The TPP would strengthen ties between Asia and the Americas, create a new template for the conduct of international trade and investment, and potentially lead to a comprehensive FTA in the Asia-Pacific. It could stimulate trade by benefiting the competitive industries of both emerging-market and advanced economies. And it could yield an innovative model for consolidating the “noodle bowl” of existing trade agreements. Asian agreements, in turn, have aimed to promote the ASEAN Economic Community in 2015, improve political relations in Northeast Asia. The TPP emerged as a US priority some years ago, but it has recently become identified with the “rebalancing” of US foreign policy toward sustaining a US presence in Asia.

In addition, that Japan prepares to join TPP is also a good news for Vietnam. “That Japan enter TPP and boost agricultural investment in the Mekong Delta is a great opportunity that Vietnam must catch so that the agriculture sector can absorb a big amount of capital, technology and expand the market”, said Le Dang Doanh. According to Le Dang Doanh’s analysis, once entering TPP, Japan must open their agriculture sector. As a result, Japanese agricultural products will have to compete in prices with other countries’ agricultural products.

Therefore, Japan arrives to a decision to boost investment into Vietnamese agriculture as Vietnam is a member of TPP with big potential in this sector. When exporting to Japan, the tax rate will be 0%. At the same time, this can meet the condition that export products must have 70% of the intra-TPP.

Merchandise exports from Vietnam to the US have helped the poor in the Southeast Asian country very much because the process of making those goods used local laborers and created jobs, said Cu Chi Loi, director of the Institute of American Studies under the Vietnam Academy of Social Sciences.

In 2014, the US overtook the EU to become Vietnam's biggest export market, a position the European bloc had held since 2012, according to the General Statistics Office (GSO) of Vietnam. Vietnam raked in $28.5 billion from exports to the US last year, up 19.6 percent compared with 2013. The fastest growth rate was seen in such groups as textiles and garments (13.9 percent), footwear (26.1 percent), wood and wooden products (12.8 percent), and electronics, computers and components (45 percent).

Vietnam becomes the 2nd largest textile and garment exporter to the US, the 3rd largest textile and garment exporter to Japan.

Figure 1: Merchandise Trade with TPP Countries (2007-2013)

	2007	2008	2009	2010	2011	2012	2013

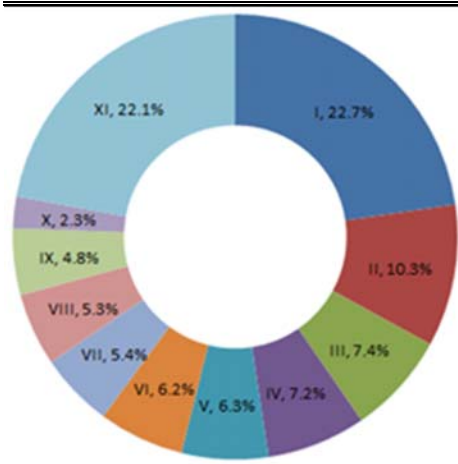
Vietnam's major commodities exports to the TPP countries including: Textiles and garments; Crude oil; Computers, electrical, spare-parts; Foot-wears; Fishery products; Wood and wooden products; Machinery, equipment, tools; Transportation, parts and accessories; Phones and parts; Handbags, purses, suitcases, headgear ; Others products (Figure 2).

Figure 2: Major commodities Exports to TPP members 2013

No.	Major commodities Exports to TPP member	Exports in TPP (%)
I	Textiles and garments	22,7%
II	Crude oil	10,3%
III	Computers, electrical, spare-parts	7,4%
IV	Foot-wears	7,2%
V	Fishery products	6,3%
VI	Wood and wooden products	6,2%
VII	Machinery, equipment, tools	5,4%
VIII	Transportation, parts and accessories	5,3%
IX	Phones and parts	4,8%
X	Handbags, purses, suitcases, headgear	2,3%
XI	Others products	22,1%



4. Impact assessment as Vietnam joins TPP

Vietnam's participation in the negotiation for TPP participation have been bringing multidimensional impacts on the economy in general as well as enterprises and people in particular. In details:

4.1. Positive impacts of TPP

Export increases are 45-75 percent higher, in dollar terms, than the corresponding income gains, but follow similar patterns. The largest gains (in either absolute or relative terms) from the addition of Japan are for the US, Australia and Vietnam. The largest gains from the addition of Korea are for Mexico, Japan and Vietnam.

In general assessment, TPP brings huge opportunities to Vietnam for the economic growth; promoting goods and service exports to the markets of Member States in the agreement, particularly the US market, with preferential tax rate of only 0-5%. And when Japan also joins TPP negotiation, Vietnam can achieve even greater benefits such as trade facilitation and efficiency enhancement in the supply chain, service sector modernization, exports tax reduction, and import restriction improvement ...According to Prof. Peter Petri, University of Brandeis - senior adviser of United States Agency for International Development (USAID)/Support for Trade Acceleration (STAR) Project, as the least developed countries among TPP participating countries, Vietnam is expected to get the largest benefits from this economic intensive and extensive integration, specifically, according to Mr. Petri, if taking the milestone of 2025 and Vietnam's becoming a TPP member, Vietnam's GDP will greatly increase, about 26.2 billion dollars greater (assuming that TPP has 11 members) or 35.7 billion dollars greater (if TPP includes Japan) compared with basic rate of 340 billion dollars (Table 1). In other words, Vietnam's GDP in 2025 when involved in TPP will be higher compared to TPP non- participation of Vietnam, approximately 7.7% (or 10.5% if Japan also joins TPP).

Table 1. Income gains under alternative scenarios, 2025

Source: Petri; Plummer and Zhai (2012), www.asiapacifictrade.org

a) Export promotion

Since the renovation in 1986, Vietnam has always regarded export as a motivation for the economy growth. With that strategy, Vietnam's export turnover has increased from $ 340 million in 1986 to $ 114.6 billion in 2012. Import turnover has also increased from $ 600 million to $114.3 billion in the same period. Economy opening (measured by the ratio of total import and export turnover over GDP has increased from 26% in 1990 to 186% in 2014, bringing Vietnam to one of the countries with the largest opening in the world.

The biggest goal of Vietnam’s joining TPP is to strengthen export to TPP member countries through their duty exemption or reduction for Vietnamese goods. Because TPP poses high demand of completely eliminating import duty right after the agreement takes effect, except for items of 3-5 or 10 year roadmap. Meanwhile, the Asia - Pacific currently accounts for 70% of total export turnover and 80% of total import turnover of Vietnam. Many major export markets of Vietnam became the members of TPP as US or upcoming Japan.

Assuming that Vietnamese export goods meets full conditions of the origin of TPP to enjoy preferential tariff of 0% among TPP, Vietnam's exports without TPP participation in 2025 will be $ 239 billion, and will rise by $ 67.9 billion (28.4%) to $ 307 billion with TPP membership (12 members including Japan).

The items with greatest increase include textiles, garments, footwear, and increase by 45.9% (from $ 113 billion to $ 165 billion) (calculated by Professor Petri).

In other words, TPP participation is expected to be the best route for exports of Vietnam to compete on price when partner’s market access. He cited: "Currently, China accounts for 50-60% of US garment and footwear market and Vietnam makes up about 10%. But China's exports will be halted because of increasing wages and its export policy re-orientation. So imagine if Vietnam wins that majority 50%?”.

Notably, Vietnamese rice will also have the opportunity to become a big exporter as the main rivals, including Thailand, India have not joined TPP negotiation ... On the other hand, so far, China, a major competitor of Vietnam has not offered its interest of participating in the agreement and this is an opportunity for Vietnam products to get price advantage if taