumption	GC	Government consumption as a share of GDP	
	Education secondary level	ED_SEC	Total enrollment ratio in secondary education	
	Investment	KF	Gross capital formation as a share of GDP	
Conditional Factors:				
1) Financial Depth				
Banking	Domestic credit growth rate	BCG	Domestic credit growth rate %, annual	World Development Indicator (WDI, 2012)
	Bank private credit	BPC	Ratio of bank private credit to GDP	
Insurance	Life insurance density	ILID	Life insurance premium per capita	Sigma, Swiss Reinsurance Company
	Non-life insurance density	INLID	Non-life insurance premium per capita	
	Life insurance penetration	ILIP	Ratio of premium volume to GDP for life insurance	
	Non-life insurance penetration	INLIP	Ratio of premium volume to GDP for non-life insurance	
Stock	Stock market capitalization	SMC	Ratio of stock market capitalization to GDP	World Development Indicator (WDI, 2012)
	Stock turnover ratio	STR	Stock market turnover rate	
(2) Financial Liberalization				
i. Degree of capital account liberalization				
	Freedom of trade internationally	FTI	Measures a wide variety of restraints that affect international exchange of goods: tariffs, quotas, hidden administrative restraints, and controls on exchange rates and capital	Frasher economic freedom (Gwartney et al, 2010)
	Chin-Ito index	CIT	Measures an index of financial openness and progress of financial liberalization	Chin-Ito index series (updated to 2010)
ii. Index of globalization				
	Economic globalization	ECOGLO	Measured by actual flows and restrictions indictors	KOF index of globalization (Dreher et al. 2008)
	Social globalization	SOCGLO	Measured by personal contact, information flows, and culture proximity indictors	
(3) Monetary Policy				
	Interest rate	INT	Real interest rate (%)	World Development Indicator (WDI, 2012) 2012)
	Broad money to reserves ratio	M2RES	Money and quasi money (M2) to total reserves ratio (%)	

Table 2. Summary statistics of the variables.

Sample	782	782	782	782
Country #	39	39	39	39
Cluster	country	country	country	country
Hausman test	Fixed effect	Fixed effect	Fixed effect	Fixed effect
Chi^2	41.53***	34.05***	31.81***	28.26***
Joint F test	3.68***	3.54***	3.63***	3.27***

Notes: ***, **, and * indicate statistical significance at the 1%, 5%, and 10% levels, respectively. Z statistics are in parentheses, and the dependent variable is growth of real GDP per capita. Panel data with the fixed effects model are utilized in the estimation model. The estimation results of year dummy are unreported in the table to save space.
For the Hausman test: the null hypothesis is that the fixed effects model is consistent, in favour of the random effects model. Joint F test jointly tests for the year-fixed effect (H_0: the jointly coefficients of all years are jointly equal to zero).

The determinants and effectiveness of the foreign exchange market interven- tion form a simultaneous equation system. Confining the attention to the determinants side, Chen, Chang and Yu (2012) regard the Japanese authori- ties' market intervention a variable that is censored from below at zero; and the latent variable is a linear model with determinants such as the current yen/dollar exchange rate, with heteroscedastic error such as Garch. This paper extends their model to a simultaneous equation system with market intervention and exchange rate as the endogenous variables. A conventional structural Tobit model is extended to cases with Garch errors. The classical MCMC estimation technique with data augmentation suggested in Chib (1992) and Nakatsuma (2000) is used. The results are compared with those in Ito (2003) who do not consider the censoring.

Keywords: Effectiveness; Garch errors; market intervention; MCMC estimation; reaction function, structural Tobit model

JEL Classification F31; F41

1 Introduction

In the early 1980s, Edison (1993) concludes that forex market interventions have marginal and temporary, if not no impact on the exchange rate. On the other hand, following the Plaza Accord in Year 1985, Dominguez (1990) and Dominguez and Frankel (1993a, 1993b, 1993c) show some effects of interventions, not only on the level of exchange rates, but also on their volatilities and risk premia.

Market intervention data had not been publicly available. It was not until July 2001 when the Japanese Ministry of Finance disclosed daily intervention records. Those records facilitate a lot of research on this topic. In a series of seminal papers (Ito 2003, 2005, 2007), he develops a framework in which intervention is described by a *reaction* function and its *effectiveness* is assessed by the impact on exchange rate. [1] While linear models (with or without Garch) are used in those papers, later on Ito and Yabu (2007) model the reaction function with an ordered probit model, in which the dependent variable equals 1 if three is *sale of yen*, and it equals -1 if there is *purchase of yen*. This approach is more appropriate as most of the daily interventions are *censored* at 0.

On the other hand, there is an interest on the endogeneity problem between the reaction and the effectiveness, possibly due to temporal aggregation. Applying the Markov-chain Monte Carlo (MCMC) approach to Japanese data, Chen, Watanabe and Yabu (2012) use data augmentation to obtain intraday intervention amounts (which is free of simultaneity) and conclude that an intervention, by the Japanese monetary authorities (the Ministry of Finance and the Bank of Japan), of 0.1 trillion yen moves the yen/dollar rate by 0.18%. This figure is twice as much using linear models. That said, their approach ceases to account for some other economic

[1] Some other interesting issues such as cost of intervention, consistency with monetary policy, and sterilization are beyond the scope of this paper. For the last issue, we need some publicly unavailable variable such as commercial banks' net receipts of yen funds. See Watanabe and Yabu (2013).

variables such as change in interest spread or stock return.

In this paper, we construct a structural censored regression model (more precisely a structural Tobit regression model) first proposed by Heckman (1978). Further, in view of the Garch effects documented in Chen, Chang and Yu (2012) and Wang, Yu and Xie (2014), we modify Heckman (1978)'s model so that Garch [2] is allowed. As with Chen, Watanabe and Yabu (2012), a *data-augmented MCMC approach* modified upon those in Chib (1992) and Nakatsuma (2000) is used. [3]

Following Almekinders and Eijffinger (1996) and Ito and Yabu (2007), this study considers the followings in explaining the reaction function: [4] (a) short-, medium- and long-term deviations from a moving average local trend; (b) the Fed's intervention in the New York yen/dollar market; (c) the interest rate spread between Japan and the U.S.; (d) the first-business-day on which intervention is arguably more effective; (e) the Nikkei 225 stock index which proxies the local economy; and (f) lagged Japan monetary authorities' interventions. As with Ito (2005), for the effectiveness function, we consider: (i) short- and long-term deviations from a moving average local trend, in lag terms; (ii) the Japan monetary authorities' intervention; (iii) the first-of week intervention effect; and (iv) the Fed's intervention in the New York yen/dollar market.

Our sample starts on April 1, 1991, when available Japanese intervention data starts, and it ends on December 31, 2010. To avoid the possible impacts of the Year 2011 Tohoku earthquake and tsunami, we do not go beyond Year 2010. Our M-CMC approach is rather data-demanding, we only divide the entire sample into two

[2]See also Ito (2003, 2005, 2007).

[3]See also Wei (1999) or Monokroussos (2013). An alternative is the simulated maximum likelihood estimation suggested in Calzolari and Fiorentini (1998) or Lee (1999). As far as Tobit-Garch model is concerned, the MCMC has recently attracted a lot of attention. On example is a Garch model of asset returns with price limits. See Wei (2002).

[4]As one can see in Figures 1-2 below, most of the Japanese intervention is sale of yen, rather than purchase of yean. In view of the limited information for the latter, this paper focuses on the former.

regimes: (I) April 1, 1991 - January 13, 2003; and (II) January 14, 2003 - December 31, 2010. [5] The first regime is sometimes called the "Sakakibara-Kuroda" period in which Mr. Sakakibara was first the Director General of International Finance Bureau, Ministry of Finance; then the Vice minister of Foreign Affairs, Ministry of Finance. In July 1997, Mr. Sakakibara was succeeded by Mr. Kuroda who shared the same intervention tactics with Mr. Sakakibara. The second regime covers the so-called "great intervention" period Year 2003 - Year 2004, which commenced when Mr. Mizoguchi succeeded the Vice minister of Foreign Affairs. Starting with small-size interventions, intervention under Mr. Mizoguchi continued with increasing frequency and increasing size.

The rest of this paper is organized as follows. Section 2 contains a detailed discussion on the reaction function and the effectiveness function, as well as that of Tobit-Garch model and its estimation method. Section 3 is devoted to the data description and the empirical findings. The last section concludes.

2 The model

2.1 Reaction and effectiveness functions

For the reaction function, we first define a latent variable: [6]

$$\begin{aligned} Sale_t^* &= \phi_0 + \phi_1 SDEV_t + \phi_2 MDEV_t + \phi_3 LDEV_t + \phi_4 DUSInt_{t-1} + \phi_5 FBD_{t-1} \\ &\quad + \phi_6 \Delta SPR_{t-1} + \phi_7 \Delta NIK_{t-1} + \phi_8 Sale_{t-1} + \phi_9 Sale_{t-2} + \varepsilon_{1t}, \end{aligned} \tag{2.1}$$

[5] Roughly speaking, we merge Ito (2003, 2005, 2007)'s four regimes into two.

[6] The IMM, net long position of currency futures in the Chicago Mercantile Exchange, is missed in this study. See the discussions in section 4 in Ito (2005).

where Δ denotes the difference operator. The *sale* of Japanese yen (purchase of U.S. dollar),

$$Sale_t = \begin{cases} Sale_t^*, & Sale_t^* > 0, \\ 0, & Sale_t^* \leq 0. \end{cases} \tag{2.2}$$

In other words, in (2.1), partially due to the limited sample size, we model the amount of sale of Japanese yen but *not* that of purchase. Denote the natural logarithm of nominal exchange rate by s_t (multiplied by 100). Further, the effectiveness function is specified as:

$$\Delta s_t = \beta_0 + \beta_1 SDEV_{t-1} + \beta_2 LDEV_{t-1} + \beta_3 Sale_t^* + \beta_4 IntIN_t + \beta_5 DUSInt_{t-1} + \varepsilon_{2t}, \tag{2.3}$$

The two functions (2.1) and (2.3) will be elaborated in order. Following Almekinders and Eijffinger (1996) and Ito and Yabu (2007), we start by considering a loss function of the monetary authority. A loss occurs when the nominal exchange rate deviates from the target rate, which in turn is a linear combination of the short-term, medium-term and long-term targets. Correspondingly, we define the short-term deviation (SDEV), medium-term deviation (MDEV) and long-term deviation (LDEV) respectively by:

$$SDEV_t = s_t - s_{t-1}, \tag{2.4}$$

$$MDEV_t = s_t - \frac{1}{21}\sum_{j=1}^{21} s_{t-j}, \tag{2.5}$$

$$LDEV_t = s_t - \frac{1}{150}\sum_{j=1}^{150} s_{t-j}. \tag{2.6}$$

In other words, the short-term target is the previous day's rate; the medium-term target is the previous month's moving-average rate; while the long-term target is the previous 150-day's moving-average rate. A negative coefficient is expected, if the monetary authority implements the so-called leaning *against* the wind; the coefficient is negative if the policy is leaning *with* the wind.

Apart from the two lags of $Sale_t$, other explanatory variables in the reaction function are $DIntUS_{t-1}$, FBD_{t-1}, ΔSPR_{t-1}, and ΔNIK_{t-1}. Both $DUSInt_{t-1}$

and FBD_{t-1} are discrete variables, where

$$DUSInt_t = \begin{cases} 1, & \text{U.S. sells yen,} \\ 0, & \text{U.S. neither sells nor purchases yen,} \\ -1, & \text{U.S. purchases yen;} \end{cases} \quad (2.7)$$

and the dummy variable for the first business day,

$$FBD_t = \begin{cases} 1, & \text{first business day,} \\ 0, & \text{otherwise.} \end{cases} \quad (2.8)$$

Further, the interest rate spread SPR_t is defined as the difference between Japan call money interest rate and the U.S. Federal Funds rate. On the other hand, the central bank may try stopping the local currency from appreciation (or invoking the depreciation) in order to maintain export competitiveness. For this sake, we use the Nikkei 225 stock index to proxy the local economy. Its natural logarithm (multiplied by 100) is denoted by NIK_t.

The effectiveness function in (2.3) is essentially Equation (2) suggested in Ito (2005). The first three terms capture the movement of the yen/dollar rate when there is intervention neither in Japan nor in any other countries. The last term captures the first-of-the-week effect. Denote Int_t as the Japanese intervention amount (either positive, 0 or negative, depending on yen-selling, no intervention, or yen-purchase).

$$IntIN_t = \begin{cases} Int_t, & Int_t \neq 0, Int_{t-1} = Int_{t-2} = Int_{t-3} = Int_{t-4} = Int_{t-5} = 0, \\ 0, & \text{otherwise.} \end{cases} \quad (2.9)$$

This term captures the special effect of surprise intervention, as opposed to continuous intervention. See, for instance, Ito and Yabu (2007). Note for sake of identification, in (2.3) one of the explanatory variable is $Sale_t^*$ rather than $Sale_t$. See the so-called "coherency condition" in (2.12) below. Moreover, the simultaneity between $IntIN_t$ and ε_{2t} is ignored. See also the next sub-section for the identification issue.

2.2 The structural Tobit-Garch model and its reduced from

Refer to the model (2.1)-(2.3) in the previous sub-sections. Write $y_{1t} = Sale_t$, $y^*_{1t} = Sale^*_t$ and $y_{2t} = \Delta s_t$. It is easy to see that our model is a special case of Heckman (1978)'s simultaneous equation system with endogenous limited dependent and/or latent variables. More precisely:

$$y^*_{1t} = \alpha_{12} y_{2t} + \gamma_{11} y_{1t} + x'_{1t}\beta_1 + \varepsilon_{1t}; \tag{2.10}$$

$$y_{2t} = \alpha_{21} y^*_{1t} + \gamma_{21} y_{1t} + x'_{2t}\beta_2 + \varepsilon_{2t}, \tag{2.11}$$

where x_{1t} and x_{2t} are some exogenous variables. Complication aries as y_{1t}, which is an endogenous variable, also appears as an explanatory variable in (2.11). Identification is attained if the following coherency condition holds:

$$\alpha_{12}\gamma_{21} + \gamma_{11} = 0, \tag{2.12}$$

which is satisfied in our model, as $\gamma_{11} = \gamma_{21} = 0$. Plugging (2.11) into (2.10),

$$\begin{aligned} &(1-\alpha_{12}\alpha_{21})\, y^*_{1t} = x'_{1t}\beta_1 + x'_{2t}\beta_2\alpha_{12} + \varepsilon_{1t} + \alpha_{12}\varepsilon_{2t} \\ \Leftrightarrow\quad & y^*_{1t} = x'_{1t}\frac{\beta_1}{(1-\alpha_{12}\alpha_{21})} + x'_{2t}\frac{\beta_2\alpha_{12}}{(1-\alpha_{12}\alpha_{21})} + \frac{\varepsilon_{1t} + \alpha_{12}\varepsilon_{2t}}{(1-\alpha_{12}\alpha_{21})}, \end{aligned}$$

Thus we may write the *reduced-from* of y^*_{1t} as:

$$y^*_{1t} = x'_t\pi_1 + \nu_{1t}, \tag{2.13}$$

where $\nu_{1t} := (\varepsilon_{1t} + \alpha_{12}\varepsilon_{2t}) / (1-\alpha_{12}\alpha_{21})$ is the reduced-form error; π_1 is the reduced-form parameter; and x_t contains all the *non-overlapping* exogenous variables. Putting (2.13) into (2.11), one obtains:

$$\begin{aligned} y_{2t} &= \gamma_{21} y_{1t} + x'_t\pi_1\alpha_{12} + x'_{2t}\beta_2 + \varepsilon_{2t} + \alpha_{21}\nu_{1t} \\ &= \gamma_{21} E[y_{1t}|x_t] + x'_t\pi_2 + \nu_{2t}, \end{aligned} \tag{2.14}$$

where $\nu_{2t} := \varepsilon_{2t} + \alpha_{21}\nu_{1t} + \gamma_{21}(y_{1t} - E[y_{1t}|x_t])$ is the reduced-form error. Needless to say, (2.14) is the *reduced-form* of y_{2t}.

2.3 The estimation method

The estimation method can be divided into four parts. Parts (I)-(II) are estimating the reduced-form equations (2.13)-(2.14). Parts (III)-(IV) are estimating the structural equations (2.10)-(2.11). Recall that $y_{1t} = Sale_t$, $y_{1t}^* = Sale_t^*$ and $y_{2t} = \Delta s_t$.

Part (I): Refer to the reduced-form equation (2.13). The reduced-form parameter π_1 is estimated with a Tobit-Garch(1,1) model.

Step (a) Given some *preliminary* estimator of π_1 (such as that ignoring Garch), we compute some reduced-form residual:

$$\hat{v}_{1t}, \text{ for } y_t = y_t^* > 0. \tag{2.15}$$

For $y_t = 0$, the $\hat{v}_{1t}$ is *generated* based on the data-augmentation method suggested in Chib (1992) who does not consider Garch. See also Chib and Greenberg (1995).

Step (b) Given the residual $\hat{v}_{1t}$ in Step (b), we estimate the Garch(1,1) parameter using a MCMC method. See, for instance, Nakatsuma (2000) and Ardia (2008). Consequently, one may compute the estimate of the variance, denoted by $\hat{s}_{1t}^2$'s. See also Chib and Greenberg (1995).

Step (c) Repeat (a) with the deflated y_{1t} and deflated x_t. That is,

$$\frac{y_{1t}}{\hat{s}_{1t}}, \text{ and } \frac{x_t}{\hat{s}_{1t}}. \tag{2.16}$$

Step (d) Repeat for $B + M$ times, Steps (b) and (c) *iteratively*, where B is the number of burning iterations, and M is the number of MCMC iterations.

Step (e) The predicted value is computed as:

$$\hat{y}_{1t}^* = x_t'\hat{\pi}_1, \text{ where } \hat{\pi}_1 = \frac{1}{M}\sum_{i=1}^{M} \pi_{1i}; \tag{2.17}$$

$$\hat{y}_{1t} = \begin{cases} \hat{y}_{1t}^*, & \hat{y}_{1t}^* > 0, \\ 0, & \hat{y}_{1t}^* \leq 0. \end{cases} \tag{2.18}$$

Part (II): Refer to the reduced-form equation (2.14). The reduced-form parameter $(\gamma_{21}, \pi_2')'$ is estimated with a standard Linear-Garch(1,1) model.

Step (a) Given the predicted value $\hat{y}_{1t}$ in (2.18). $(\gamma_{21}, \pi_2')'$ is estimated by the quasi-maximum likelihood (QML) estimation, with $(E[y_{1t}|x_t], x_t')'$ replaced by $(\hat{y}_{1t}, x_t')'$.

Step (b) The predicted value is computed as:

$$\hat{y}_{2t} = \hat{\gamma}_{21}\hat{y}_{1t} + x_t'\hat{\pi}_2, \text{ where } (\hat{\gamma}_{21}, \hat{\pi}_2')' \text{ is the QML estimator.} \tag{2.19}$$

Part (III): Refer to the structural equation (2.10). The structural parameter $(\alpha_{12}, \gamma_{11}, \beta_1')'$ is estimated with a Tobit-Garch(1,1) model. The procedure is exactly the same as that in Part (I), with x_t replaced by $(\hat{y}_{2t}, \hat{y}_{1t}, x_{1t}')'$. See (2.19) and (2.18).

Part (IV): Refer to the structural equation (2.11). The structural parameter $(\alpha_{21}, \gamma_{21}, \beta_2')'$ is estimated with a standard Linear-Garch(1,1) model. The procedure is exactly the same as that in Part (II), with $(\hat{y}_{1t}, x_t')'$ replaced by $(\hat{y}_{1t}^{*}, \hat{y}_{1t}, x_{2t}')'$. See (2.17) and (2.18).

3 Data description and empirical findings

3.1 Data description

Refer to the model described in the previous two sections. We use daily *raw* data which span from April 1, 1991 to December 31, 2010. The variables we use consist of:

(a) Int_t, daily amount of the Japanese monetary authorities' intervention: 0.1 trillion yen. A positive value indicates sale of yen (purchase of dollar), while a negative value indicates purchase of yen (sale of dollar).

(b) $USInt_t$, daily amount of the Fed's intervention: billion dollar. A positive value indicates sale of yen (purchase of dollar), while a negative value indicates purchase of yen (sale of dollar).

(c) Exc_t, yen per dollar rate.

(d) Rjp_t, daily close of Japanese call money interest rate: annual percentage.

(e) Rus_t, daily close of Federal Funds rate: annual percentage.

(f) FBD_t, dummy variable for first business day (see (2.8)): dummy variable.

(g) $Nikkei_t$, daily close of Nikkei 225 Stock Index: Index.

The Japanese intervention data are obtained from the Ministry of Finance of Japan ($http://www.mof.go.jp/english/international_policy/reference/feio/index.htm$) while the Fed's are obtained from the St. Louis Fed ($http://research.stlouisfed.org/$). Other variables are obtained either from St. Louis Fed or from Datastream. Altogether there are 5155 observations, after deleting the missing values for weekends and public holidays. In addition, we split the whole sample into two sub-samples. The first sub-sample spans from April 1, 1991 to January 13, 2003, while the second one spans from January 14, 2003 to December 31, 2010. The first sub-sample amounts to 3076 observations and the second one amounts to 2079. The summary statistics for the entire sample can be found in Table 1 while the time plots of the first three variables are depicted in Figure 1.

[Insert Table 1 here]

[Insert Figure 1 here]

Refer to the two equations in (2.1)-(2.2). The two key variables are defined as:

$$Sale_t = \begin{cases} Int_t, & Int_t > 0, \\ 0, & Int_t \le 0, \end{cases} \tag{3.1}$$

$$\Delta s_t = 100\left(\log(Exc_t) - \log(Exc_{t-1})\right). \tag{3.2}$$

In other words, $Sale_t$ is the daily Japanese sale of yen (in 0.1 trillion) while Δs_t is the daily return of yen/dollar rate. And it is clear from (2.4) that $SDEV_t = \Delta s_t$.

On the other hand,

$$SPR_t = Rjp_t - Rus_t, \; \Delta SPR_t = SPR_t - SPR_{t-1}; \qquad (3.3)$$

$$\Delta NIK_t = 100\left(\log(Nikkei_t) - \log(Nikkei_{t-1})\right). \qquad (3.4)$$

[Insert Table 2(A) here]

[Insert Table 2(B) here]

[Insert Table 2(C) here]

In essence, ΔSPR_t is the daily change in interest spread while ΔNIK_t is the daily return of Nikkei Stock Index. The other variables $MDEV_t$, $LDEV_t$, $DUSInt_t$, FBD_t and $IntIN_t$ are defined, respectively, as in (2.5)-(2.9). The summary statistics for the whole sample, the first sub-sample, and the second sub-sample can be found in Table 2(A), Table 2(B) and Table 2(C), respectively.

3.2 Empirical findings

The empirical findings of the structural and reduced-form parameters are reported in Tables 3(A)-3(B) and Tables 4(A)-4(B) respectively. To save space, we do not report the findings of the Garch(1,1) parameters, which are available upon request. Further, we also report in Tables 5(A)-5(B) the results that ignore Garch. That is, the findings with the conventional Heckman (1978)'s approach.

[Insert Tables 3(A)-3(B) here]

[Insert Tables 4(A)-4(B) here]

[Insert Tables 5(A)-5(B) here]

Comparing the results in Tables 3(B) and 5(B), one may conclude Garch does not alter the results for effectiveness, except possibly the first-of-the-week effect, which is captured by $IntNT_t$. In sum, both estimations, which correct for simultaneity, contrast with those conclusions in the literature. We found (i) intervention is effective; and (ii) controlling for interventions, the exchange rate does not follow a random walk. See, for instance, Table 3 in Ito (2005), for comparison. That said, the insignificant coefficients may due to the low goodness of fits in the reduced form equation of Δs_t, judging from the low t-values in Table 4(b).

Ignoring the fact that the whole-sample results may suffer from the time-varying parameter issue, let us look at the sole significant variable $IntNT_t$. The coefficient is 0.6583 which means one 0.1 trillion yen (about 1 billion dollar) sale of Japanese yen results in 0.66% rise in the yen-dollar rate. This is 3 to 4 times of that estimated by Chen, Watanabe and Yabu (2012), who also correct for simultaneity and Garch.

Next we turn to Table 3(A). For both regimes, coefficients for $DUSInt_{t-1}$, $Sale_{t-1}$ and $Sale_{t-2}$ are by and large significant, and have the correct positive signs (which means that interventions are positively correlated). The results are qualitatively the same in Table 5(A). Further, the first-business-day is significantly positive in the second regime, which suggests the monetary authorities take this advantage and no wonder the period of "great intervention" is described as "frequent intervention".

On the other hand, the coefficients for the three "deviations" are all negative in the first regime (see Table 3(A)). This suggests the authorities adopted the "leaning against the wind" policy. This is consistent with the negative coefficient of ΔSPR_t. Interestingly, the exactly opposite signs in the second regime (except that of $LDEV_t$) suggest that a "leaning with the wind" policy was adopted instead. Somewhat puzzling is ΔNIK_t. The coefficient is negative in the first regime which suggests "leaning with the wind" and it is negative in the second regime which suggests "leaning against the wind". Further investigation on how to interpret these results is needed.

4 Concluding remarks

In this paper, we construct a structural censored regression model, more precisely a structural Tobit-Garch model and apply it to two functions, namely reaction function and effectiveness function, of market intervention in yen-dollar rate. Using daily data publicized by the Japanese monetary authorities, we show evidence that: (i) Intervention is not effective; (ii) The Japanese monetary authorities adopted the "leaning against the wind" policy during Year 1991 to Year 2002, and they adopted the "leaning with the wind" policy during Year 2003 to Year 2010 except possibly stabilizing the long-term (150 days) exchange rate target.

Our results throw doubt on the existing conclusions in the literature which are based on methodologies that do not control for (a) the intervention amount being censored at 0; (b) simultaneity in the reaction and effectiveness functions; and/or (c) Garch. Having said that, it is unclear the insignificance in the effectiveness equation is due to the problem of "weak instruments", as one may conclude from the low t-values in one of the reduced-form equations.

Our version of MCMC approach with data augmentation is relatively new. First, a multivariate Garch model is not considered. Second, the Tobit-Garch model (for the reaction function) is not estimated with one single log-likelihood function (see Steps (b)-(c), Part (I) in sub-section 3.3). All these issues will be pursued in the future research.

Long-Term Trends in Audit Market Shares: Effects of BIG-4 Pricing Strategies or Non BIG-4 Market Power?[1]

We analyze changes in audit fees and market shares of the BIG-4 audit firms (KPMG, PWC, D&T, E&Y) as compared with those of NB-4 (Non BIG-4) auditors in the period 2000-2011. Both relative fees and relative market shares (compared across BIG-4 and NB-4) auditors changed radically over this period due to the enactment of the Sarbanes-Oxley Act (SOX). In addition, one of the major audit firms, Arthur-Andersen (AA) was driven out of business. We exploit variations in the effects of these two events across industries and across size quintiles to examine changes in pricing strategies and market shares of BIG-4 and NB-4 auditors. In particular we examine whether the market share changes have been driven primarily by the BIG-4 deterring clients through pricing strategies (which we characterize as 'cherry picking') or through more effective competition by NB-4 auditors (which we characterize as NB-4 market power). Our empirical results suggest that both these factors have played a significant role in the realignment of the market share for audit services across BIG-4 and NB-4 auditors following the enactment of SOX and the collapse of AA.

Keywords: BIG-4, Audit Fees, Market Share, Oligopolistic Competition.

We also thank participants at AAA Mid-Atlantic Regional Conference, CAAA annual Conference, and Auditing Section Midyear Conference, AAA annual Conference in 2013.

1. Introduction

Following the enactment of the Sarbanes-Oxley act in 2002 (hereafter SOX) and the demise of Arthur-Andersen (hereafter AA), audit fees have risen sharply and the market share for the BIG-4 auditors (KPMG, PWC, D&T and E&Y) has fallen dramatically (Figure 1).[2] In addition, the difference in fees between BIG-4 and other auditors (hereafter, NB-4), usually referred to as the BIG-4 premium, has increased over this period (Ghosh and Pawlewicz 2009). The goal of this paper is to examine whether the fall in market share is primarily a result of the increase in the BIG-4 premium, or whether, after controlling for the effects of the increase in the BIG-4 premium, increased competitiveness of NB-4 has also contributed to the decline in BIG-4 market share.[3] While these two effects have been discussed individually in earlier studies, our paper studies them jointly. Specifically, we examine the correlation between increases in the BIG-4 premium and decreases in the BIG-4 market share across each of thirteen different industry codes[4] in the post-SOX and AA period, 2003-2011. To augment this analysis, we study the switching behavior from BIG-4 to NB-4 auditors of individual firms and examine whether NB-4 empowerment has played any role in the erosion of BIG-4 market share.

At the industry level, we find that (percentage) industry market share losses of the BIG-4 are inversely correlated with industry rankings based on fee premia, that is, the BIG-4 lost *least* market share in industries where the excess premium is highest (Fee Premia measures I and III) or alternatively, in industries where the premium increased the most post-SOX (Fee Premia measure II). This finding is *inconsistent* with the market equilibrium being driven purely by BIG-4 pricing strategies -- greater BIG-4 selectiveness in choosing clients who are willing to pay large premia should lead to a smaller BIG-4 market share rather than a larger one. Analogously, at a firm level, we find that firms that are charged a larger *residual premium* (after controlling for mean industry fee effects) are *less* likely to switch to an NB-4 auditor in the following year. We also find that industries where the NB-4 held a lower market-share pre-SOX are also the ones where firms were more likely to switch *post-SOX* (after controlling for the excess BIG-4 premium). Together, these findings suggest that there has been a shift in terms of the perceived market value of NB-4 audits relative to BIG-4 audits on an industry-by-industry basis even after controlling for the pricing strategies of the BIG-4.

---

[2] Papers that have documented fee increases following the enactment of SOX include (Asthana, Balsam and Kim 2009; Griffin and Lont 2007). BIG-4 market share losses have also been noted in earlier literature though we could not find a systematic reference documenting the effects that are categorized in Table 3 of this paper.

[3] Cassell, Giroux, Myers, and Omer (2013) analyze a list of firms they consider to be second-tier auditors and argue that the reference documenting the effects that are categorized in Table 3 of this paper. competitive position of these second-tier firms has improved post-SOX. Our evidence suggests that this phenomenon is more widespread and applies to other smaller NB-4 audit firms as well.

[4] Industry membership follows Ashbaugh, LaFond, and Mayhew (2003) and is determined by SIC code as follows: agriculture(0100-0999), mining and construction (1000-1999, excluding 1300-1399), food (2000-2111), textiles and printing/publishing (2200-2799), chemicals (2800-2824; 2840-2899), pharmaceuticals (2830-2836), extractive (1300-1399; 2900-2999), durable manufactures (3000-3999, excluding 3570-3579 and 3670-3679), transportation (4000-4899), retail (5000-5999), services (7000-8999, excluding 7370-7379), computers (3570-3579; 3670-3679; 7370-7379), and utilities (4900-4999).

The economic theory of the market for public audits focuses on the fact that audit quality is not observable by investors either before or after the use of audited information (that is, audit services are credence goods (Eamons 1997). This property leads to a theoretical prediction that auditor reputation will be used by the market as a proxy for audit quality and that the "deep pockets" of BIG-4 auditors serves as an observable proxy for auditor reputation (Dye 1993; Datar and Alles 1999; Mayhew 2001). Further, (contemporaneous) unobservability of audit quality helps sustain equilibrium in rational expectations where large auditors hold a preponderant market-share (Bar-Yosef and Sarath 2005). The higher perceived quality of BIG-4 audits translates to better market prices for their clients. However, deep pockets also imply greater payouts from litigation (if the plaintiffs succeed) and this expected cost has to be recovered through higher fees. Summarizing, the overall economic consequences of the unobservability of audit quality leads to a theoretical prediction of two components that constitute the BIG-4 premium – (i) a (partial) recapture of the market value to the client-firm associated with higher BIG-4 reputation and (ii) a (partial) recovery of greater expected litigation payouts that act as the implicit guarantee of better quality audits by the BIG-4. All these predicted theoretical factors, namely the existence of a BIG-4 premium, the presence of market benefits for BIG-4 clients, and greater payouts to settle litigation claims by BIG-4 auditors have been tested extensively in the empirical literature. [5]

A simple decision model of auditor choice is useful for developing our arguments further. We view client firms as collecting quotes from both BIG-4 and NB-4 auditors. The BIG-4 act as market leaders and set their prices first while NB-4 act as market followers and set their prices in response. Firms then weigh the benefits that will accrue from choosing a more reputable (i.e. BIG-4) auditor against the extra fees they will have to pay to this auditor. If the perceived value of a BIG-4 audit reduces while quoting strategy stays constant, firms are more likely to switch to an NB-4 auditor.[6] This is equivalent to a (downward) shift in the demand curve for BIG-4 services as a function of the premium charged by them. Conversely, if the perceived value of a BIG-4 audit goes up, the demand curve will shift up *ceteris paribus.* Similarly, if the perceived benefit stays constant while BIG-4 firms increase fees relative to NB-4 (i.e. increase the premium), the market share of the BIG-4 will go down but the clients who remain with the BIG-4 will pay higher fees. This is equivalent to a shift in

[5] The existence of a BIG-4 premium is now a standard feature of Audit Fee models as documented in the next section. There is a considerable stream of empirical literature attempting to document the market value generated by BIG-4 auditors. For example, Beatty (1989) associated BIG-8 auditors with reduced under pricing for their clients at the time of Initial Public Offerings. Teoh and Wong (1993) found the earnings response coefficient (ERC) is higher for firms audited by BIG-4. Pittman and Fortin (2004) and Mansi, Maxwell, and Miller (2004) suggested that debt financing costs are lower for firms audited by BIG-4. Khurana and Raman (2004) showed that the ex-ante cost of equity capital is lower for firms audited by BIG-4 than for companies audited by NB-4 audit firms.

[6] This is a variant of the classic Hotelling (1929) model on consumer choice. In that model, customers with heterogenous tastes try to decide on a preferred supplier while the suppliers compete through price and location choices. Adapted to the audit setting, publicly traded firms have heterogenous benefits from choosing a BIG-4 auditor, and BIG-4 firms set prices to maximize profits taking this heterogeneity into account. Further details are provided in Appendix B.

the supply curve of services offered by the BIG-4. A more rigorous development of these economic forces is provided in Appendix B.[7]

Drawing on this decision model, our analysis focuses on examining whether supply side pricing decisions of the BIG-4 can explain the shifts in market shares across BIG-4 and NB-4 auditors or whether downward demand shifts (i.e. the greater propensity of client-firms to choose NB-4 auditors) have also played a significant role in driving these market share changes. These effects cannot be separated by studying the market as a whole; however, by studying the effects across individual industries where each industry exhibits a different relationship between premium shifts and market share changes, we find evidence *inconsistent* with pure supply side effects. Specifically, if market share changes are driven primarily by BIG-4 pricing strategies (that is, by cherry picking clients willing to pay high fees), we would expect to see a positive relationship between the size of the premium charged and loss in market share. However, we find that there is a negative relationship between the industry ranking by BIG-4 premium and industry ranking by loss of BIG-4 market share. This negative association is suggestive of a demand side shift (see Figure B1 Panel C of Appendix B).

To conduct this cross-industry test, we first construct a measure of the BIG-4 premium, based on the literature examining the determinants of audit fees. We use the pricing model from Blankley, Hurtt, and MacGregor (2012) and combine it with the industry fee effects analysis in Ashbaugh et al. (2003). We estimate a BIG-5/4*industry premium separately for the periods 2001-2002 and the periods 2003-2011. These estimates show that: (i) the BIG-4 premium is significantly different across industries; (ii) that the BIG-4 premium increased in *every* industry in the 2003-2011 period relative to 2001-2002 and (iii) there were differences in the premium increases across industries. We then construct three industry rankings related to the BIG-4 fee premium: Fee Premium Ranking I based on the median BIG-4 excess fees *after controlling for average industry and BIG-4 effects*; Fee Premium Ranking II based on the increase in (the average) BIG-4*industry coefficient across the two periods; and Fee Premium Ranking III based on the level of the BIG-4*Industry coefficient in the period 2003-2011.[8] We next construct three rankings of these industries related to BIG-4 percentage market share losses based on three different ways of computing market share: (i) the proportion of clients choosing BIG-4 in that industry (ii) the proportion of fees collected by the BIG-4 relative to the total industry fees; and (iii) the ratio of BIG-4 fee share (above) divided by BIG-4 market share. The third measure captures the pricing power of the BIG-4 in that industry. We then examine the correlations of each of the fee rankings with each of the market share rankings.

[7] There is of course the possibility that firms may decide to go private because of increases in audit fees. This does not pose significant empirical difficulties for our study for two reasons. First, the decision to go or not go public is influenced by many other more weighty factors than audit fees so the market of publicly traded firms is more or less inelastic in audit fees. Second, it is likely that firms that weigh these fees heavily are small firms that would disproportionately choose NB-4 auditors if they were present in the market and this would only strengthen our results.

[8] We do not use separate BIG-4 and Industry dummies in these last two regressions because of the fact that the BIG-4 hold such a large market share making the BIG-4*Industry dummy highly correlated with the industry dummy; the sum of all the BIG-4*Industry dummies is collinear with the BIG-4 dummy so a BIG-4 dummy cannot be included as an independent regressor.

The correlation between the rankings based on excess fee premia (or increase in fee premia) charged by the BIG-4 with the rakings based on their loss of market share is negative in all the nine cases based on a Spearman Rank Correlation Test. That is, the BIG-4 lost *less* market share in industries where the excess fee has a higher median (Fee Premia ranking I) or, increased the most post-SOX (Fee Premia ranking II) or had the highest level (Fee Premium III). This finding is inconsistent with the market equilibrium being driven purely by BIG-4 pricing strategies -- greater selectiveness in choosing high-fee paying clients should lead to a higher market share losses as the selectiveness increases. We then repeat the analysis using the market share of AA in each of these industries to see if the BIG-4 premium increases are related to AA's market share in 2001. The underlying economic argument is that the competitive strength of the BIG-4 would be higher in industries with a larger proportion of AA clients, and hence, these industries would have seen a greater increase in BIG-4 premium. We find that AA rankings have a less significant, but mainly positive relationship with the premium rankings, that is, excess premia are larger in industries where AA held a greater share pre-2002.

It is important to underline the motivation behind our choice of industry and rank correlation tests to examine the effects of SOX. Given just one observation, it is impossible to determine whether an equilibrium shift is driven by demand or supply effects. However, the heterogeneity in supply and demand curves *across industries* allows us to treat each industry as a separate observation on the effects of SOX on the market equilibrium.[9] The overall pattern suggests that the effects of SOX and AA were broadly similar across industries resulting in an increase in the BIG-4 premium and a reduction in BIG-4 market share, but differed in terms of magnitude. We exploit these cross-sectional differences to test for the relative effects of BIG-4 fee strategies as compared to NB-4 competitive power. In addition, there has been considerable current literature on the effects of factors such as office location (Craswell, Donald and Laughton 2002) or state regulation (Anatharaman and Wans 2012) on audit fees. The choice of the average (or median) industry premium should, at least in theory, diversify away such "microstructure" effects making it possible to draw inferences about market-wide relations between BIG-4 premia and market shares.

Our second test uses a Logit switching model, based on Landsman, Nelson, and Rountree (2009), to examine the effect of (firm-specific) BIG-4 premium (estimated in the first test) on the propensity to switch to an NB-4 auditor. The idea here is that if the reason for switching to an NB-4 auditor is due to supply side effects, that is due to an increase in the BIG-4 premium, we should expect to see firms which are charged a high premium (in the year before the change) switching more often to NB-4 auditors. On the other hand, if the client-firms are deciding to switch to NB-4 auditors because of a higher perceived value for NB-4 auditors, a proxy for NB-4 market power will also be significant. We use the industry-

---

[9] While we consider the enactment of SOX and the collapse of AA as the primary shocks that occurred in this period, we note that there were also other changes such as rule FIN 48 or AS-5 or market-wide effects such as the 2007 recession that might have affected audit fees and/or auditor choice. Our approach does not separate out the effects of these other shocks in any specific way. We do show (Table 6, panel C) that our findings are robust across different time periods so it is likely that the enactment of SOX was the main cause for the market shifts. In any case, this has no bearing on our main empirical findings that demand shifts took place and prior literature has mainly attributed such demand shifts as a consequence of SOX.

market-share of NB-4 auditors *prior to 2002* as a proxy. In other words, we examine whether the competitive position of the NB-4 pre-SOX has any effect on the switching behavior post-SOX *after controlling for the effects of BIG-4 premium changes.*

Firms that pay a larger *residual premium* (after controlling for mean industry fee and BIG-4 effects) are *less* likely to switch to an NB-4 auditor in the following year. This finding suggests a self-selection bias where only firms with above average market benefits from choosing BIG-4 auditors stay with them and (pay a higher fee). It is inconsistent with switching being driven primarily by a BIG-4 auditors requiring a higher risk premium, for if this were the case, firms whose fees have risen (perhaps due to greater audit risk) *above* their market benefits would be the ones who switch to NB-4 auditors leading to a positive relationship between firms-specific pricing and probability of switch. The Logit model also shows that firms are more likely to switch to NB-4 auditors over the period 2003-2011 in industries where the NB-4 had a low market share *prior to 2002.* This is additional evidence that NB-4 market power has played a role in attracting clients -- industries where the NB-4 were more competitive pre-SOX and AA demise are also the ones where the NB-4 are more likely to capture clients in the post-SOX era.

We also examine both our tests for demand shifts on a size quintile-by-quintile basis. As is to be expected, there is very little switching to NB-4 auditors in the highest quintile. However both our main empirical findings hold up in the middle quintiles. The Logit model shows that the effects of fees and NB-4 market power is significant in size quintiles 2, 3, and 4 where there is active competition between the BIG-4 and NB-4 for clients but is not significant in the lowest and highest quintiles. In other words, the effects of SOX and the collapse of AA has realigned economic incentives for medium sized firms but has had relatively little influence on the smallest firms that have historically provided clientele for NB-4 auditors or the largest firms that typically benefit from hiring large auditors.

There are several papers analyzing changes in the levels of audit fees post-SOX (Ghosh and Pawlewicz 2009; Griffin and Lont 2007; Huang, Raghunandan, and Rama 2009). There is also analysis in the prior literature about the types of firms that switched from BIG-4 to NB-4 auditors after the enactment of SOX (Landsman, Nelson, and Rountree 2009). Our analysis adds to these prior papers in three ways. First, we focus on the BIG-4 *premium* rather than *fees* as theory suggest that the premium rather than the level of fees determines client-firm choice of a BIG-4 or NB-4 auditor. Second we exploit potential heterogeneity in the effects of SOX (and the demise of AA) across industries by correlating the premium (and changes in the premium) with changes in market shares across industries. Last, we analyze the effects of the BIG-4 premium and 2001 NB-4 market share on the probability of an individual firm switching from a BIG-4 to an NB-4 auditor post-2003 adding to earlier research on client-firm behavior.

While we do not directly depend on them, the studies by Maher, Tiessen, Colson, and Broman (1992) and Menon and Williams (1991) had a significant impact on our methodology. Maher et al. (1992) report declining audit fees from 1977 to 1981 because the profession dropped many of its restrictions against competition. Menon and Williams find that audit fees increased in the 1980s but stayed flat in the 1990s. There is a significant increase in 1988 because The Auditing Standards Board issued the "expectation gap" standards. Menon and Williams (1991) also mentioned that BIG-8 mergers had a short-run, instead of a long run, effect on fees. Our focus is on similar economic phenomena in the period 2000-2011. In these years, we find a significant jump in fees due to the enactment of SOX. As in Menon and Williams (1991) we have a reduction in the number of large audit firms (due to the exit of AA rather than mergers). The post-SOX increase in audit fees and the drop in BIG-4 market share is so significant that descriptive statistics establish the trend. Our focus is on trying to establish whether the changes were primarily driven by changes in BIG-4 pricing strategies post-SOX and the collapse of AA or by other changes in the economic structure resulting from SOX. Our results suggest that SOX also influenced the competitive position of NB-4 auditors and this is reflected in the shifts in fees as well as market shares.

We contribute the prior literatures in three ways: i) We explore the long-term effects on audit market structure arising from the enactment of SOX and the collapse of AA; (ii) we show that there is a negative correlation between BIG-4 audit fee increase and market share decrease suggesting that these changes may be driven by factors other than BIG-4 pricing strategies; and (iii) we show a relationship between prior NB-4 market share and firm switching behavior after controlling for the effects of audit fees. We lay out these findings by first discussing related literature (Section II), developing Hypotheses (Section III) and presenting the sample, methodology and results in (Section IV). Section V offers concluding remarks.

2. Related literature

We review prior literature on the BIG-4 premium and the effects of SOX and AA's collapse on the post-SOX market share held by the BIG-4. Cross-sectional differences in audit fees can represent either the effect of quantity differences (in terms of hours of audit) or price differences in terms of hourly fee (Simunic 1980a). In addition, there may be quality differences in terms of differentiation of services (DeAngelo 1981) and the association between high fees and high quality may not be straightforward (Choi, J., J. Kim, and Y. Zang. 2010a). As noted earlier, audit quality is generally unobservable to investors and has to be inferred through differences in prices (Simunic 1980a). It is primarily the unobservability of audit quality interacting with auditor wealth that supports a BIG-4 premium in equilibrium as argued in both empirical studies (Simunic 1980a; Carcello and Palmrose 1994; Danos and Eichenseher 1986) as well as theoretical studies (Dye 1993).

Because wealthy auditors have more to lose from litigation consequent to audit failure, they can be expected to exercise a higher level of control over audit quality (Simunic and Stein 1996b). The higher expected litigation losses of BIG-4 would, in equilibrium, result in higher fees relative to NB-4 auditors. In addition, the fact that the inferred quality of BIG-4 audits is higher should also translate to additional rents for BIG-4 auditors. For both these reasons, we expect that BIG-4 firms would charge a premium to compensate them for the extra litigation risk and that client-firms would be willing to pay this premium because of the perceived higher quality of audits conducted by BIG-4 firms There are also extensive empirical studies about market differentiation across BIG-4 and NB-4 auditors.

Empirical tests of the existence of a BIG-4 auditor premium include Palmrose (1986) and Beatty (1989). Palmrose found that the BIG-8 audit firms charge higher audit fees and explained it as arising from their monopoly powers. Beatty (1989) however argued that reputation led to better pricing of IPO's audited by the BIG-8. Francis (1984) also found that the BIG-8 charged higher audit fees than non BIG-8 firms while Blokdijk, Drieenhuizen, Simunic and Stein (2006b) found that NB-4 audit firms are less efficient in their work than BIG-4 firms, which reflect low audit quality. Shockley and Holt (1983) provide evidence that auditors whose client firms represent the highest market value are perceived as providing higher quality audits. However, Dopuch and Simunic (1980a) and DeAngelo (1981) found that the quality of audit services is very difficult to measure. Danos and Eichenseher (1986) found that clients choose auditors for good economic reasons, based on both the (perceived) quality of auditor services and the audit fee as well as client specific factors. For example, they assume a link between audit firm market share and comparative advantages for larger clients (Dopuch and Simunic 1980a, Danos and Eichenseher 1986). A 2006 GAO (Government Accountability Office) report suggests auditees don't want to be audited by NB-4 firms because of the recognized difference in reputation.

In summary, both the theory literatures and the empirical literatures suggest that big auditors have (or are perceived to have) an advantage that should be reflected as a pricing premium. Whether perceived or real, there is a long-stream of literatures on audit fee determinants that include a component for the BIG-4 premium. We rely on this long precedent in assuming that a BIG-4 premium is present in audit fees and is determined primarily by the belief that BIG-4 auditors generate market value for their clients.

We rely on the literature on the determinants of audit fees (Simunic 1980a; Francis 1984; Maher et al. 1992; Ashbaugh, LaFond, and Mayhew 2003; Kealey, Lee, and Stein 2007; Ghosh and Pawlewicz 2009) in order to empirically isolate the BIG-4 premium. We use one of the latest published papers in this stream of literature (Blankley et al. 2012), to estimate both an overall BIG-4 premium and an industry-by-industry BIG-4 premium. We emphasize that our goal is not to study the BIG-4 premium *per se,* but to see how this premium is related to changes in market share across BIG-4 and NB-4 auditors. Our methodology is discussed in more depth when developing our hypotheses in the next section.

The effect of SOX in increasing audit fees has been documented in many earlier studies (Asthana, Balsam and Kim 2009; Griffin and Lont 2007; Huang 2009) while the increase in the BIG-4 premium has been documented in Ghosh and Pawlewicz (2009). The possibility that SOX has increased NB-4 competitiveness has been studied indirectly in Cassell, Giroux, Myers, and Omer (2013). This paper finds a post-Andersen improvement in the perceived financial reporting credibility of clients of Second-Tier (NB-4) auditing firms relative to clients of BIG-4 auditing firms. Also, they find that BIG-4 clients had a lower *ex-ante* cost of equity in the period before AA collapsed suggesting that some of the BIG-4 reputation for audit quality had eroded due to the negative publicity surrounding the Enron scandal.

Our sample takes this analysis up to 2011. While there has been a small downward trend following the 2006 recession, audit fee increases have remained high over a long-horizon. Simunic (1980a) argues that if the BIG-8 firms collude to increase prices in the "large" auditee segment, their NB-8 competitors would seek to expand market share and price consistent with their own cost conditions, rather than to maintain the cartel price. Using the same argument, we argue that the increase in the BIG-4 premium has led to increased market share for NB-4 auditors but that other factors have also contributed to this increase. Danos and Eichenseher (1986) indicated a more generalized movement to the BIG-8 across all client firms from 1973 to 1980. They argue that the observed change in market share reflects a long-term adjustment to a fairly stable equilibrium distribution of clients across large and small audit firms. In contrast, the enactment of SOX and the collapse of AA disrupted supply and demand patterns in the audit market. This led to both the increases in prices discussed earlier and to other effects as well. We draw on the evidence in Cassell et al. (2013) to reinforce the popular sentiment that SOX has strengthened NB-4 auditors relative to BIG-4 auditors. We bring both these strands of literatures together to analyze whether the shifts in market share can be viewed as primarily driven by new price strategies adopted by the BIG-4 (Choi, Doogar, and Ganguly 2004b) or whether SOX has shifted the preference of client-firms, at least in some section of the markets, towards NB-4 auditors *after controlling* for the effects of price on market share.

While the overall pattern of shifts in pricing and market shares suggests that SOX was the major event over the long-window 2003-2011, the effects of the collapse of AA also had significant impact particularly in the period 2003-2004. Several prior studies have examined the switching behavior of Arthur Andersen clients (for example, Blouin, Grein, and Rountree 2007). While the reputation of AA suffered, Krishnamurthy, Zhou and Zhou (2006) found that firms which were former audit clients of Andersen and then switched to other BIG-4 audit firms had higher returns suggesting these were either intrinsically better quality firms (and signaled the high quality by staying with a BIG-4 auditor). Our focus is somewhat different but related to this finding. We argue that the supply curve was disrupted to a greater extent in industries where AA held a larger share and consequently, that the shift in equilibrium audit prices and BIG-4 market shares should be influenced by AA's pre-2001 footprint in that industry.

Our second test builds on the literature regarding auditor choice. We use the "mismatch" variable developed in Shu (2000) (see Appendix A for details) and the model in (Landsman et al. 2009) to control for firm-specific factors that may induce switching from a BIG-4 auditor to an NB-4 auditor. After controlling for these factors, we examine whether excess fees (measured after adjusting for an average BIG-4 effect and Industry effect) increase or decrease the probability of switching from a BIG-4 to an NB-4 auditor. In addition to fees, we examine whether the competitive position of NB-4 auditors in the prior equilibrium (measured by pre-2002 NB-4 market share) has any relationship to the new equilibrium post-SOX and demise of AA. That is, we see whether switching behavior of individual firms had any relation to NB-4 competitiveness after controlling for other factors and the effects of BIG-4 pricing strategies.

3. Hypotheses development

We outline again the basic economic factors that motivate our study. The audit market involves a complex fee and quality structure where audit quality is credence good. For this reason, BIG-5/4 auditors are able to set up a quasi-oligopoly and charge a higher fee than NB-4 auditors. We abstract away from within BIG-4 competition and view this as a Stackelberg Oligopoly Equilibrium with the BIG-4 acting as leaders and NB-4 as followers (Vives 1999, 200–205). Firms are willing to pay this premium as they recover the costs through a better price in the stock market (e.g. through a lower cost of capital). Despite the premium charged, large audit firms also held a preponderant share of the market for audit services, generally increasing their market share over a long period prior to 2000. However, this process was interrupted by two major events in 2002 – the collapse of AA and the enactment of SOX. Our hypotheses pertain to shift in the market equilibrium after these two events.

Because the total market for audit services is (almost) inelastic with regard to audit fees,[10] an increase in the BIG-4 premium should result in a reduction in market share for big auditors. However such a market share reduction could be further enhanced if the competitive position of NB-4 auditors has been strengthened due to SOX. The main focus of our analysis is to try and see if we can find evidence for stronger market competition from NB-4 auditors post-SOX through a careful analysis of the relationship between premium increases and changes in market share.

An increase in the premium suggests either that the BIG-4 had greater pricing power post-SOX and AA collapse or that they raised fees due to some other reasons such as a differential increase in Litigation costs (as compared with NB-4). Under the first argument, there would typically be very little erosion of market share due to the increase in the premium. However, the data show that there was a sharp fall in the market share of BIG-4 auditors. This suggests the premium increase could have been a deliberate strategy to shed less profitable clients perhaps as a reaction to increased risk post-SOX for BIG-4 auditors (relative to NB-4 auditors).

It is also possible that the loss of market share was due to the fact that the benefits associated with a BIG-4 audit declined post-SOX and the collapse of AA. This would lead directly to a loss in market share for the BIG-4. However, it would also typically lead to a reduction in the premium as BIG-4 auditors reacted to the reduction in their perceived value by reducing fees. At the very least, the reduction in market share and changes in premium would be positively correlated, that is, the greater the increase in NB-4 market power, the more downward pressure would be exerted on the BIG-4 premium coupled with a greater loss in market share.

Summing up these arguments, the relationship between the BIG-4 premium and market-share losses could be either positive or negative depending on the relative effects on the supply side and the demand side. Exploiting the fact, established in earlier studies, that there are significant industry differences in both audit fees and market shares (Cahan, Jeter and Naiker 2011) we can treat each industry as a "separate" experiment on the effects of the BIG-4 premium increase on BIG-4 market share losses, or equivalently, NB-4 market share gains. As we document in Table 3 Panels F & B, the premium increased in every industry and the NB-4 gained market share in every industry, but there was variation both in terms of the premium increase and market share decrease. If the primary driver of the market realignment post-SOX was the fee strategies set by the BIG-4 auditors, we would typically expect that industries where the premium increased the most are also the ones where the BIG-4

[10] The cost of going private and avoiding the need for an independent audit generally involves costs that are much larger than audit fees, so the effect of an increase in audit fees on the total number of publicly traded firms is generally small.

eliminated a larger share of clients, that is, that industry market share losses and industry premium increases are positively correlated. Note that there is a clear alternative possibility here – that NB-4 market share increased because of an increase in client-demand for NB-4 services. Under this second scenario, the increase in the BIG-4 premium will be lowest in industries where NB-4 power increased the most and we would also see a greater market share loss in these industries, in other words, that premium increases and market share losses would be negatively correlated.

In order to further examine the effects of competitive factors, we introduce two empirical variables that may plausibly affect the ability of the NB-4 to attract clients in the post-SOX environment: (i) the proportion of the market held by AA (*pre*-SOX) and (ii) the proportion of the market held by NB-4 auditors *pre-SOX*. Each of these factors could influence the equilibrium post-SOX, but the direction of influence is unclear from a theoretical perspective. For example, if AA held a larger share in an industry in 2001, the collapse of AA would disrupt the supply curve but could also lower the demand curve because the perceived value of a BIG-4 audit may have fallen due to the Enron scandal. Analogously, the enactment of SOX may have strengthened NB-4 auditors uniformly across all industries, more in industries where they were previously *more* competitive or more in industries where they were *less* competitive. For these reasons, we do not have directional predictions based on theory as to which way AA market share and pre-SOX NB-4 market share will influence client-switching behavior from BIG-4 to NB-4 post-SOX (H2, H3, and H4).

Out first hypothesis (in null form) is that the shift in market shares is primarily attributable to the fee strategies of the BIG-4 post-SOX and AA. If this were the case, industries where the BIG-4 is more selective should see both higher BIG-4 premia and greater losses in market share:

H1: *The fee premium charged by the BIG-4 post-SOX will be higher in industries where their market share declined more (i.e., fee premium will be positively correlated with (NB-4) BIG-4 market share losses (gains)).*

The second hypothesis is connected with the joint effects of the collapse of AA and SOX. The premise is that the larger AA's market share in that industry in 2001, the greater will be the increase in pricing power for the surviving BIG-4 firms. In addition, the lower the shift in competitive advantage to NB-4 auditors, the less the pricing power for BIG-4. This leads to our second hypothesis (in null form):

H2: *The fee premium charged by the BIG-4 post-SOX in any industry will bear the same relationship to the SOX effect (as in H1) irrespective of AA's market share in that industry in 2001.*

The last two hypotheses are associated with the probability of switching from a BIG-4 firm to NB-4 firm in the period 2003-2011. If cherry picking by the BIG-4 is the main significant factor driving the switch to NB-4 auditors, we expect that firms that are being charged a high premium by the BIG-4 (in the prior year) are more likely to switch to NB-4 auditors. In null form, this reduces to:

H3: *A high fee premium charged by the BIG-4 (in the previous year) will not affect the probability of switching to an NB-4 auditor.*

Our last conjecture related directly to the hypothesis that the enactment of SOX and the overall perception that all auditors were now required to do a better job mitigated concerns about the overall quality of audits. Given an increase in audit quality (either real or perceived) the role of reputation and/or deep pockets as a proxy for audit quality would be muted. Therefore, we would expect more switching to NB-4 in industries where the market power of the NB-4 auditors increased the most. To test for this possibility, we use the competitive position of the NB-4 in the pre-SOX period as an instrumental variable for measuring the strength of NB-4 auditors in that industry. We conjecture that SOX helped the competitive position of NB-4 auditors but that it was differential across industries.

H4: *The industry strength of NB-4 auditors prior to SOX does not change the probability of switching to an NB-4 auditor post-SOX.*

We now describe our methodology and statistical tests to try and reject the null hypotheses H1-H4.

4. Sample, methodology and results

Sample and Descriptive Statistics

To form the sample, we collected data from audit analytics covering the period from 2000 to 2011. This resulted in a total of 150,908 observations. If a client has two or more auditors in a sample year (but did not change auditors), we sum the audit fees for the specific year. Therefore we have a single fee observation for each client-firm for each year. If a client-firm switched auditors, we delete these observations eliminating 6,701 observations from the sample. Next, we merge with Compustat to collect financial data. 55,723 observations were deleted because the financial data was not available. In addition, 26,703 observations did not have information about business segments and were deleted. We use the industry analysis methodology of Ashbaugh et al. (2003) and eliminate the financial services industry (SIC 6000-6999) losing 10,040 observations in this process. In the final step, we exclude firm years with missing Compustat data in the auditor switch model and as a consequence, 6,714 observations were deleted. Our final sample for the audit fee model consisted of 51,732 observations. 8,636 firm year observations are before 2003, while 43,096 firm year observations are after 2002. In addition, for the switching model, we delete 2,020 observations before 2001, because of missing data regarding auditor switches. Then we delete 6,735 firm year observations before 2002, because we focus on the influence of fee premium after 2002. Our final sample for switching model is 28,263.[11] The representation of each industry in our sample is closely aligned with the overall industry composition listed in COMPUSTAT.

[11] If the firm was a foreign filer or failed to issue a SOX 404 Internal Control report, we define going concern, material weakness and modified opinion as 0, so we did not lose observations in this process.

Table 3 Panel A describes the ratio of audit fees by NB-5/4 audit firms divided by total fees from 2000 to 2011 in different industries. While this also shows the same time-trend, what is striking is that the share of revenues does not exceed 13% in any industry showing the enormous market-share advantage held by the BIG-4. Table 3 Panel B shows the market share audited by NB-5/4 from 2000 to 2011. From this table, it is obvious that the market share of NB-4/5 firms increased significantly post-SOX and AA. (See also Figure 1). Table 3 Panel F shows the increase in the size of BIG-4 firms over the period 2001-2007. The panel shows that firms grew rapidly in the years 2001-2004 when they absorbed the former clients of AA but this expansion slowed in the years 2005-2007 and reversed slightly in the period 2007-2011. Table 3 Panel G shows the number of firms audited by BIG-5/4 on an industry basis from 2000 to 2011. From the evidence in Table 3, it is obvious that the market share of NB-4/5 firms increased significantly post-SOX and AA. (See also Figure 1 Panel B).

Methodology

Our methodology involves two different approaches. In both approaches, our goal is to first construct measures for the post-SOX "excess fee" charged by BIG-4 auditors. Then our second step is to see if these excess fees determine the propensity of client-firms to choose NB-4 auditors post-SOX, or whether other factors are also influential. In the first approach, we use an industry based model similar to Numan and Willekens (2012). In this approach, we use three measures of differential pricing across BIG-4 and NB-4 auditors in each industry to capture the effects of BIG-4 pricing strategies post-SOX. Then we measure the relationship between BIG-4 premium increases and industry market-share changes using a Spearman Test. Specifically, we examine the relationship between industry rankings related to the BIG-4 premium with both the market-share gains of NB-4 auditors and the market share held by AA before their collapse. In this first set of tests, the underlying idea is that if the increase in the premium was the main factor driving market-share shifts, the industries with the largest premium increases (or levels) should also see the greatest market share reductions.

The second test follows Landsman et al. (2009) and uses an auditor choice model. Here, we restrict the sample to BIG-4 clients and use the residual from an audit fee regression as a measure of the firm-specific abnormal fees charged by BIG-4 auditors. We then see if a large residual in one year increases the probability of switching in the following year. Our second test variable is the 2001 market share held by the NB-4 firms. The underlying idea here is that the competitive position of NB-4 auditors pre-SOX should change post-SOX and affect the switching behavior of firms.

In both set of tests, we do not specifically adjust for firms that may have entered or exited the market. Overall, the total number of firms entering or exiting the market is very small relative to the total sample and keeping or removing these firms has no effect on the measure of market shares or the measure of the premium. In our switching model, we only use firms that are BIG-4 clients and then switch to an NB-4 auditor. The length of the audit engagement is a control variable in this model and adjusts for the fact that a new entrant may have a lower probability of switching auditors. In summary, the entry and exit of firms has minimal or zero effects on our tests.

Audit Fee Models

One of our primary goals is to get an estimate of the fee premium charged by the BIG-4 on an industry-by-industry basis. To isolate the BIG-4 fee premium, it is necessary to estimate what the fee "would be" based on firm and industry characteristics had the firm been audited by a small auditor. Models that tie audit fees with firm characteristics have been extensively developed starting with Simunic (1980a). Most of the models in the following years have used variations of Simunic's model. In particular, the models are log-linear in audit fees and firms' assets. Other variables such as account receivables are used to control for risk. Many recent models extend and improve on Simunic's original model. We use the following model from Blankley et al. (2012) as it provides a convenient reference point for our subsequent industry based analysis:

$$\begin{aligned} LAF_{i,t} = {} & \alpha_0 + \alpha_1 LTA_{i,t} + \alpha_2 CR_{i,t} + \alpha_3 CA\_TA_{i,t} + \alpha_4 ARINV_{i,t} + \alpha_5 ROA_{i,t} + \alpha_6 LOSS + \alpha_7 FOREIGN \\ & + \alpha_8 MERGER + \alpha_9 BUSY_{i,t} + \alpha_{10} LEV_{i,t} + \alpha_{11} INTANG_{i,t} + \alpha_{12} SEG + \alpha_{13} OPINION_{i,t} \\ & + \alpha_{14} MATWEAK_{i,t\text{-}(t\text{-}1)} + \alpha_{15} BIG5/4_{i,t} + \alpha_{16} INDCON_{i,t} + \varepsilon_{i,t} \end{aligned} \quad (1)$$

We take the natural log of audit fees.[12] If a firm is audited by Arthur Andersen, Deloitte & Touche, Ernst & Young, KPMG, or PricewaterhouseCoopers (or just the last 4 after AA's collapse), the BIG-5 Dummy equals 1 and 0 otherwise; The control variables are consistent with prior research (Simunic 1980a; Palmrose 1986; Whisenant, Sankaragurusuvamy, and Raghunandan 2003; Francis, Reichelt, and Wang 2005; Hay, Knechel, and Wong 2006). The audit effort measures are assets (LTA); the presence of mergers (MERGER) or foreign operations (FOREIGN); the number of business segments (SEG); and the auditors issue a going concern opinion (OPINION).Further, Audit risk measures are CR; CA_TA; ARINV; ROA; LOSS; and INTANG. Financial leverage (LEV) captures long-term financial structure of the client. We also include industry dummies following Ashbaugh et al. (2003), since our analysis is based on industry premium. To control for internal control quality, we also use a variable as the company has material weakness in the current year (Ettredge, Li, and Sun 2006; Doyle, Ge, and McVay 2007). Finally, we include a variable if the company's fiscal year end is December 31st. The BIG-4 coefficient estimated over the period 2003-2011 in our sample is significantly higher than a similar BIG-5 dummy coefficient estimate over the years 2000-2002 suggesting that the BIG-4 "premium" increased significantly post-SOX (as documented for a different sample by Ghosh and Pawlewicz 2009).

Industry Effects

Audit fees vary significantly across industries. Different patterns of production, raw materials and intangible assets change the nature of the external auditor's verification process. Less clear are arguments as to how auditor specialization in industry affects fees. Both Palmrose

---

[12] An alternative to transforming the fee variables by their natural log is to scale the fee variables by total assets. (Ashbaugh et al. 2003) We do not use this transformation because our focus is the magnitude of fees instead of the relative cost of audit-related services to the client.

(1986) and Menon and Williams (1991) find no association is observed between audit fees and industry specialization. Other scholars suggest that fee differences across BIG-4 and NB-4 as well as fee differences within the BIG-4 should vary across industries. Danos and Eichenseher (1986) said that market share differentials are maintained in the public utility, oil and gas, and railroad industries from 1950 to 1980 due to client regulation. They found a significant positive correlation between industry-specific auditor concentration levels and the percentage of industry members listed on the American and New York Stock Exchanges. Previous researches also pointed out the possibility that large audit firms have comparative advantages in highly regulated industries (Danos and Eichenseher 1986). Craswell, Francis, and Taylor (1995) found that BIG-6 auditors could charge a higher price than non specialist BIG-6 auditors. They attribute this effect to the fact that industry specialists make investments in order to achieve their industry specific expertise.

Based on these earlier results, we expect to see significant differences across industries in terms of the mean BIG-4 premium and in terms of the effects of SOX. To test this, we run the same regression as (1) with industry coefficients.

$$\begin{aligned} LAF_{i,t} = {} & \alpha_0 + \alpha_1 LTA_{i,t} + \alpha_2 CR_{i,t} + \alpha_3 CA\_TA_{i,t} + \alpha_4 ARINV_{i,t} + \alpha_5 ROA_{i,t} + \alpha_6 LOSS + \alpha_7 FOREIGN \\ & + \alpha_8 MERGER + \alpha_9 BUSY_{i,t} + \alpha_{10} LEV_{i,t} + \alpha_{11} INTANG_{i,t} + \alpha_{12} SEG + \alpha_{13} OPINION_{i,t} \\ & + \alpha_{14} MATWEAK_{i,t-(t-1)} + \alpha_{15} BIG4{*}INDCON_{i,t} + \varepsilon_{i,t} \qquad (2) \end{aligned}$$

We do not use a separate BIG-4 dummy in this regression because it is the sum of the BIG4*INDCON interactive dummies. We also do not use a separate industry dummy because it is highly correlated with the interactive dummy as the BIG-4 hold a preponderant market share in every industry. The results are tabulated in Table 4 and show that the coefficients varied significantly across industries, that is, the BIG-4 premium was industry dependent. The t-statistics are adjusted for clustering and the F-test after Table 4 rejects the equality of the BIG-4 dummy coefficient across industries.

Fee Premium Measures

We use the residual from Equations (1) and the BIG-4*Industry coefficient in Equation (2) to construct our empirical measures of the excess fees charged by the BIG-4. As the right-side regressors in Equation (1) include both firm characteristics as well as average BIG-4 and industry effects, the residual measures firm-specific excess fees. If this residual is large, it is indicative of being charged high "excess" fees by the BIG-4 (due to unobservable firm specific factors). To the extent that the market equilibrium is being driven by BIG-4 pricing strategies, we would expect the firms being charged high excess fees to be the ones that switch to NB-4 auditors. We test this in two ways: first, by determining the correlation between market share changes and excess BIG-4 fees on an industry-by-industry basis, and second, by examining switching probabilities at the firm level.

For the first test, we rank industries with regard to the BIG-4 premium in three ways: (i) based on the median residual from Equation 1; (ii) based on the *change* in the BIG-4*Industry coefficient across the periods 2000-2002 and 2003-2011 in Equation 2; and (iii) based on the *level* of the BIG-4*Industry coefficient in Equation 2. We compare each of these industry rankings based on the BIG-4 premium with three Industry rankings defined through the percentage loss of BIG-4 market share measured either (i) in terms of the number of firms, or, (ii) by the total fees charged, or, (iii) as a ratio of these variables. Then we test to see if the rankings of industry based on fee premia corresponds positively or negatively with those on NB-4 market share losses. If fee strategies of the BIG-4 were primarily responsible for market share shifts, we would expect that a positive correlation between BIG-4 excess fee rankings and NB-4 market share gains (H1).

We now turn to the industry-specific market share changes arising out of the effects of exit of AA. We measure the influence of the exit of AA on the market equilibrium based on their market share (either in terms of firms audited or in terms of revenues). We then examine how the rankings of industries based on AA's market share correlate with the post-SOX shifts in market share across BIG-4 and NB-4 (H2).

Audit Switch Model

For the second test, we build on the auditor switch model from (Landsman et al. 2009). The structure of that model and our test variables are described below in Equation 3.

$$\begin{aligned}SWITCH_{i,t} = {} & \alpha_0 + \alpha_1 ABAFEE_{i,t-1} + \alpha_2 {*} TestVar + \alpha_3 GROWTH_{i,t-1} + \alpha_4 ABSDACC_{i,t-1} + \alpha_5 ARINV_{i,t-1} \\ & + \alpha_6 GC_{i,t-1} + \alpha_7 MODOP_{i,t-1} + \alpha_8 TENURE_{i,t-1} + \alpha_9 ROA_{i,t-1} + \alpha_{10} LOSS_{i,t-1} \\ & + \alpha_{11} LEVERAGE_{i,t-1} + \alpha_{12} CASH_{i,t-1} + \alpha_{13} BIG4{*}MISMATCH_{i,t-1} + \alpha_{14} EXPERT_{i,t-1} \\ & + \alpha_{15} SIZE_{i,t-1} + \alpha_{16} MERGER_{i,t-1} + \varepsilon_{i,t} \end{aligned} \tag{3}$$

TestVar

1.NB-4MarketShare in 2001

2.AAMarketShare in 2001,ABAFEE*AAMarketShare2001

3.AAFeeShare in 2001,ABAFEE*AAFeeShare2001

To control for audit risk, we include GROWTH, ABSDACC, INVREC, GC, MODOP, and TENURE (Stice 1991; DeFond and Subramanyam, 1998). We include other variables to control for client-specific aspects of the audit engagement related to audit risk, like INVREC, GC, MODOP and TENURE (Dopuch, Holthausen, and Leftwich 1987b; Stice 1991; Krishnan 1994a; Krishnan and Krishnan 1997b; Johnstone and Bedard 2004). To control for financial risk, we include ROA, LOSS, CASH, and LEVERAGE. We also include the MISMATCH variable as a proxy for misalignment (Shu 2000; Landsman et al. 2009) as a further control. Finally, we include industry fixed effects, EXPERT, SIZE and MERGER as additional control variables. (Hogan and Jeter 1999), because companies are more likely to switch auditors after a merger or acquisition if the two companies involved had different auditors prior to the merger. After controlling for all these factors that have been advanced as influencing switching behavior in earlier papers, we focus on the effects of our test variables that measure the effects of fees and market share variables on switching behavior.

The GAO (2006) report suggests that audit firms are more sensitive to client risk after Arthur Andersen collapsed, so we expect that BIG-4 auditors increased the premium more for clients with high-risk characteristics. However, assuming that their benefits from going to a BIG-4 auditor did not change (or did not increase commensurate with the fee increase), they are more likely to switch to NB-4 auditors. Even otherwise, if the increase in BIG-4 fees were driving firms to the NB-4, we would expect that large *abnormal* fees (after controlling for mean BIG-4 and Industry effects) encourage switching (H3). In addition, if the fee strategies are mainly driving switching behavior, we should see no influence of NB-4 market power on switching behavior. For this reason, we use the NB-4 industry market share in 2001 as a test variable to see if it influences the probability of choosing an NB-4 auditor post 2003 (H4). For similar reasons, we test whether AA's pre 2001 market share either influences the probability of switch directly, or in interaction with the abnormal fee.

Results

Before presenting our results, we outline some statistics that form the background for our analysis. The BIG-4 market share reduced significantly over the period 2003-2011. The descriptive statistics are compelling. [13] The results documented in Tables 3 – 4 show that the cross-sectional variation both in market share losses and BIG-4 premia increases are considerable across industries. Our fundamental economic premise is that the enactment of SOX and the demise of AA affected both the demand and supply curves for audit services (as a function of the BIG-4 premia). In particular, we wish to study how strongly changes in the demand curve have affected market structure. If the primary force for change has been cherry picking of profitable clients by the BIG-4 through their fee strategies, we would expect to see a positive association between the level of fee premia and changes in market share. If however, demand curve shifts have also been influential, we would expect to see more negative correlations between the industry premium and industry market share declines (Appendix B B1). Table 5 shows that the correlation between each of the fee rankings and each of the market share rankings is significantly negative (using a non-parametric Spearman test), that is, H1 is rejected. Although the premium has gone up and may have reduced the BIG-4 market share, other factors besides the increase in premium are necessary to explain the negative correlation (such as a downward shift in the demand curve for BIG-4 services for at least a portion of the market).

Analogously, if the demise of AA disrupted the supply curve more than the demand curve, we would expect to see higher premia in industry where AA had a larger market share. In contrast, if NB-4 auditors were better able to compete in industries where AA initially had a greater market share (because the remaining BIG-4 was weaker), we would expect to see a negative association. The results are not very conclusive using a non-parametric Spearman test (Table 5 Panel C), positively significant with regard to Fee Premium III but not the others. The finding suggests that the premium is higher in industries where AA had a larger footprint and at least in this case, supply side effects have led to larger absolute fee levels in industries where AA had a stronger presence. We also examined the relationship between fee premia and the proportion of AA clients switching to NB-4 auditors in the industry (AA-

---

[13] Although we do not report them here, we formally tested and rejected null hypotheses that there was no change in NB-4 market share from 2001 to 2011 both at an industry level and in aggregate.

switch-share in Table 5). Again, the results are not very strong but suggest a negative association between high fees and NB-4 auditor choice. That is, industries where larger numbers of AA clients switched to NB-4 auditors also had low excess fees, perhaps as a consequence of the fact that NB-4 auditors were more competitive in these industries.

Table 6 documents the tests on switching behavior by BIG-4 clients to NB-4 auditors during the years 2001-2011. Although our main focus is on columns C and D which cover the years 2003-2011, we include the period 2001-2002 for comparison purposes. First, we show that the audit fee residual from Equation 1 has a negative coefficient in the switch model. The inference is that firms with larger residual (i.e., larger abnormal fees paid to BIG-4 auditors) were less likely to switch to NB-4 auditors. This is inconsistent with an assumption that customers were dropped or driven away from the BIG-4 by the use of large audit fees. If firms realized that they were paying excess fees *after adjusting* for the mean industry and BIG-4 premium, they should be more willing to consider an NB-4 auditor. Instead, we find that such firms are less likely to switch auditors. One possible explanation is that of a survivorship bias. Firms that continue to retain BIG-4 auditors perceive some special benefit from this relationship above and beyond that implied by their observable characteristics.

In this table, it is also shown that industries in which the NB-4 had higher market share in *2001* (the last variable in Table 5 termed as NB-4 market share in 2001) also had a lower probability of switching in the period *2003-2011*. The inference from this finding is that NB-4 market power also influences switching behavior. More precisely, SOX seems to have improved the ability of the NB-4 to compete more effectively in industries where they had less influence prior to SOX. To sum up, the overall findings in Table 6, Columns C and D are that switching behavior seems to be influenced by demand-side factors such as a greater attractiveness for BIG-4 audits for some firms (who are willing to pay high excess premia) or a greater preference for NB-4 audits for other firms in industries where the NB-4 were less competitive pre-SOX.

It is also instructive to compare the differences between the coefficients over the period 2001-2002 as compared with 2003-2011 (Table 6, Columns B compared to Columns C and D). We note that the fee residual here has a positive coefficient. Our interpretation is that fees were already starting to rise in this period and firms that were fee sensitive switched in 2002. Note also that in Column A, the AA-market share variable is negative and significant at the 10% level, suggesting that firms in industries where AA held a larger share were more likely to stay with other BIG-4 auditors. In other words, we find that the demand for BIG-4 auditing did not shift sharply due to the failure of AA.

We note that all the results in the switching model are derived after controlling for the mismatch variable (Landsman et al. 2009). This variable is determined based on optimal cut-off score (based on certain firm characteristics; see Appendix A) that creates the least misclassification of auditor selection. In other words, the optimal cutoff score is chosen in such a way that a specification that all firms below the cutoff should choose an NB-4 auditor whereas firms above the cutoff should choose BIG-4 produces the smallest number of auditor-auditee misclassifications. Then firms below the cutoff that choose BIG-4 or firms that are above the cutoff but choose NB-4 are classified as mismatched firms. As in Landsman et al. (2009) we find that mismatched firms are more likely to switch but the negative effect of the residual fee holds even after controlling for mismatched firms.

In order to better understand both aspects of the change, we analyze the switching model on a size quintile-by-quintile basis. As may be expected, we find that the switching model, with one or two minor exceptions, is stable across the middle quintiles but is significantly different in the highest and lowest quintiles. First, the key variable of abnormal fee is significantly negative in the middle quintiles suggesting that higher than normal (lagged) audit fees do not induce these firms to switch. In addition, the level of market share held by NB-4 auditors prior to 2001 also significantly influences switching post-SOX, that is, more switching has taken place in industries where NB-4 were more competitive prior to 2001. Firms that were "mismatched" with the BIG-4, that is, firms whose observable characteristics suggested that they would be better off with NB-4 auditors, were significantly more likely to switch in these middle quintiles quintiles (insignificant in the two extreme quintiles). Combining the findings on the explanatory variables: (i) abnormal fees (ii) and 2001 NB-4 market share, analysis of the switching model by size-quintiles confirms the influence of demand side shifts in the market post-SOX and AA.

While not pertinent to our hypotheses, we comment briefly on some of the other firm-specific control variables in Table 6 Panel A. Growth is negative (or insignificant) in all quintiles suggesting that growing firms are less likely to switch to BIG-4 auditors. Interestingly, Cash is also negative suggesting that cash-rich firms are less willing to pay for a BIG-4 audit. Audit tenure is also negative suggesting that firms who have been with a BIG-4 auditor for longer are less willing to switch to an NB-4 auditor. This is intuitive for two (related) reasons: (1) most firms will stick with an auditor for several years before investigating the possibility of change and (2) firms that are deriving value from BIG-4 audits may become less certain about this (lack of value) over time and thus be less open to switching to an NB-4 auditor. Somewhat surprisingly, the loss variable is not stable in sign suggesting that multiple economic factors may affect the auditor choice of loss-making firms. While such firms may be unwilling to switch to an NB-4 auditor because of the negative signal it sends to the market place, they may also be more sensitive to fees (and hold less readily available cash).

Our results show that although the BIG-4 premium has risen significantly, the relative competitive position of NB-4 auditors has strengthened with regard to a significant proportion of the market. To augment this finding, we run the switching model separately on each quintile (Table 5 Panel B). The results are consistent with the overall findings across the lowest eight quintiles. In the largest quintiles, there is almost no switching from BIG-4 to NB-4 auditors. This result confirms the common-sense conclusion that the competitiveness of NB-4 auditors has been the dominant feature for about 80% of the market whereas the largest firms are contributing to the significant increase in the BIG-4 premium even after employing the standard controls for size used in prior literatures.

Sensitivity Tests

Statistical issues

We tested for potential multicollinearity problems by examining the Variable Inflation (VIF) statistic. The VIF for equation (2) is 1.37 and 3.24 in equation (3) so multicollinearity is not a concern. We used several different statistics (such as the Ramsey RESET test) to test the robustness of our results to potential omitted variables. The Breusch-Pagan and White test for heteroskedasticity were positive. However, using heteroskedasticity- robust standard errors did not change the ranking of the Industries based on the BIG-4 incremental premium. We did not find any significant changes in the ranking of the industries by BIG-4 pricing power although there were some occasions when industries changed places with the ones immediately above or below. These changes had some effect on the Spearman ranking correlation score but the effects were small and did not suggest any changes in the conclusion of a negative association between industry-premium increases and market share changes.

Alternative audit fee models

We also checked for alternatives in the Ashbaugh et al. pricing model, but the quantitative impact of these changes were small and were not worth reporting. In particular, the documented increase in the BIG-4 price premium from the 2000-2002 periods to the 2003-2011 periods and the ranking of industries by the level of premium changes was robust across alternative pricing models. We also checked an alternative measure of the premium using a fitted fee model. That is, we estimated a fee model for NB-4 auditors and then measured the premium as the excess charged by the BIG-4 over the predicted fee that would have obtained for an NB-4 auditor using the estimated regression coefficients. Again, the industry fee-premium rankings were stable and did not change the negative coefficient in the Spearman Test. In the switching model, this alternative measure was used to calculate the ABAFEE (here, simply the estimated BIG-4 premium) and it did not change the negative coefficient on this variable or the 2001 NB-4 market share.

Second tier auditors

We examine whether the shift to NB-4 is concentrated in Second Tier auditors (See Cassell, Giroux Myers and Omer 2013 for a list of auditors that are considered to be second-tier). Table 3 Panel D&E show that second tier auditors market share increase, either measured as a proportion of fees or as a proportion of client-firms accounted for a very small portion of the shift away from the BIG-4. Therefore, the growth in market share is spread broadly across all NB-4 firms and not just second-tier firms.

Switching model robustness

Another robustness check was to run the switching model on all the firms in the sample rather than restricting the sample to only the firms that were with the BIG-4 in 2003. The results were qualitatively unchanged though the significance increased with the inclusion of firms that switched from NB-4 to BIG-4 in the years 2004-2011 (i.e., using the sample of all firms that were with a BIG-4 auditor in at least one of the years from 2003-2011). This set consisted of 545 firms and a total of 2337 firm-year observations which was small relative to the total sample of 28,263 firm-year observations. None of these firms switched back to an NB-4 auditor.

Capacity constraints

The collapse of AA led to a sudden shift in demand to the surviving BIG-4 auditors. As documented in Table 3 Panel C, the surviving BIG-4 grew very rapidly in 2003-2004. However, this expansive trend slowed down sharply in 2005-2006 and seems to even have reversed in later year. Viewing this evidence from a longer perspective of the entire period 2003-2011, there is little evidence that capacity constraints were a significant economic force in terms of lost market share at least in the later years. To ensure that our findings are robust to capacity constraints, we run our model over different time periods and find that our results are qualitatively similar whether we run it over the period to 2006 when capacity constraints may have been stronger or over longer time periods when these constraints would no longer be part of the economic pressures.

Time-Sensitivity

In addition to checking the capacity constraints, we also tested our model over different time periods. Using time periods 2003-2006, 2003-2007 or 2003-2009 did not change any of the results of the switching model (Table 6 Panel C). In particular, the 2001 market share continued to be positive and significant over each of these time periods suggesting that the role of NB-4 market power has exerted a long-term influence on changes in market shares.

Other Regulatory Effects

The period covered by our study also saw other changes in regulation both on the market side and on the accounting side. Some of these other events may also have played a part in changing the BIG-4 premium. Specific examples are the requirement of fair value disclosures (Fin 48) or Auditing standard 5. Such disclosures inevitably involve estimates that may increase audit failure costs, imposing greater risk on the BIG-4. While we acknowledge this possibility, it does not affect our basic analysis of whether premium increases have resulted in market share shifts or whether NB-4 market power has also played a role. In summary, while there is a legitimate argument that other events besides the enactment of SOX may have added to the increase in the BIG-4 premium, these effects do not affect the main empirical findings of our analysis that market share shifts have been affected by NB-4 market power as well as BIG-4 pricing strategies.

5. Conclusion

The market for auditing services is highly concentrated with BIG-4 audit firms. In 2002, one of these auditors, Arthur Andersen, went out of business. In addition, a comprehensive set of new regulations concerning auditing (SOX) went into effect. Subsequently, in the period 2003-2011, there were significant increases in audit fees (both for BIG-4 and NB-4 auditors) as well as significant decreases in market share for BIG-4. Prior literature has advanced two possible explanations for these shifts in market structure: (i) a deliberate attempt by BIG-4 auditors to concentrate on (fewer) more profitable clients (characterized in our paper as "cherry picking"); and (ii) that better regulation and enforcement post-SOX has increased confidence in the reports of NB-4 auditors (characterized as "NB-4 market power"). By examining cross-industry correlation between reductions in market share and the size of the BIG-4 premium, as well as the relationship between audit fees and switching behavior, we are able to provide some new insights on these two effects.

An increase in NB-4 market power should typically lead to a *decrease* in the BIG-4 premium (the excess oligopoly or other rents) extracted by BIG-4 auditors. However, the BIG-4 premium increased significantly over this period suggesting that the combined effects of the demise of AA and the increased requirements of SOX enhanced the pricing edge for BIG-4 auditors. In addition, the market share of the BIG-4 decreased significantly. Taken together, this pattern suggesting that cherry-picking of high-fee paying clients by the BIG-4 may have been the driving force in reshaping the market for audit services. However, if cherry picking were the dominant influence, we would expect to see that the more selective the BIG-4 became, the higher would be the premium and lower the market share. In contrast, if the increased NB-4 market power played a significant role, then the BIG-4 would lose market share even if they reduced the premium they charged over NB-4 auditors. An industry-by industry analysis shows that BIG-4 industry premium and market share losses are inversely related (higher premium associated with smaller market share losses) showing that market changes were driven by factors additional to pricing strategy shifts by BIG-4 auditors.

To cross-check this finding, we examine whether higher *residual* fees (after controlling for firm characteristics), affect the probability of a client-firm switching from BIG-4 to an NB-4 auditor. The underlying logic is that if firms are essentially switching because of high fees, we would expect to see a positive association between high firm-specific (lagged) fees and switching to NB-4 auditors. However, if what is happening is that firms which see high (firm-specific) values for BIG-4 audits continue to retain them, it is possible that increases in the BIG-4 premium reflect a capture of this value and that there may be a lower likelihood of switching for firms that pay a high BIG-4 premium. Our results show that high residual fees reduce the probability of a switch to an NB-4 auditor suggesting that firms that see less value in BIG-4 audits have already switched to NB-4 auditors whereas firms that see high value in BIG-4 audits have remained with them despite the high fees (i.e., a demand side effect). This finding is further confirmed by the fact that there has been more switching in industries where the NB-4 were weakest *pre-2002* suggesting that the enactment of SOX has made it easier for NB-4 to compete in these industries.

While the collapse of AA and enactment of SOX were major economic events, there have been many other changes in the audit environment over the period 2003-2011 as well as a major market recession. We do not examine these features individually but do show that our results are stable across different time windows within this period, and in particular, that excluding or including the recession does not affect our findings. In addition, SOX have changed many other aspects of corporate structure including governance. Although we control for many firm-specific features connected to audit fees, we do not study the role of governance or management incentives on the decision to retain a BIG-4 auditor. Managers (and/or the board) may see value in hiring a BIG-4 auditor even if the extra premium is not recovered through the equities market. One of the challenges for the future is to examine whether agency conflicts may lead to the retention of BIG-4 auditors even if such retention does not directly benefit shareholders.

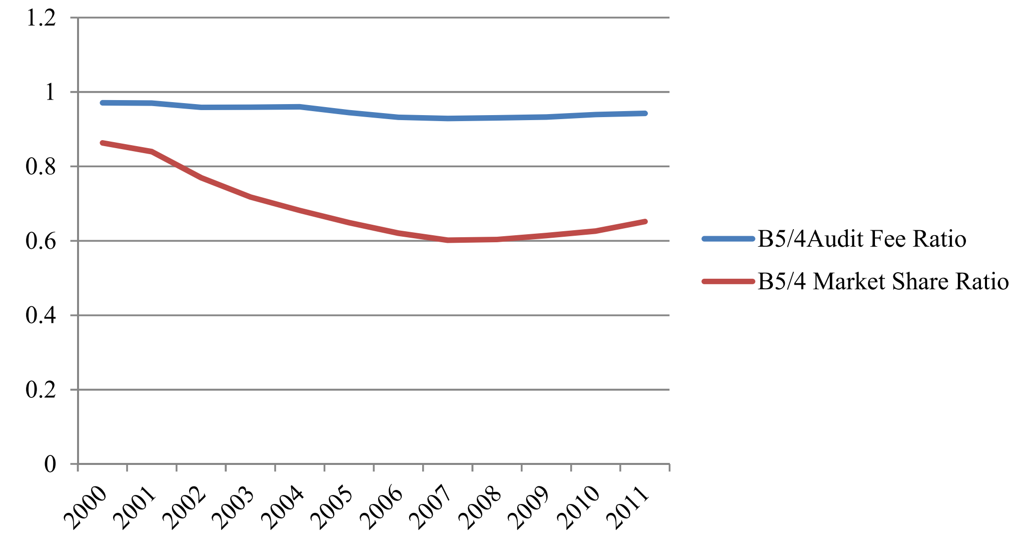
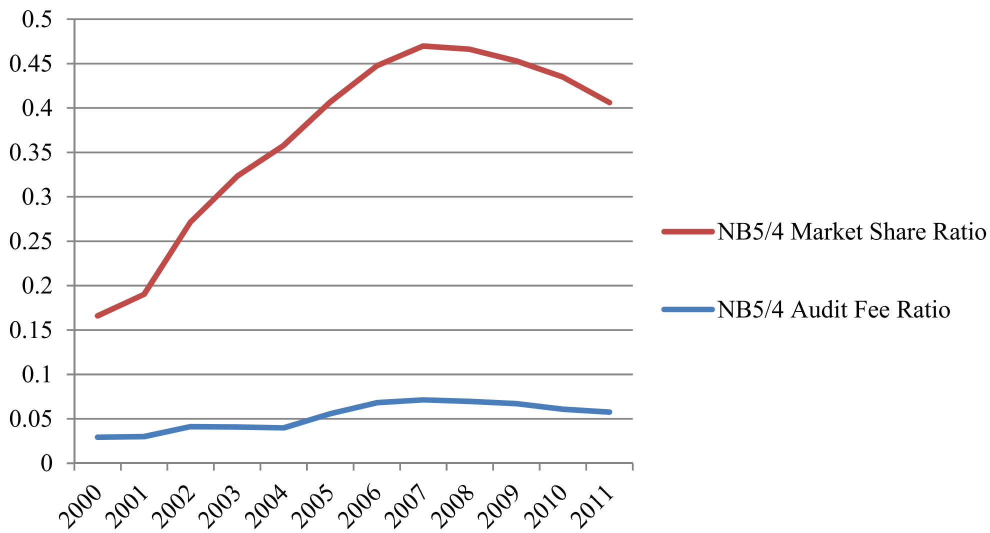
Figure 1

Trends in BIG-5/4Market Share Ratio and Fee Ratio

Panel A: BIG-5/4 Audit Fee Ratio and Market Share Ratio



Panel B: NB-5/4 Audit Fee Ratio and Market Share Ratio



Panel A plots BIG-5/4 Market Share Ratio and BIG-5/4 Fee Ratio from 2000-2011. BIG-5/4 Market Share Ratio is the number of firms audited by BIG-5/4divided by the total number of firms in the audit market. BIG-5/4 Fee ratio is audit fee from BIG-5/4's clients divided by the total audit fees in the audit market from 2000 to 2011. Panel B plots NB-5/4 Market Share Ratio ad Fee Share Ratio for the same time period.

Table 1

Sample Composition and Attrition

	Audit Fee Model	Switch Model
Firms year observations from Audit Analytics	**150,908**	
Less:	(6,701)	
One firm one year has more than one audit fee observation in a fiscal year		
No financial data	(55,723)	
No business segment	(26,703)	
Financial Industries have been deleted	(10,040)	
Final firm year observations	**51,732**	
Missing Compustat data		(14,714)
Final firm year observations		37,018
Firm year observations in 2001		(2,020)
Firm year observations after 2001		**34,998**
Firm year observations before 2002	(8,636)	(6,735)
Final firm year observations after 2002	43,096	28,263

We start with 150,908 firm year observations collected from Audit Analytics covering the period 2000-2011. Then we deleted 55,723 observations since financial data was not available on COMPUSTAT and 26,703 observations were deleted because business segments data was missing. Then we deleted 10,040 observations which belong to financial institutions. Our final sample consists 51, 732 firm year observations. 14,714 of these observations have been deleted for missing value in the audit switching model. Our final sample for the audit switching model consists of 34,998 observations. Our subsample has 2,020 observations in 2001, and 6,735 observations in 2002.

2011	13	82	55	105	72	218	140	519	242	163	276	226	445

Panel A&B describes the market shares (the ratio of the NB-5/4 market share divided by the total market share) and fee shares (the ratio of fee share divided by the total audit fee) by each industry from the 2000 to 2011(in percentage), which we define as SOX effect. Panel C indicates the declines of market share for surviving BIG-4 firms. Panel D&E shows the market share and fee share for second tier audit firms (in percentage). Panel F&G shows the whole market audit fees and number of clients for BIG-5/4.

This table shows the results of audit fee model in different samples. Sample A is from 2000 to 2011. We get the similar results as Blankley et al. (2012). We add BIG-4*Industry in Sample B, we would like to show that after SOX, BIG-4 auditors charge a higher premium over some industries, while charge a lower premium over some other industries. We add Big-4 dummy in Sample C&D. We would like to show that after SOX, Big-4 auditors charge a higher premium. Our results prove the hypothesis. F test shows that the coefficient of BIG-5/4 is significantly different before and after SOX at 10% level. ***, **, * Indicate statistical significance at 1%, 5% and 10% level, respectively.

Arthur Andersen Fee Share	-0.159		0.007		-0.159	**0.242**

Panel A shows three measures of Fee Premium. Fee Premium I is ranking based on the median of the Industry residual in Table 4 Column D; Fee Premium II is ranking based on the change in the coefficient of BIG-4*INDUSTRY before 2002 and after 2002 in equation (2); Fee Premium III is ranking based on the magnitude of the coefficient of BIG-4*INDUSTRY after 2002 in table 4 Column (B).

Panel B presents three measures of SOX effect and AA effect. Fee/Market is ranking based on the difference of NB-4 Audit Fee divided by Market Share in 2001 and with the same ratio in 2011. Market Share is ranking based on the increase in NB-4 market share between 2001 and 2011; Fee Share is ranking based on the increase in NB-4 fee share between 2001 and 2001. Arthur Andersen Switch Share I is ranking based on prior AA clients in the industry switching to NB-4 as a proportion of AA clients in the industry in 2003. Arthur Andersen Switch Share II is ranking based on prior AA switching to NB-4 clients as a proportion of total clients switching from BIG-4 to NB-4 in 2003; Arthur Andersen Market Share is ranking based on Arthur Anderson's market share in 2001; Arthur Andersen Fee Share is ranking based on Arthur Anderson's fee share in 2001;

Panel C presents the Spearman rank test results, which is used in this table to indicate the relationship between Fee premium, SOX effect, and Arthur Andersen collapse effect.

*means including agriculture industry; ** means excluding the agriculture industry because it consisted of only seven firms; ***4AT is the first four asset quintiles. Bold indicates statistical significance at 10% level or higher.

This table shows the results of auditor choice model over the years 2001-2011 (we omit 2000 because the model uses lagged fees). Panel A Sample A covers the period 2001 to 2011 whereas Samples C & D shows the clients switching behavior across 2003-2011. Sample B considers the period 2001-2002 to examine whether switching behavior changed after SOX. ABAFEE is the residual from Table 4 Column A in the year *before* they switch. The Mismatch variable is based on Landsman et al. (2012) in Appendix A. As we only consider BIG-4, we use Mismatch*BIG-5/4 in our regressions (i.e., to see if mismatched clients with the BIG-5/4 were more likely to switch to NB-5/4). Our sample exhibits properties similar to the previous study (see Appendix). Our results show that clients are *less* likely to switch if they are paying a *higher* premium (in the post-SOX period) and *less* likely to switch in the years *2003-2011* in industries where NB-4 had a large market share *in 2001*. Panel B shows the audit switch behavior broken out for 5 assets quintiles. The results show that NB-4 2001 market share decreases the probability of switching in the low size quintiles. Panel C shows the same results across different time period. F test shows that the difference of abnormal fees on audit switching model before and after SOX is significant at 1% level. ***, **, *, indicate statistical significance at 1%, 5% and 10% level, respectively.

APPENDIX A

ESTIMATION OF CLIENT MISALIGNMENT

We follow the methodology in Shu (2000) to indicate the probability a firm is misaligned with its current auditor. Specifically, we estimate the following model separately for each year in the sample period, using all available observations from Compustat:

$$BigN_t = \alpha + \alpha_1 Size_t + \alpha_2 Acquisition_t + \alpha_3 ExFinance_t + \alpha_4 \Pr ofitability_t + \alpha_5 MktBk + \varepsilon_t \quad (A1)$$

Where,

BigN=1 if the company had a Big N auditor, and 0 otherwise 1[14];

TABLE A1
Estimation of Client Misalignment

Panel A: Coefficient Estimate Summary Statistics from Annual Estimations of the Client Misalignment Model

Variable	Mean	Standard Error	P-Value
INTERCEPT	-2.18	0.0270	<.0001
SIZE	0.58	0.005	<.0001
ACQUISITION	-0.03	0.11	0.77
EXFINANCE	-0.02	0.02	0.19
PROFITABILITY	-0.00007	0.0007	0.92
MKTBK	-0.00006	0.00004	0.15

Panel B: Estimated Cut-Off Probabilites

Year	N	Estimated Cut-Off Probability
2000	4,717	0.64
2001	6,495	0.63
2002	8,069	0.63
2003	8,517	0.64
2004	8,434	0.64
2005	8,329	0.64
2006	8,164	0.64
2007	7,824	0.73
2008	7,350	0.74
2009	7,199	0.72
2010	7,049	0.73
2011	6,335	0.73

The coefficient estimates from this regression are utilized to estimate the probability of having a Big N auditor in a certain year. The point at which the BIG-N and NB-N auditor distributions cross is an estimate of the optimal cut-off level. If the probability of having a BIG-N auditor falls below the cut-off point, the client is expected to have an NB-N auditor. So if the client has a BIG-N auditor, then we define MISMATCH equals to 1. We choose different cut-off levels until we get the best cut-off level which will minimize the MISMATCH. Our results before 2005 is different from Shu (2000) and Landsman (2009), we think the difference comes from the limitation about the data.

[14] Shu (2000) defines the dependent variable to include all "large "auditors, defined as Big-N auditors and any auditor identified by an individual auditor code on Compustat, Because our analysis is to find the probability that if the client is misaligned with a Big-N auditor. So we follow Landsman et al (2009), utilize the Big-N auditor as the dependent variable.

APPENDIX B: A Model of Demand and Supply for Audit Services

We combine a consumer choice model with a litigation driven model to arrive at demand and supply curves for audit services in a competitive market. Recall that these curves are written in terms of proportion of market share held at a particular premium by a BIG-4 auditor. The demand curve is based on a client-side trade-off of the extra fee charged and the extra value generated by the BIG-4 auditor relative to the NB-4 auditor. The supply curve is based on the need of the BIG-4 auditor to charge enough to compensate for the risk of the firm relative to the NB-4 auditor. Therefore, our models are formulated in terms of the differences in fees, extra market value and financial risk across BIG-4 and NB-4 auditors.[15]

B1. The Audit Demand Curve

A client firm has certain observable characteristics, X, and an unobservable private value for a BIG-4 audit denoted by the random variable $\tilde{\varepsilon}$. This is the equivalent of heterogeneous tastes in the classic paper of Hotelling (1929). The client-firm will choose the BIG-4 auditor provided that the premium π charged by the BIG-4 auditor is less than the additional value provided by the BIG-4 auditor, that is if $\pi \leq V(X) + \varepsilon$ where $V(X)$ denotes the value of a BIG-4 audit based on the observable characteristics, X. Let $F(\text{ò})$ denote the cumulative distribution function of $\tilde{\varepsilon}$.[16] Then the probability of a client-firm with characteristics X having a big auditor is:

$$\text{Prob}\{\pi - V(X) \leq \text{ò}\} = 1 - F(\pi - V(X)) \tag{B1}$$

Assuming that the empirically observed market share is close to this true probability,[17] the market share of the BIG-4 auditor across clients of characteristics X at a premium π is given by the right-hand-side of (B1). The aggregate market share is given by averaging across all client-firms.

Given this formulation, we consider changes in the demand curve resulting from shifts in the distribution function $F(\text{ò})$. In particular, consider a change to a new distribution function $F_{new}(\text{ò})$ where:

$$F(\text{ò}) \text{ first-degree stochastically dominates } F_{new}(\text{ò}). \tag{B2}$$

[15] Such a profit function can also be written in terms of fees but this simply introduces additional terms related to audit cost. Intuitively, we assume that the NB-4 sets a certain fee structure based on audit costs and "normal profit" whereas the BIG-4 auditor charges an "excess BIG-4 premium" that recaptures some of the market benefits obtained by going to such an auditor.

[16] Making the private value conditional on X does not lead to any qualitative differences in the analysis.

[17] This is a law of large numbers argument. If there are many firms with observed characteristics X, then the empirically observed market share of BIG-4 auditors will approximate the true underlying probability for each value of X.

In other words, consider a reduction (in a distributional sense) of the private value for BIG-4 audit service. By the definition of first-degree stochastic dominance,

$$F_{new}\left(\pi - V(X)\right) \quad \geq \quad F\left(\pi - V(X)\right) \text{ for every } \pi \text{ and } X$$

showing from (Figure BI) that the market-share for the BIG-4 auditor falls for every client characteristic and every choice of premium. Therefore, the market share shifts downward in the premium as illustrated in Figure B1, Panel A.

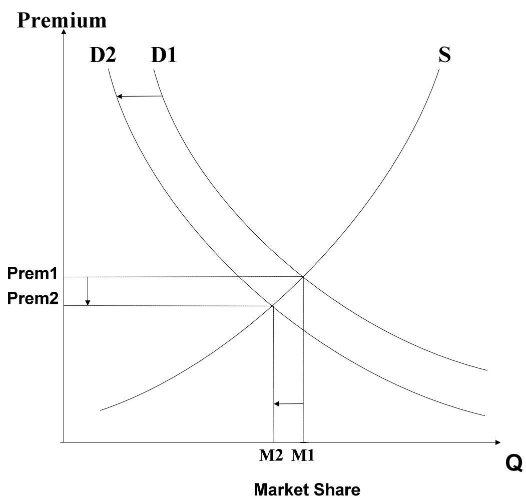
B2. The Audit Supply Curve

The focus of our analysis is to examine whether the changes in audit market shares result from a downward shift in the demand curve as described in the previous paragraph or due to a deliberate policy by BIG-4 firms to limit services to risky clients. In order to capture this tension, we introduce the excess expected litigation cost for a firm of characteristics X to a BIG-4 auditor which is denoted by $L(X)$. The BIG-4 auditor will accept a client-firm of characteristics X.provided that the excess fee offsets the excess litigation risk, that is if $\pi \geq L(X)$. (Simunic and Stein 1996b). The advent of SOX is supposed to have increased the financial risk of certain client firms so as to make them unattractive for the BIG-4 audit firms. In order to capture this notion, we consider a new expected litigation risk function denoted by $L_{new}(X)$ where $L_{new}(X) > L(X)$ for every client-firm characteristics X. Under such circumstances, the supply curve will shift upwards after the enactment of SOX as described in Figure B1 Panel B.

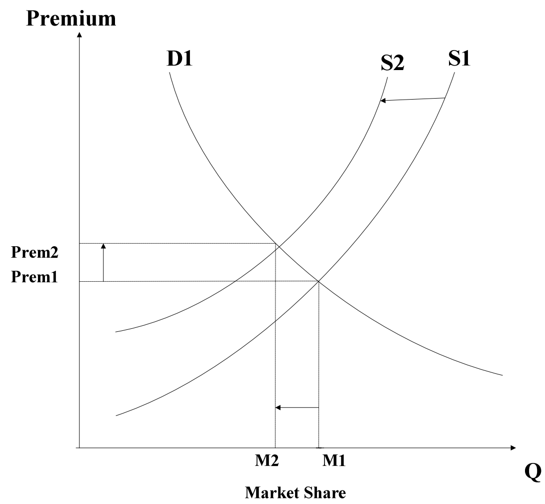
Figure B1

Economic Equilibrium for fee premium and market-share for BIG-4 firms

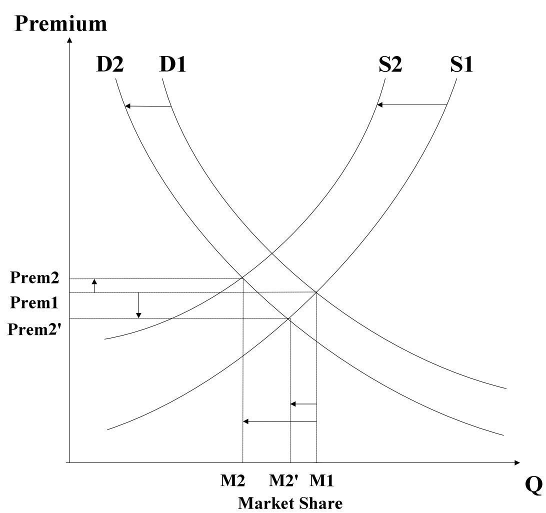
Panel A: Only Demand Curve for BIG-4 Shifts down



Panel B: Only Supply Curve for BIG-4 Shifts up



Panel C: Supply Curve shifts down and Demand Curve Shifts down



This figure shows the effects of demand and supply curve shifts in the BIG-4 premium. Panel A shows the effects of the demand curve shifting down. Panel B shows the effects of the supply curve shifting up while the demand stays constant. Panel C shows that the pattern we observe is consistent with both curves shifting, that is, the changes in market share and premium being inversely correlated (compare Premium 1 with Premium 2).

TABLE B1 SUPPLY AND DEMAND FUNCTION

Panel A: Reasons for Demand Curve Shifts

Trends of Demand for BIG-4 Auditors	Reasons	Market Share & Premium for BIG-4
Down	Tarnished reputation as a result of AA collapse & scandals	
Down	Work of regulators & others to increase NB-4 reputation	Drop
Down	Overall fees going up with addition of 404 requirement	
Up	"Tried and true" in face of new regulatory requirements	Increase

Panel B: Reasons for Supply Curve Shifting up

Trends of Supply for BIG-4 Auditors	Reasons	Market Share & Premium for BIG-4
Up	Capacity constraints (Excess demand shifts pricing curve up)	
Up	Fewer BIG auditors more Oligopoly power	Market Share drops, but less clear what happens with fees and premiums
Up	Cost of risky audits have gone up—charge higher risk-premium for clients	

The 23rd Annual Conference on Pacific Basin Finance, Economics, Accounting, and Management (2015)

□ □ □ □ □ □ Selective Disclosure: The Case of Nikkei Preview Articles

William N. Goetzmann
Yale School of Management and NBER Yasushi Hamao,
University of Southern California
Hidenori Takahashi, Kobe University,
Japan
william.goetzmann@yale.edu

Nihon Keizai Shinbun (Nikkei for short) is a leading Japanese daily newspaper specializing in economy and business. It is also the largest vendor of Japanese financial and economic databases. During earnings announcement season, the Nikkei morning edition often publishes “preview” articles that are about companies’ sales and earnings. However, these pre-date the actual company announcements, and forecast more accurately the actual results than the existing forecasts, making the Nikkei forecasts value-relevant information. We identify 2,899 preview articles in the newspaper from 2000 to 2010. We examine the circumstances under which these preview articles are written and the impact they have on the market. Our (preliminary) findings show that the market reacts to the information even before the preview articles are printed, suggesting some leakage of the information to market participants. The costs and benefits (or incentives) for companies, Nikkei, and investors are investigated using changes in returns and information content around the events.

> "If you wanted to find out what Toyota Motor Corp., NTT Docomo Inc. and Canon Inc. earned last year before they reported results, the best guide wasn't analyst or company predictions. It was the Nikkei newspaper….. Of the 45 Nikkei articles analyzed by Bloomberg News that contained profit figures that preceded the formal release results, 37 gave a number that was within 10 percent of the company's result, or predicted a range that turned out to be correct."[1]

> "… But in Japan, regulators seem to have turned a blind eye to the "Nikkei previews," allowing stories appear and then, within a few hours, letting companies issue rote statements saying the stories are not based on anything they have announced….. Last year the Nikkei announced it would no longer supply instant English translations of stories to its 364,000 online subscribers. But given that between 60 and 70 per cent of trading in Tokyo stocks is by foreigners, the effect of publishing earnings previews in the local language only is akin to "insider trading", says Mr. [Nicholas] Smith of CLSA [in Tokyo]"[2]

1. Introduction

With about three million subscribers (in 2008), Nihon Keizai Shinbun ("Nikkei Newspaper," or "Nikkei" for short) has the 4th largest printed and on-line circulation in Japan. It specializes in business and economy and is almost a "must" read for business people in Japan.[3] There is a curious institutional phenomenon that has existed for a number of years in the Japanese market. In earnings announcement season, highly accurate sales and/or earnings numbers are reported by Nikkei before the firms' official announcement. These preview announcements appear exclusive to Nikkei, and as we show below, the Nikkei's preview articles are generally more accurate than managements' own most recent publicly disclosed forecasts. In short, they contain value-relevant information.

Regulation Fair Disclosure (Reg FD) was enacted in 2000 in the United States. Its

[3] The ranking of Japanese newspapers on circulation is as follows: 1. Yomiuri (circulation: 10 million); 2. Asahi (8 million); 3. Mainichi (3.9 million); and Nikkei (3 million); source: *World Press Trends 2008*, World Association of Newspapers. In comparison, the circulation of The Wall Street Journal is 2.3 million, and Financial Times is 650,000. Source: The Alliance for Audited Media and Deloitte.

intent was to create a level informational playing field for participants in the U.S. equities markets. The regulation stopped selective disclosure of value-relevant information about publicly traded companies. Corporations could no longer favor specific analysts or disclosure channels. Prior to its enactment, large institutional investors raised objections to Reg FD. Selective disclosure presumably gave large investors an edge – the potential to trade on information before it became widely known. Cohen, Frazzini, and Malloy (2010) find evidence that Reg FD significantly impacted returns to well-connected U.S. mutual fund managers, suggesting that selective disclosure was one source of excess return. Research on the effects of Reg FD suggests that it improved liquidity and increased trading volume (Heflin, Subramanyam, and Zhang 2003; Bushee, Matsumoto, and Miller 2004 and Bailey, Karolyi, and Salva 2006). Researchers have found that cost of capital and liquidity effects have led to voluntary adoption of Reg FD standards by cross-listed firms even though they are explicitly exempt (Francis, Nanda, and Wang 2006; Crawley, Ke, and Yu 2011). Chen and Matsumoto (2006) find that analysts' forecasts were more accurate prior to the barring of selective disclosure and document a correlation between favorable recommendations and selective disclosure; suggesting a quid pro quo relationship based on information.

In general, the empirical evidence on selective disclosure, gleaned from studies around the promulgation of Reg FD in the year 2000 indicate that, prior to the law, publicly traded firms faced a tradeoff between liquidity and price efficiency. The research literature has not yet completely explored this tradeoff.

One of the challenges in studying the effect of selective disclosure on market prices, volatility and liquidity around Reg FD is that there is little cross-sectional variation. When the law was enacted, it applied universally across firms with respect to information affecting the value of their common stock (except for cross-listed companies). In contrast to the U.S. market, in Japan, there is heterogeneity in the institutional structure for information disclosure. Some firms choose to regularly communicate with Nikkei for preview articles prior to the official release of earnings and sales information while others do not. This heterogeneity provides us an opportunity to examine corporate tradeoffs between liquidity and price efficiency.

The fact that selective disclosure is intermediated by a single news source introduces an additional level of usefulness. Nikkei – rather than the corporation – may realize the benefits of intermediating value-relevant information. Once Nikkei reporters have met with corporate executives to gather information for the preview article, they effectively share the potential value of this non-public information.

As a newspaper/news service, Nikkei presumably disseminates information to all subscribers simultaneously, however in doing so, it creates a potentially exploitable event – a disclosure date that is likely to have an effect on stock prices. Nikkei revenues derive from circulation to individual investors and subscriptions to data feeds to institutional clients. Both groups would recognize the potential benefits of an accurate preview of an adjustment to prior earnings forecast. However, if one group knew before-hand the content of the preview, the potential for exploiting other Nikkei subscribers is significant. In this study we are not able to discern how some investors become aware of Nikkei previews prior to publication, and furthermore this is not the focus of the paper. Rather we are interested in using these events as a means to understand which firms find selective disclosure more beneficial and why.

We hypothesize that firms held widely by institutional investors have an incentive to do previews that would allow fund managers to generate positive alpha. Jiang and Sun (2014) provide evidence consistent with this hypothesis for U.S. mutual funds. Stocks held by firms taking unusually high positions in the company around earnings announcements experience positive returns. The authors interpret this as evidence that some fund managers in the U.S. trade on private value-relevant information about earnings surprises. On the other hand, firms that are closely held – for which adverse selection is a significant concern for uninformed investors – are more likely to eschew selective disclosure which would exacerbate bid-ask spreads and illiquidity.

We further hypothesize that the particular information structure we identify in the Japanese market allows informed investors to exploit pre-earnings announcement previews in order to trade in an environment that is less suspicious of adverse selection. Unlike earnings announcement dates which are known in advance, Nikkei previews are not pre-scheduled and thus can be scheduled unexpectedly prior to announcement at a time when noise-traders and market-makers are less likely to expect to trade against informed traders.

Some accounting research has approached selective disclosure from the behavioral angle. DellaVigna and Pollet (2009) attribute attenuated price response around earning announcements on Fridays to investor inattention. Neissner (2014) finds that managers strategically exploit the inattention effect by disclosing negative information on Fridays. Hand (1990) showed that market prices reacted to the disclosure in annual filings of events disclosed in prior quarters, suggesting that markets only partially react to value-relevant news.

This is the main hypothesis behind the well-documented post-earnings announcement drift phenomenon (Bernard and Thomas 1989) and the subject of papers by Hirshleifer and Teoh (2003), Hirshleifer, Lim, and Teoh (2009, 2011) and others. One broad result of their analysis of accounting anomalies is that these are consistent with limited investor attention and capacity for analysis. In a setting where a large quantity of potentially value-relevant information is disclosed around the same time, the Hirshleifer et al. framework would predict sub-optimal reaction to the news. If, for example, investors use a pecking order to decide which of many securities to trade after a joint earnings announcement, this would lead to trades for which information is considered timely, reliable and significant enough to overcome the cost (in money and attention) of exploiting. Knowing this, the manager of a publicly traded firm who believes the market price fails to incorporate private, positive information would choose to shift the timing of value-relevant news to times when investor information overload is less, to choose a venue in which the disclosure is most credible (i.e., the risk of "cheap talk" is minimal). The management would also prefer disclosure to sophisticated investors who understood its relevance, and for whom the motivation – in terms of trading profits to speculators – is non-trivial.

Recent research has explored corporate use of alternative communication channels to increase awareness about firms around key events such as insider sales and earnings announcements. Bushee, Core, Guay, and Hamm (2009) show that media coverage around earnings announcements mitigate asymmetric information concerns. Fang and Peress (2009) find media coverage is a component of security prices. Lou (2014) documents an increase in advertising expenditure in the year before negative earnings surprises and around a period of insider sales. Madsen and Neisner (2014) use observed advertising to rule out reverse causality as a potential explanation for the association between insider sales and advertising expenditures.

Not having Reg FD (as in Japan) presents a set of opportunities for management disclosure strategies. For example, giving one news source with a broad subscriber base an "exclusive" is a means to ensure that the disclosure will be highlighted and will attract sufficient investor attention. Disclosing big changes that are worth the transactions cost to exploit will motivate trading. Finally, and perhaps most controversially, it may be in the interest of a firm whose price suffers from the market's failure to incorporate information, to allow information to leak in advance of a public (and even an exclusive) announcement to ensure that some market participants with the capacity to move prices are sufficiently incentivized to trade.

This strategy may seem contrary to the interest of shareholders, however price inefficiency due to behavioral limitations of the market also presents problems for the corporation and its shareholders. These include higher cost of capital, segmented cost of capital across financing forms and locations, inaccurate compensation rules and categorization at the margins of the firm as a small cap or value stock, with further costs of capital. Selective disclosure that results in speculative profits by informed traders at the expense of uninformed shareholders may be the cost of insuring that the market fully impounds good news.[4]

Although Reg FD and the zero-tolerance enforcement of insider trading laws in the

[4] There is a long literature about the costs and benefits of allowing insider trading (Fishman and Hagerty 1992; Leland 1992).

U.S. restrict the ability to examine the instances and effects of strategic disclosure, the structure of information dissemination around earnings announcements of Japanese companies allows us to test what is lost and what is gained with Reg FD. While insider trading is against the law, it is not uncommon to see unusual price movement and volume prior to significant events in many markets. This might be a consequence of a free rider problem. Grossman and Stiglitz (1980) point out that a market must compensate investment research through trades that are profitable enough to support it. In such a market, the majority of investors (and firms) can enjoy the benefits of free-riding on price efficiency. However removing channels for profitable research such as private discussions with management reduces the arbitrage in expectations that enforce markets. Information leakage prior to announcements may be one strategy to address free-riding.

In this paper we collect data on Japanese firms around earnings announcements and identify a large sample of preview news articles that report accurate sales and/or earnings numbers. Using this sample we test the following hypotheses using an event study methodology.

First, we test whether preview announcements actually contain value-relevant information. We find that stock returns around positive preview articles are positive and significant, consistent with the hypothesis that firms release value-relevant information prior to the official earnings announcement. We also ask whether – consistent with management seeking to reduce market under-reaction to good news – Nikkei previews that report positive earnings surprises are more frequent. We find that they are: the ratio of positive to negative earnings news in preview articles is 1.63. Looking more closely at the preview forecasts, we find that positive previews are relatively conservative (they are less likely to report numbers higher than those subsequently officially released) and negative forecasts are relatively optimistic (they are more likely to report numbers higher than those subsequently officially released).

In terms of stock price reactions, for non-previewing firms we find that prices rise significantly around release of positive earnings news and drop around release of negative earnings news. For previewing firms we find only a positive price reaction. This is consistent with an endogenous choice made by firms to preview. Firms may only release bad news via a preview when they believe it will not hurt stock price (or will not induce short-selling), and they may release good information via a preview when they believe it will cause a positive price jump.

For previewing firms the significant price movement occurs around the date of the preview article. There is little evidence of a "double reaction" i.e., first at preview, and then once again at the official release of earnings information. In other words, there is little evidence of under-reaction to recent prior news released via Nikkei.

One interesting difference between the reactions around preview articles vs. earnings announcements by non-previewing firms is that the spread in cumulative average residuals (CAR) is persistent over the next two weeks for previewing firms but converges for non-previewing firms. If anything, this is evidence for market over-reaction to the official earnings announcement as opposed to the widely documented post earnings announcement under-reaction. This differential is consistent with the hypothesis that the firms use the Nikkei channel to disseminate value-relevant information to sophisticated investors who will correctly interpret it and react quickly and permanently to it.

We also document evidence that the value-relevant information is released prior to both official earnings announcements for non-previewers and also for Nikkei previews. Price changes measured from open to open on the day prior to the official announcement (made during trading hours) or the Nikkei preview (available prior to market open) indicates leakage of news. For both groups, the returns on announcement day itself are flat. This is consistent with the hypothesis that information when it appears in the news is already impounded in stock prices.

Taken together, the evidence suggests that Japanese firms use selective disclosure to strategically incentivize market participants to impound positive information into stock prices. Nikkei previews are evidently an important channel. They serve as a coordinating event around which (i.e., before which) informed investors trade and move stock prices. This strategy results in permanent changes to firm market value that are positive, on average. In contrast, price increases due to informed trading in shares of firms that do not preview their results appear to be temporary.

This paper proceeds as follows. In Section 2, we describe the data. Sections 3 through 6 characterize the preview articles in terms of their role as a disclosure medium of information to the market. In Section 7, we examine market's reactions to the Nikkei preview articles. Section 8 investigates incentives and costs/benefits for all parties (Nikkei, companies, investors and regulators). Section 9 concludes.

2. Data

During the annual corporate earnings announcement season, all listed firms' announcements are published in the Nikkei Morning Edition in the form of tables. In this table, financial results (sales, operating income, ordinary income, net income, earnings per share, and per share dividends) of the most recent year are tabulated, as well as the numbers from the previous year and management forecast for the next year. Similar announcements are made and tables are published, at the half-year point, again on the day following the announcement. The management forecast of the coming half-year may be updated, based on the information available to the firm at this time. This management forecast is reported by almost all listed firms (Kato, Skinner, and Kunimura 2009). Management forecasts may be revised, not only in half-year intervals, but also when there is a substantive new information about corporate performance. These "stand-alone" revisions of management forecasts are also reported in Nikkei the next day. Due to the internationalization of the Japanese equity market, beginning in 2004, the Tokyo Stock Exchange started to encourage its listed firms to report quarterly figures, in addition to half-year results. Quarterly reporting became mandatory from October, 2008. Now all firms announce cumulative quarterly results. Management forecasts, however, are not on quarterly basis, and announced only on a half-year basis and stand-alone basis.

In addition to the tables of corporate financial reporting, Nikkei writes text articles on some selected firms. In another paper, Goetzmann, Hamao, and Takahashi 2014) we use sentiment analysis applied to the text content of these articles in order to examine the interaction between price, sentiment and news.

Like all news organizations, Nikkei also writes about companies as other news occurs.

However, before the annual, semi-annual or quarterly financial performance is officially announced by a firm, Nikkei often writes articles that effectively "preview" the results.

We extract all news articles that appear to have information on performance figures that are about to be announced from a database of over a million Nikkei text articles from 2000 to 2010, using text searches. We rely on keywords that refer to fiscal year, unit (Japanese Yen), and expressions pertinent to previews such as "about" or "likely to be."[5] As a result, we obtain more than 8,000 potential previews, although the actual number may be more. After extraction, we read all of them and isolate articles that preview financial results, prior to actual announcements. These articles explicitly discuss forthcoming figures on sales and/or operating income and/or ordinary income and/or net income. Also, we exclude articles that mention other accounting matters such as cash flow or asset turnover, but do not mention earnings related figures. Although some firms announce both consolidated and parent-only results, especially in the early years of our sample, we put priority on consolidated financial reporting over parent-only. We look at annual (full-year) and second quarter (half-year) earnings reports. For cumulative quarterly figures, net income is mostly not written up on preview articles. Therefore, we take numbers in the following order of priority: 1. Net income; 2. Ordinary income; and 3. Operating income.

We set the following rules to capture preview articles. First, the preview article has to appear after the last management forecast update (published the next day by Nikkei) prior to the annual (full-year), or half-year earnings announcement. Second, we take a conservative 60 calendar day period before the actual earnings announcement date (including the

[5] For instance, Nikkei article reports that "(*Firm name*)'s net income at (*fiscal year*) is likely to be about (*preview figure*), and this figure is the best ever for this firm."

announcement day itself). We drop preview-like articles written about firms' financial performance appearing a long time before the announcement, since they are not immediately value-relevant. Note that we do include "zero day" preview articles that are published on the day of announcement, a few hours ahead of the actual release by the firm. Third, we do not include preview-like articles that discuss only sales, but not income (ordinary, operating, or net) figures. As a result, our final sample contains 2,899 preview articles. Table 1 shows the details of the number of articles.

To our knowledge, the "preview" phenomenon has not yet been documented in the academic literature. We thus characterize our data in a descriptive fashion below. Some summary statistics are therefore deferred to sections below as needed.

3. Timing of the Preview Articles

First, we calculate the number of days before the actual announcement (calendar day difference between Actual Announcement Date minus Nikkei Preview Printed Date). We also calculate days after the latest management update, which is the calendar day difference between Preview Publishing Date minus Management Forecast Update Announcement Date (Nikkei publishes these updates in the next day's paper).

Figure 2 shows the number of preview articles. The horizontal axis represents that calendar days prior to the announcement date. From 60 days prior to the announcement date, the frequency of preview articles increases gradually, but from 7 calendar days before the announcement, it increases above 100 per day. On the day of the announcement (Day 0), the number of preview articles peaks.

Figure 3 shows the frequency of appearance of preview articles over time, from

January 2000 to December 2010. The articles appear more frequently from 2008, reflecting the fact that quarterly reporting (numbers reported are cumulative) became mandatory from that year.

Table 2 summarizes the timing of the preview articles. These articles are written close to the actual company announcement. The mean and median number of days before the announcement are 19.44 and 14 days respectively, but many appear on the day of the announcement (the mode is 0, i.e., the morning of official announcement), and after the update of the latest official management forecast (mean of 120 days, median of 85 days).

4. Are the Previews Biased?

In this paper we make the assumption that the firm itself voluntarily communicates with Nikkei prior to the official announcement. We have no explicit evidence on the precise nature of this information channel. Under the assumption that selective disclosure by the firm (via whatever channel) is a strategic decision, it is of interest to see if preview articles have a bias toward positive or negative forecasts. Kato, Skinner, and Kunimura (2009) find a positive bias in initial management forecasts, issued at the time of the release of the most recent year's results. We test to see if this is true of the Nikkei previews as well.

We divide the preview sample to two groups: (1) the figures actually announced turned out to be strictly better than the most recent management forecast update; and (2) the announced figures came out to be worse than (or equal to) the most recent management forecast. We use the management forecast as a benchmark because in Japan analysts do not conduct earnings forecasts actively, and there is no average or consensus forecast.[6] In case (1) above, we count the number of preview articles as "over" forecasting if they state numbers higher than the actual announcements, "under" forecasting if they are below the management forecasts, and "between" if they are in between the actual and management figures. In case (2), the "over" forecasts are when the preview articles point to numbers above the management forecasts, "under" forecasts are when previews mention estimates below the forthcoming announcements, and "between" when the previews lie below the management forecasts but above the actually announced numbers. If a preview article mentions two or more of sales, operating, ordinary, and net income, they are counted as separate reports (thus the total number of previews is 5,119).

Table 3 shows the breakdown of counts of the preview articles. Information contained in the previews is more often "good news." Out of 5,119 reports, 3,155 (61.6%) of them are written when actual performance is going to be better than the most recent management forecast (i.e., positive earnings surprise); whereas 1,964 (38.4%) of them are written when the announcement is going to be below the forecast (i.e., negative earnings surprise). Within the "good news" cases, about 70% of them are "modestly optimistic" and do not over-shoot in a sense that the previews report numbers in between the prior management forecast and the actual announcement. About 23% of the articles report higher number than actual, and only 7% of them under-forecast performance (i.e., the preview forecast is in the wrong direction). On the other hand, for bad news 50% of previews report numbers in between the recent management forecast and the actual (i.e., bad news is softened, or under-played in the

[6] Ota (2006) finds that Japanese analyst forecast is generally of less quality than management forecast.

preview articles), and 44% of them report worse figures than the actual (i.e., overplay bad news). Only 6% of the articles go in wrong direction (over-forecast).

The ratio of good-news to bad-news articles is consistent with management taking action to highlight positive earnings surprises, as opposed to a journalistic desire to attract readership by equally reporting both positive and negative surprises. To the credit of both management and Nikkei, 38.4% of articles are bad-news. This is a substantial fraction, and strong evidence of a functional, efficient information structure in Japan. The imbalance is also not surprising in light of the long-documented phenomenon in the U.S. that analysts upgrades of stocks are much more common than downgrades. This imbalance in the U.S. was generally attributed to selective analyst access to management prior to Reg FD, presumably based on a strategic choice by firm management. The ratio of positive to negative earnings surprises in Japan is also consistent with the strategic choice by the firm and the press. Of course there are other possible explanations that may be tested; e.g., prior management forecasts may be conservative or Nikkei subscribers prefer news about positive earnings surprises (perhaps due to the relative difficulty in exploiting negative news).

The asymmetry in the over- vs. under-prediction has the result of rendering the official announcement following the Nikkei preview article relative good news in the case of both positive and negative earnings surprises. In the case of the positive earnings surprises, the official announcement has a 70% probability of being better the Nikkei preview. In the case of negative earnings surprises, the official announcement has a 44% of being better than the Nikkei preview. This is consistent with a strategic prior management forecast. For example, Cheng and Lo (2006) find that U.S. firms strategically manipulate forecasts to reduce share prices prior to insider purchases. As we discuss below, we examine various theories about the extent to which the market properly adjusts for strategic information release. In simple terms, however, is the market "fooled" by the bias in over- or under-prediction in the previews?

5. Which Firms Are the Subject of Previews?

Nikkei does not write preview articles on all publicly traded firms. We examine which firms are written-up and how persistent it is. This is important, because investor reaction to the news is based upon expectations conditional upon the information channel and potentially understanding and relying on repeated patterns of disclosure. If management uses Nikkei previews in a strategic game of selective disclosure, do the market participants understand and rely on the rules of this game?

There are 1,065 firms that are previewed at least once by Nikkei (the numbers of listed firms are 3,488 in December, 2000 and 3,693 in December, 2010). Table 4 shows the yearly counts of preview articles for the most frequently written-up firms. While some of the names of those firms may be familiar due to their widely known consumer products, it is not obvious from inspection of the table what types of firms are more frequently previewed. For the analysis we develop below, we single out firms that was previewed in the prior year, and then previewed again in the current year. For these firms, investors may expect the preview articles to appear in the current year as well, and so it indeed appears. We examine these firms in comparison to firms that are never previewed by Nikkei in terms of market reactions to the events such as preview publications and company announcements. We find 800 firm-year observations of these firms, which we call "serially-previewed" firms. As a control, we create a sample of market-cap matched firm-year observations for the firms that have no previews published in 2001 – 2010. Table 5 reports firm characteristics of "serially-previewed" and "never-previewed" firms.

Table 6 presents the results of a probit regression on the characteristics that distinguish "serially-previewed" from "never-previewed" firms. The table shows that larger firms with relatively high turn-over (i.e., liquidity) are more likely to be previewed. This is not surprising in light of Nikkei subscribers and market position. Big, widely held and traded companies are obviously of interest. From the perspective of traders who have the benefit of selective disclosure, the higher relative liquidity of these firms means that price impact is lower and hence trading profits on private information more profitable. The different specifications of the regression in Table 6 are also instructive. Not controlling for size, the proportion of foreign ownership (as opposed to Japanese domestic institutional ownership) is a positive predictor of previewing behavior. This is interesting in light of Nikkei's recent decision to release preview articles in Japanese language only – presumably giving domestic investors a slight edge in interpretation of the subtlety accompanying and interpreting the numbers (a more complete analysis of this soft information component is the subject of our on-going research).

6. Accuracy of Previewed Results

The Nikkei preview articles are equivalent to "selective disclosure" in the pre-Reg FD U.S., except that they are published (solely) by Nikkei. A natural question is whether such previews are more accurate than previously available forecasts. We compute and compare forecast errors for the most recent management forecast and the forecast in preview articles. Table 7 reports the results.

Since there are relatively more preview articles published from seven calendar days before to the day of firms' announcements, we also look at the accuracy of the [−7, 0] previews. Table 7 shows that these preview forecasts are much more precise than the updated management forecast. Further, within the [−7, 0] previews, we separate "serially-previewed" firms. This table essentially documents that the preview news is potentially value-relevant. Tables 8-1 and 8-2 report the accuracy of the preview forecast, compared with that of the latest management forecast. Table 8-1 is for all previews; 8-2 is for serial previewers, 8-3 is for the non-serial previewers. Table 8-4 is a test of the difference between the serial previewers and the non-serial previewers. Serially previewers have consistently more accurate information.

7. Price Effects around Previews and Company Announcements

Kyle (1985) is the main theoretical framework for empirical predictions about rational investor behavior in a market with asymmetric information – as trading goes to continuous time, prices are fully revealing and martingale, and speculators make positive profits thanks to "noise traders." As a first step we test whether price dynamics around information events allow profits to informed investors. As a second step we examine the dynamics of various proposed microstructure measures. If, for example, strategic disclosure has benefits for the firm and its shareholders by improving price efficiency, there might be tradeoffs along other dimensions such as bid-ask spreads, lower volume and/or higher volatility.

Figures 4A and 4B illustrate the basic price results. For previewing firms (Figure 4A) we find a positive price reaction to positive news but no negative price reaction to negative news. For non-previewing firms, 4B, prices rise significantly around the release of positive earnings news and drop around the release of negative earnings news. We also document evidence that the value-relevant information is released prior to both official earnings announcements for non-previewers and also for Nikkei previews. Price changes measured from open to open on the day prior to the official announcement (made during trading hours) or the Nikkei preview (available prior to market open) indicates likely leakage of news. For both groups, the returns on announcement day itself are flat. As pointed out above, this is consistent with the hypothesis that information when it appears in the news is already impounded in stock prices, and with a rational model of investor decision-making in the presence of asymmetric information where the probability of informed trade is correctly estimated by uninformed investors.

The flat CARs for bad news are consistent with the hypothesis discussed above that firms may only release bad news via a preview when it is not expected to hurt stock price (or to not induce short-selling). The figures also show that the spread in CARs is persistent over the next two weeks following preview announcements but it converges for non-previewing firms around the official announcement. This suggests that the market may over-react rather than under-react to the official earnings announcement.

The post-earnings announcement drift is documented in other countries, most prominently in the U.S., but is less prevalent in the Japanese market. It is generally believed to be associated with behavioral limitations of investors. Given the regulatory structure of the U.S. market it makes it difficult to test cross-sectional differences in post earnings announcement drifts (PEAD) dependent upon different strategies for selective information disclosure by firms. The Japanese evidence suggests that firms use the Nikkei channel to disseminate value-relevant information to investors around earnings announcements, and these are effective at addressing potential under or over-reaction. The over-reaction around the official announcement days is a puzzle and the subject of further analysis.

Figure 5 shows the price dynamics for previewing firms sorted out by the number of days separating the preview announcement and the official announcement. CARs are synchronized around the event day defined by the official news announcement. It shows no evidence of a "double reaction" i.e., first at preview, and then once again at the official release of earnings information. There is little evidence of under-reaction to recent prior news released via Nikkei.

8. Incentives, Costs and Benefits of the Nikkei Previews for Related Parties

Market microstructure research (Admati and Pfleiderer 1988) predicts that the presence of asymmetric information should be empirically manifested in lower volume (i.e., buyers and sellers trading on their disagreement between about the economic value of the security), higher volatility (arguably a measure of disagreement), and an increase in bid-ask spreads (indicative of concerns about adverse selection by market-makers), as informed and uninformed investors strategically adjust the timing of their trades to maximize profitability or minimize adverse selection.

Our hypothesis is that preview articles provide an opportunity for informed traders to exploit an environment with lower spreads (hence less concerns about adverse selection).

As earnings season approaches, investors will naturally anticipate increasing probability of informed trades. News services provide an earnings calendar with expected dates for earnings releases. Investors use this information to assess the likelihood of informed trading. Krinsky and Lee (1996) show that spreads related to adverse selection increase prior to earnings announcements in the U.S. market. In contrast, the dates of the appearance of preview articles are not public, thus spreads may not increase as much in days prior to previews, making informed trading more profitable. In other words, the preview – particularly if it is not by a serially previewing firm, may be a strategy for allowing more profitable exploitation of private information. In the spirit of Admati and Pfleiderer (1988), the preview can be used to create an information event before which informed traders can trade in a less-suspicious environment.

Table 9 reports average daily bid-ask spreads for three intervals abound previews and official announcement days. For official announcement day spreads we construct a matched sample of non-previewing firms based on size in the same fiscal year. We divide the table into good news and bad news events. We first test whether the spreads around preview days are higher or lower than the spreads for a matched sample of non-previewing firms on the days around official earnings announcement days.

Our null hypothesis is that the spreads are the same. Our alternative is that the bid-ask spreads for the day of the release of value-relevant information to informed traders -- when the date is known ex-ante -- are greater than when the date is not known ex-ante. For good-news announcements, we find that spreads are significantly lower for previewers compared to non-previewers prior to and around the event date. Evidence reported above helps us assess market expectations about the timing of information released to informed traders. For official earnings announcement days, we show above that prices move a day or two before the release date. If the timing of this selective disclosure is common knowledge, then we would expect spreads due to adverse selection to increase over the same time interval. In contrast, if the day of the selective disclosure prior to a preview is unknown, or at least less predictable than disclosure dates preceding announcement days, then this would imply a significantly lower adverse selection-based bid-ask spread prior to previews compared to official announcements.

We find strong evidence against the null. For the −3 to −1 day window, in which stock prices have been shown to move in the direction of earnings revisions, the difference in the bid-ask spread is significant for both good news and bad news events. For good news events, the difference in spreads are significant in all three intervals: t-10 to 1-4, t-3 to t-1 and $t = 0$. For bad news events, the t-10 to t-4 and t=0 intervals are not significant. [check one-tailed test].

Table 9 shows several other interesting things. Note the change in spreads from the period t-10 to t-4 to t-3 to t-1. For previews, this increase is small. For the matched sample, the increase is large. Spreads widen considerably in the three days prior to the official announcement compared to the preview sample, consistent with a rational anticipation of leakage in the days immediately preceding the announcement. The difference between the spreads in these two event windows is significant for the matched sample and not for the preview sample (check). Another feature of note is that the average spreads are significantly higher for bad news than for good news for all reported windows, for both the preview and matched samples. This is a puzzle. It is consistent with the hypothesis that investors are more sensitive to negative disclosures compared to positive disclosures, however it is inconsistent with the hypothesis that firms are more likely to disclose positive information. In a "game" of selective disclosure we noted above that companies appear to allow positive information to reach the market prior to preview or announcement, which would increase the probability of private information rather that decrease it when that information is good news.

One additional complicating factor relevant to the interpretation of Table 9 results is that the decision to preview may be conditional upon price trends or bid-ask spread trends. For example, a firm planning to preview might not do it if the spreads or prices suddenly spike upwards, eliminating the benefit or necessity of selective disclosure via management-related channels.

9. Discussion and Conclusion

The Nikkei preview phenomenon provides a unique opportunity to examine the selective disclosure strategies that differ from the current practice in the U.S., which is constrained by Regulation FD, and from the disclosure practice that prevailed in the U.S. prior to the enactment of Reg FD. Nikkei's virtual monopoly on media release of earnings numbers prior to official announcement allows us to use one specific channel of press disclosure.

The structure of information release in Japan offers a means to more sharply differentiate the response by investors to different types of information. Prior research on investor response to the probability of information asymmetry. has relied on more general information structures. Vega (2006) for example, uses the Easley and O'Hara (1992) PIN measure to show that post-earnings announcement drift is lower when the probability of informed trading is higher. Our results are consistent with hers, but support the hypothesis that firms may play a decisive role in moving prices towards efficiency. Our also results provide additional insight into those reported by Tetlock (2010). While he also detects evidence of informed trading prior to the news, and documents a negative association with a liquidity, which is mitigated upon the news release. We are able to separate the release of information into two types: one for which the date of release is well-anticipated, and one for which it is less-so. We find that this leads to different patterns of investor behavior, and consequently different behavior of asset prices.

We are able to document several features of the Nikkei preview phenomenon that suggest that it is strategically used by corporations to improve price efficiency. Preview numbers are more accurate than prior forecasts, which themselves may be strategically formed to ensure that the Nikkei updates are more likely to be perceived as good news. Price reactions around previews are positive for good news and flat for bad news. The company stock price on average benefits from this disclosure event and the benefits are permanent – in contrast to temporary effects around official earnings releases. This suggests that the prices discovered via the Nikkei preview process are efficient.

We find evidence that an early disclosure via Nikkei preview is accompanied with leakage prior to the preview event, resulting in a rise in share price before article publication. Price dynamics indicate that leakage occurs for official earnings announcements as well. By the same token, the absence of price movements on the actual day of information release suggests that uninformed as well as informed investors adjust their priors about the probability of informed trading. Evidently the fact that one sees something in the news is *prima facia* evidence that prices already incorporate it. We find some evidence that uniformed investors are motivated to trade by a company appearing in the news – evidence documented in earlier markets. We also find that prices that were moved by the news (around the official earnings announcements) later revert – suggesting that there were not based on value-relevant economic fundamentals.

Taken together, these phenomena suggest that the previews play a role in a complex strategic interaction among several parties. We conjecture that previews allow informed agents to trade in advance of wider spreads associated with adverse selection concerns around the official earnings announcement. The company may use Nikkei as the informational intermediary to facilitate this trading, and in doing so may weigh the costs and benefits of informed trading in its shares when selecting whether to preview.

The natural question is why this particular information revelation structure suits the various parties: firms, Nikkei, investors and regulators. From the firm's perspective, the benefits to informed trading enumerated in Leland (1992) are straightforward: stock prices are higher, cost of capital lower, market prices are more fully revealing and investor risk is reduced. The cost to shareholders who sell shares at an adverse price may be small compared to the net benefits to long-term shareholders of the firm.

Viewed through the lens of behavioral finance, previews provide opportunities for firms to reduce investor inattention and its adverse effects on share price and liquidity – to the extent that one component of liquidity is a consequence of breadth of ownership and awareness. Barber and Odean (2008) document the strong positive price effects of awareness due to stocks being in the news.

From Nikkei's perspective, the ability to provide timely, accurate and exclusive information about corporate performance is the hallmark of a leading financial news provider. By serving as the principal medium for selective corporate disclosure they make themselves highly valuable to subscribers and to companies.

From the perspective of various investor clienteles, the incentives are mixed. For investors who trade prior to news release, there is a potential enforcement risk if indeed their trades violate insider trading laws, however the performance benefits may be significant. We have not yet examined changes in institutional holdings to understand which clienteles exploits these opportunities. Bris (2005) documents a trade-off between profitability and enforcement of insider trading laws. In the Japanese case the sustained evidence of informed trading prior to the event may thus be associated with modest profitability.

From a regulator's perspective, one of the principal motivations of Reg FD was the promotion of liquidity through the reduction of information asymmetry. Improved liquidity seems like a good think, although as the volume of trade by uninformed speculators increases, so do uncompensated transactions costs. In our study, since the decision to use previews is endogenous, liquidity differences between previewing and non-previewing firms will not likely be informative, and thus this paper does not address net welfare benefits of a non-Reg FD environment.

The case of Japan's Nikkei preview articles demonstrates that, in the absence of Reg FD, a richer strategy space for information disclosure, timing of trades and avoidance of adverse selection emerges.

13.12	37313	347604	230483	200.8	130.0	
14.12 予	38500	360000	240000	179.9	130.0	

Legend of the above:

キヤノン: Canon, 7751: Japanese security code or SEDOL, 米国基準: US GAAP, Date of SH mtg.

Yr. Mo.	Sales	Cur. Inc.	Net Inc.	EPS	Dividends/share
	100M	¥M	¥M	¥	¥

14.12 予: Management forecast for the fiscal year ending December 2014

記 stands for "commemorative dividends"

Figure 2. Number of Preview Articles Over Time

This figure shows the time-series distribution of the Nikkei Preview articles, relative to the date of company's announcements. The announcements are on sales and/or operating income and/or ordinary income and/or net income. Our priority rule is to take the last (net income) and go reverse, if not available.

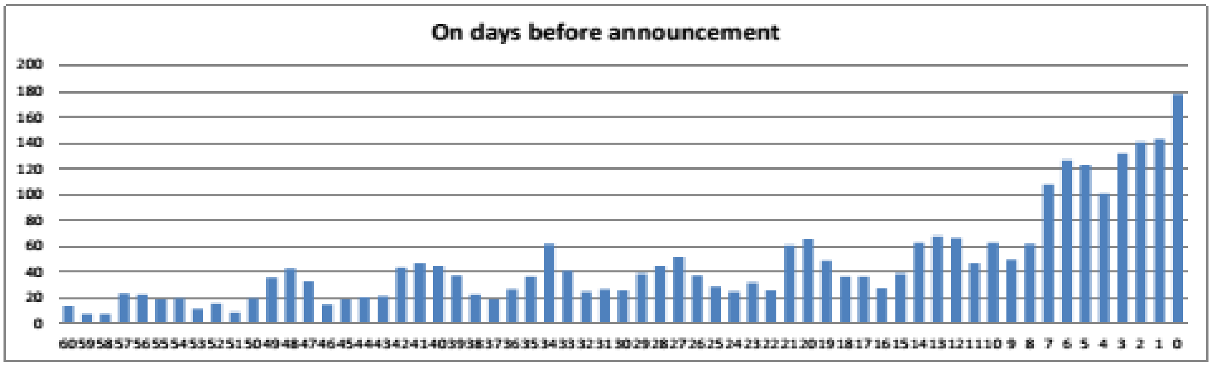

Figure 3. Preview Articles over Time

The figure shows the time-series distribution of the Nikkei Preview. The announcements are on sales and/or operating income and/or ordinary income and/or net income. Our priority rule is to take the last (net income) and go reverse, if not available.

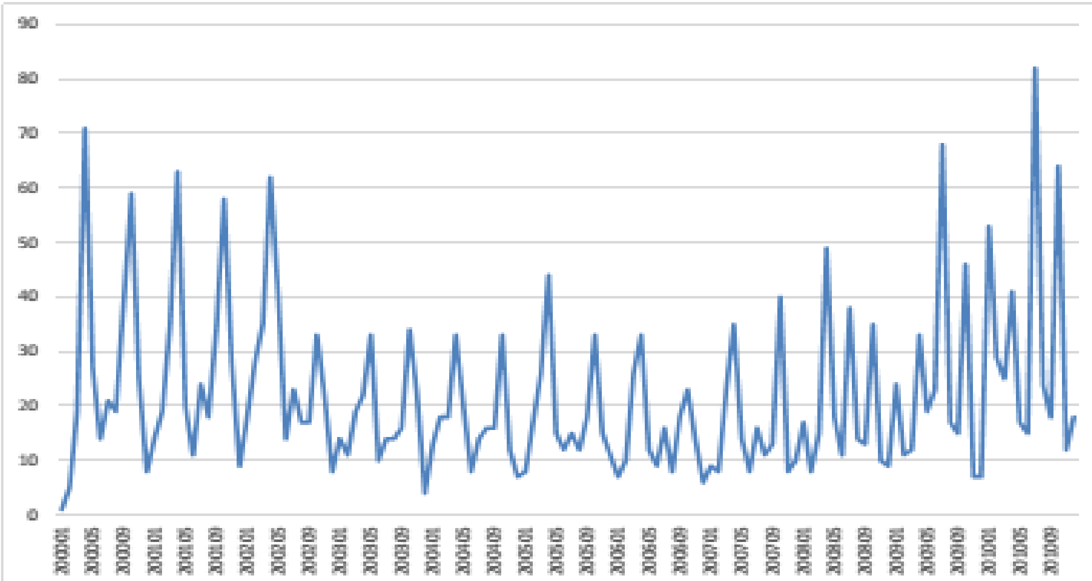

Figure 4A. CARs for Preview Article Publications

"Day0"is the day of the preview article publication.

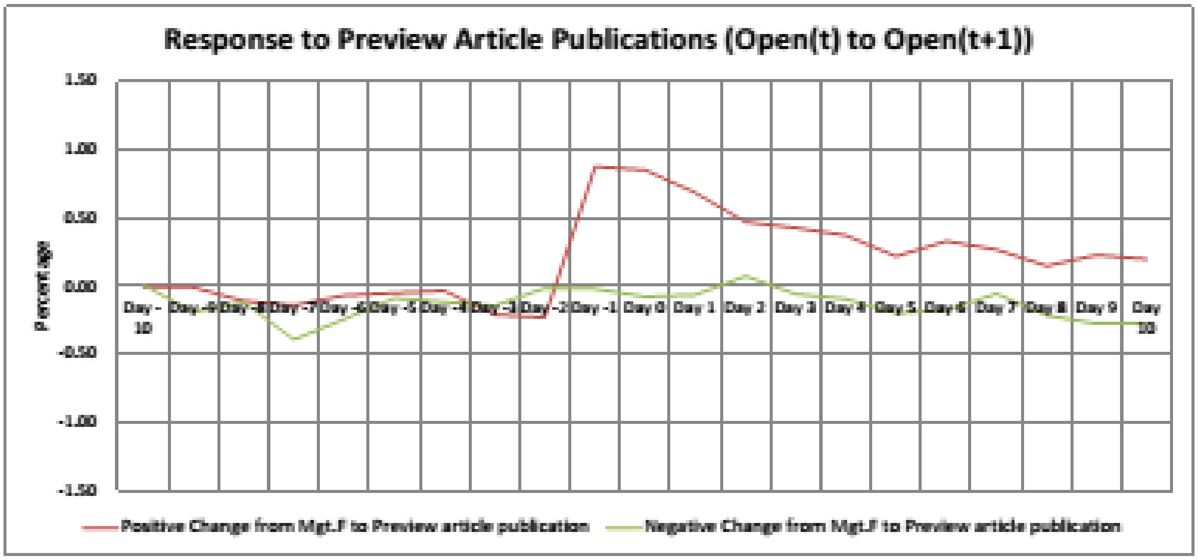

Figure 4B. CARs for Company Announcement Publications (for Non-Previewers)

"Day 0" is the day of publication of company announcement.

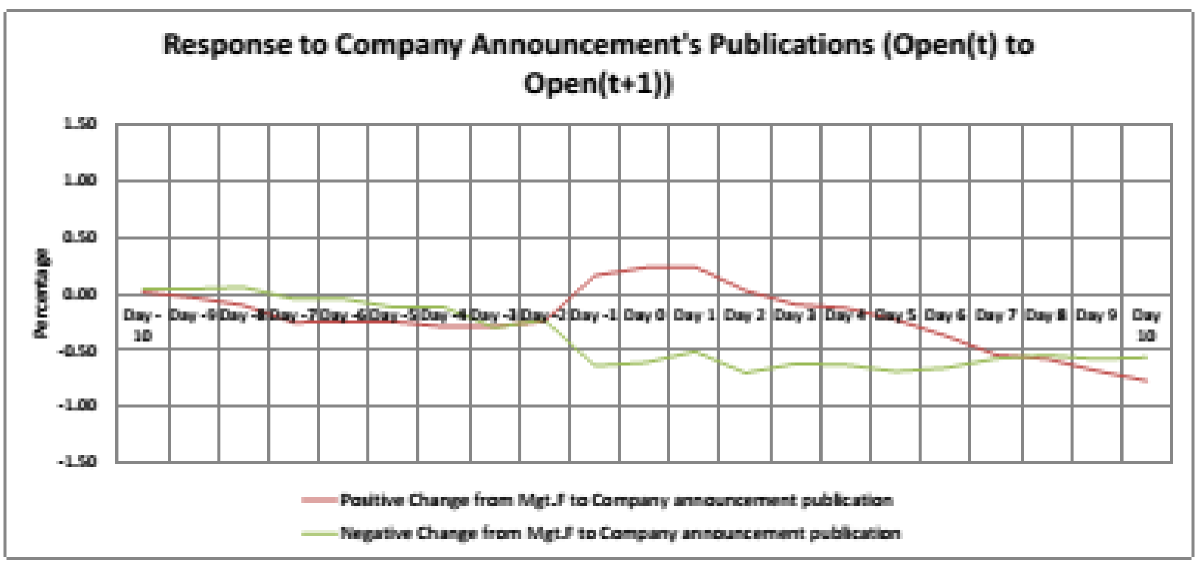

Figure 5. CARs for [-7, 0] Preview Publications

"Day0"is the day of the preview article publication.

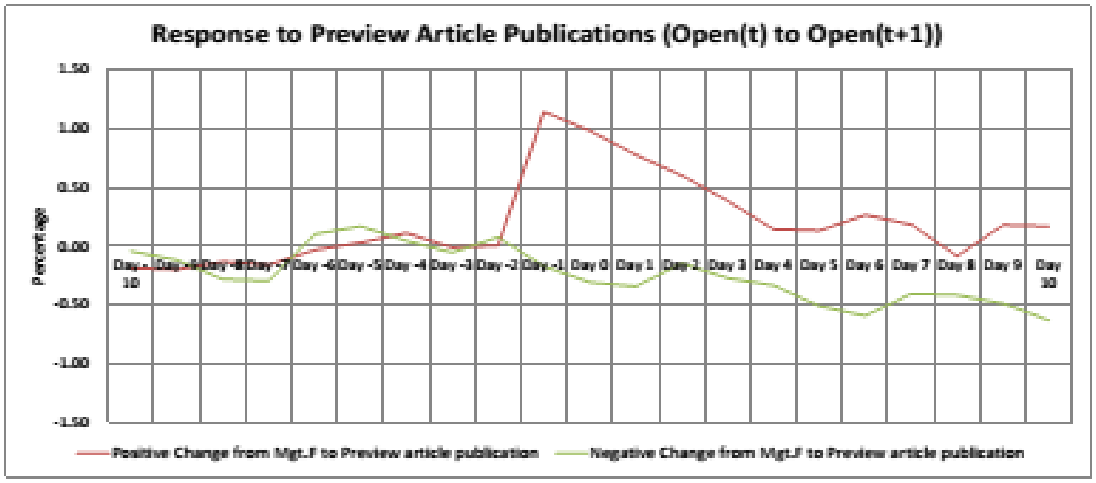

Figure 6. Responses to Company Announcement for [-7, 0] Previews

This figure reports CARs plotted from 10 days before to 3 days after the company announcement for previewed firms whose articles appeared 7 days before to the day of the announcement. Vertical axis is in percentage. "0" is the previews published on the day of the announcement, "-1" is the previews published one day before the announcement, etc.

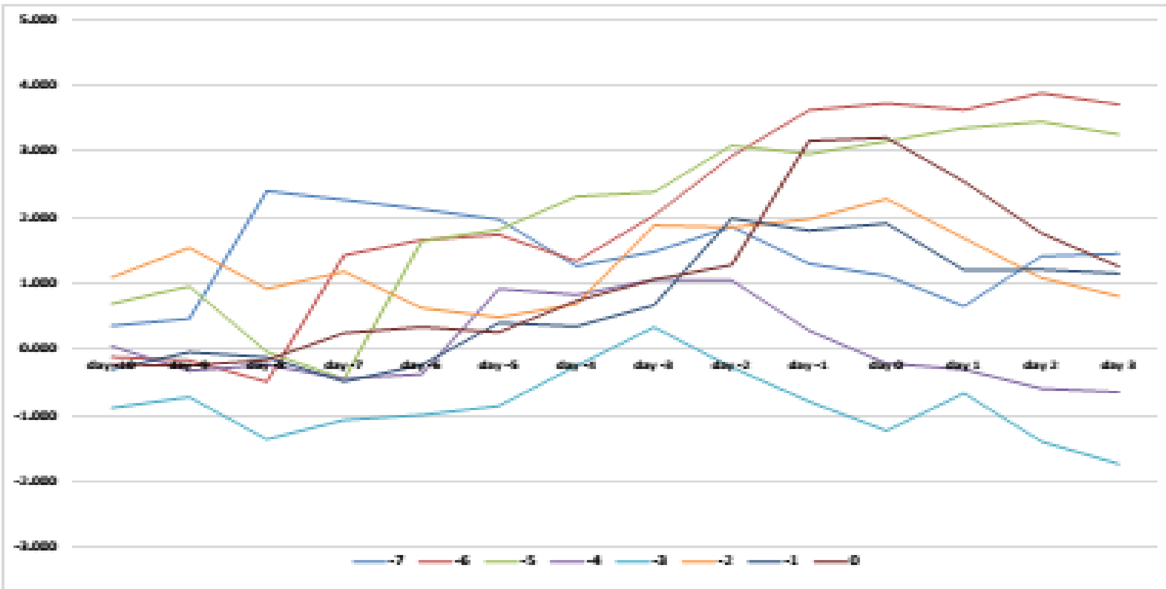

Table 1. Number of Preview Articles

	Number of articles				
Preview about	Total	Annual (12 month period)	Quarterly (9 month period)	Quarterly (6 month period)	Quarterly (3 month period)
Sales	2,563	1,117	166	957	323
Operating income	1,799	734	132	679	254

Table 5. Firm Characteristics of Serially Previewed vs. Non-Previewed Firms

Firms with preview are the ones that are written up in Nikkei preview articles in year t and $t + 1$ during 2000 – 2010. Firms without preview are the ones that were never written up in the same period (sample starts in 2001), and matched with firms with preview by market cap. ***, **, and * indicate significance at the 1%, 5%, and 10% levels, respectively.

	Firm-year obs. with preview						Firm-year obs. without preview						Mean Test (With - W/O)		Median Test (With - W/O)

Table 6. Regression on Which Firms Are Previewed

This table reports the regressions coefficients for a probit model. Standard errors (in parentheses) are clustered around firms. The dependent variable is equal to one if the firm-year with preview is the firm-year that has preview articles in that year (t) and year t-1. There are 800 such firm-year observations. Market-cap matched observations of "never previewed" firms are added. The independent variables and their definitions of the independent variables are as follows: the logarithm of market capitalization (in million yen), proportion of individual investors is the number of shares owned by individual investors relative to the total number of shares, proportion of institutional investors is the number of shares owned by financial institutions, financial product dealers, and other corporations relative to the total number of shares, proportion of foreign investors is the number of shares owned by foreign corporations relative to the total number of shares, proportion of the special few shareholders is the number of shares owned by insiders and closely-affiliated firms relative to the total number of shares, floating shares is the number of freely floating shares relative to the total number of shares, turnover is the monthly average of the number of shares traded divided by the total shares outstanding, listed on TSE 1st section equal to one if the firm is listed on the first section of the Tokyo Stock Exchange. The estimation includes industry fixed effects and year fixed effects. The sample includes between 2000 and 2010. ***, **, and * denote coefficient estimates significantly different from zero at the 1%, 5%, and 10% levels (two-sided), respectively.

Table 9. Abnormal Returns, Volatilities, and Volumes, and Spreads

Cumulative abnormal return is the value of daily abnormal returns, summed over the window indicated. Daily abnormal returns during the event window are defined as the raw return minus the expected return, which is estimated using market model. Abnormal return volatility is the absolute value of daily abnormal returns, summed over the window indicated. Abnormal trading volume is the difference between trading volume and the mean of daily volume for that stock over the pre-preview (or pre-announcement) publication window [-270,-21], normalized by the mean volume, then summed over a window. Spread is defined as end of the day quoted (ask-bid)*100/((ask+bid)/2) (averaged over the window indicated). Panel A presents the results of abnormal returns, volatilities, volumes, and spreads response to good news. Panel B presents the results response to bad news. ***, **, and * indicate significance at the 1%, 5%, and 10% levels, respectively.

This paper focuses on the impact of a Trans-Pacific Partnership (TPP) Agreement on Vietnamese textile and garment industry to the United States (U.S) market. This study also analyzes the opportunities as well as challenges facing by Vietnamese textile and garment industry upon its integration into the U.S market through TPP. Based on reference research papers and conducting online survey with 65 Vietnamese textile and garment enterprises, the research has successfully identified the factors contributing to Vietnamese enterprises' levels of consensus for the country's membership application to TPP. Of all the factors, tariff rates factor generates the greatest concern among the business circles. In addition, the research suggests some recommendations for boosting Vietnamese textile and garment producers' export performance into the U.S market in the case of Vietnam official participation on TPP.

Keywords: textile and garment, TPP, export, levels of consensus.

1. Introduction

Through many years of negotiation, the countries participating in negotiating the Trans-Pacific Partnership Agreement (TPP) is accelerating progress towards the end of negotiation in 2015. Compared to the previous agreements such as BTA, AFTA, and WTO, TPP expanded strongly in investment, trade in goods, trade in services, and intellectual property. It also includes many other issues such as government procurement, environment, and labor unions. The participation of Vietnam in TPP will lead to more opportunities and challenges to domestic enterprises as well.

TPP has a wide scope adjustment. With the trend of strong liberal negotiations, tariff has to reduce most of the tariff lines (at least 90%) in implementation immediately or in a very short progress; Service sector should increase the degree of openness, particularly in financial services; Investments need to strengthen the regulations related to foreign investment and investor protection; Intellectual property rights have to enhance the level of protection of intellectual property rights so that it can be higher than the that of the WTO; Competition and public procurement should enhance competition, especially in the field of public procurement; The labor issues, especially the issue of the right of association (union), the right to aggregate and negotiate of general laborers should prohibit the use of all forms of forced labor and exploitation of child labor. Regulations fighting against discrimination in the workforce are governed by the Agreement; The non-trade issues such as increasing environmental requirements for the TPP participants.

Textile industry is one of the most affected sector when Vietnam takes part in TPP, as this is a sector accounting for a large proportion of exports, creating jobs for labors. By joining TPP, Vietnam's garment industry will have more opportunities to entrance foreign market through exporting way. However, it has to face significant challenges, particularly when exporting to the U.S market. Therefore, it is necessary to conduct a research to find out the impact of TPP as well as analysis of the opportunities and challenges for Vietnamese textile and garment industry to the U.S market.

2. Methodology

This research uses the secondary data which collected from the General Department of Customs from 2008 to 2013, and the primary data which collected through surveys 65 textile enterprises of Vietnam by using the online questionnaire from January to March 2014. Descriptive statistics and regression analysis methodology are used to analyzed the results.

3. The current situation of Vietnamese garment and textile industry

3.1. *The export situation from 2008 to 2013*

In the 2008-2013, the U.S was always a major exporting market of Vietnam garment. The export turnover of Vietnam's garment to the U.S market increased over the years with the top value and proportion in all the export markets of Vietnam. For example in 2009, exports reached US $4,995 billion, gaining 97.9% compared with 2008, accounting for 55.1%; in 2010 was 6.12 billion US dollars, an increase of 122.5%, accounting for 54.6%; 2011 was 6.92 billion US dollars, an increase of 113.1%, the proportion was 49.3%; 2012 was $ 7.6 billion, an increase of 108.9%, accounting for 44.2% is; 2013 was $ 8.6 billion, an increase of 111.6%, the proportion was 43% (Table 1).

The average of import turnover of textiles is about 80 billion U.S dollars per year. With current export turnover, Vietnam is ranked as a 2nd supplier of textiles (after China) in the U.S market. Structure of Vietnam's garment exports to the US includes garments, fibers, fabrics, towels, curtain, etc which team apparel accounts for approximately 95% of total exports.

Table 1. Exports of Vietnam textiles 2008-2013 periods.

Unit: billion US dollars

Market	2008		2009		2010		2011		2012		2013	
	value	%	value	%	value	%	value	%	value	%	value	%

Source: General Department of Vietnam Customs, 2008-2013

3.2. *The current situation of raw materials import*

Vietnam's garment industry is heavily dependent on imported raw materials from abroad. The garment manufacturers in Vietnam are imported mainly from China, Korea, Taiwan or Hong Kong, etc. with the value of import raw materials accounts for nearly 70-80% than the value of export turnover. Most of the countries and territories that Vietnam imported raw materials accounted for a large proportion do not join TPP such as China, Taiwan, Hong Kong, while Korea only intends to join TPP.

In 2013, Vietnam imported textile fabric which worth 8,397 million U.S dollars, up 19.28% compared with the same period last year. China is the main market supplying textile fabrics for Vietnam, the total import turnovers from China was up to 3,887 million U.S dollars, accounting for 46.2% of the total value of imports of textiles and garments in 2013. China now plays a huge role in governing the issue of providing raw materials for the Vietnam textile industry, providing about 50% of all textile materials for Vietnam. TPP is likely to be signed in the coming years. When being take part in TPP, Vietnam’s garment and textile enterprises must comply the rules of origin from the fibers proposed by U.S to get the benefit from tax incentives of TPP while exports to the U.S market, which is not imported raw materials from countries not participating in TPP, including China. This is one of the major challenges for Vietnam's garment industry.

Table 2. The value of import raw materials import 2012 to 2013

Market	2012 (USD)	2013 (USD)	+/- (%)
China	3,040,772,008	3,887,791,400	27.86
Korea	1,409,747,353	1,713,007,408	21.51
Taiwan	1,073,407,119	1,241,484,802	15.66
Japan	599,123,789	563,562,276	-5.94
Hong Kong	353,348,106	350,110,174	-0.92
Malaysia	48,174,107	62,832,748	30.43
America	26,872,428	24,054,073	-10.49
Singapore	2,867,697	3,679,702	28.32

4. The opportunities for Vietnam textile industry exports to the U.S market when Vietnam participates in TTP

4.1 Expansion of export markets

Although TPP is in the negotiation process, the contents remain confidential, but in the field of trade in goods, TPP is expected to have the commitment of strong trading liberalization, the tax rates 0% immediately. Studies on International Trade affirmed TPP will increase trade between countries. Petri (2011) has applied general equilibrium model to calculate and show the benefits of each country participating in TPP. GDP of Vietnam could reach 235 billion US dollars, up 28% and income by 36 billion in 2025; GDP of U.S could reach 20 337 billion, up 0.7% additional income and $ 39 billion.

Table 3. Expected results TPP in 2025

Unit: billion dollars

Country	New Zealand	Singapore	Australia	Japan	Malaysia	Mexico	Peru	America	Viet Nam
GDP in 2025	206	386	1,426	5,332	422	1,999	311	20,337	235
GDP (%)	1	0.6	0.4	1	2.7	0.6	2.5	0.7	28

Table 4. Opportunity in increasing exports to the other markets

Country	(%)
America	90.63
Australia	46.88
New Zealand	34.38
Chile	31.25
Peru	28.13
Singapore	28.13
Malaysia	21.88
Brunei	15.63

Source: Survey of 65 textile enterprises

In particular, the survey results on 65 textile enterprises have shown that more than 90% of firms expecting to join the TPP will get a opportunity to boost exports of textiles to the U.S market. Meanwhile, the number of other markets are much lower (Table 4). This expectation has basement and be reasonable when an average tariff on textiles Vietnam in the U.S market today is quite high as 13.69% [2]. When this tax rate equals 0%, there is a large opportunity for garment enterprises exports to the U.S market.

4.2 Enhancing capacity of production

Besides export flows, the increase in imports from TPP countries to Vietnam are not only challenging but also containing many opportunities. When Vietnam joins TPP, Vietnam's garment and textile enterprises will import garment products from TPP countries with a large volume and competitive prices. This reduces production costs, improve the competitiveness of Vietnam's products as well as enhance production capacity of Vietnam.

Table 5. Opportunity increase in imports of raw materials and machinery

Country		America	Peru	Chile	Australia	New Zealand	Singapore	Brunei	Malaysia
Business (%)	Raw materials	46.88	34.38	31.25	37.50	37.50	28.13	18.75	34.38
	Machines, devices	81.25	12.50	9.38	43.75	37.50	28.13	53.13	9.38

The U.S is a country that Vietnam surplus. If Vietnam increases in imports from the United States, Vietnam will restrict imports from China. The local enterprises hope that reduction of import tariffs will enable them to import raw materials, machinery and equipments from the member countries of TPP, especially from the U.S. There are 81% of enterprises expect to import machinery and equipment from the U.S market when they participate in TTP; 47% of enterprises expect to be able to import raw materials from the U.S. Obviously, the technological level of the U.S would be an opportunity for Vietnam enterprises.

5 Challenge of Vietnam's textile industry when export to the U.S market

5.1 Rules of origin

The first challenge is that Vietnam must comply with the principals of the origin of goods from the U.S yarn onwards to enjoy preferential tariffs under the TPP. This forces textile enterprises use raw materials produced domestically or imported from other countries which joining in TPP, not allow to use materials from countries that do not join in TPP. Currently, in the production chain from cotton, fiber, spinning, weaving, dyeing, finishing, garment products, Vietnam is only dominant in the end of the garment process. While weaving, dyeing, and finishing are still very weak and fail to meet the requirements. But an ongoing paradox is that Viet Nam still imports most of the fabric overseas in spite of the redundancy of yarn and 60% - 70% exporting value of the yarn produced in the country. Thus, with the current strength of ancillary domestic industries, it is obvious that requirements of origin given by the U.S is a disadvantage of Vietnam's garment industry because the main material for production of textile production Vietnam's garment was imported mainly from countries which are not members of TPP, especially China. If Vietnam do not solve this issue in the negotiations, joining TPP will bring no benefit to Vietnam textile industry when exporting to the U.S market.

5.2 Enterprise is no longer protected by the government

When TPP was officially signed, Vietnam will reduce tariffs and remove non-tariff barriers for products imported from TPP member countries. A deep level of commitment of the participating countries TPP will certainly force domestic firms to compete on equal terms with the main imported products even in countries where the market is no longer entitled the protective measures of the state. At that time, Vietnamese enterprises have to rely on the competitiveness of its own to compete.

Table 6. The challenge of competing against imported products

Country	Ability of competitiveness
Brunei	3.38
Chile	3.13
Malaysia	3.06
Singapore	2.69
New Zealand	2.66
Australia	2.44
Peru	2.34
America	2.13

(1: low competitiveness, ..., 5: high competitiveness).
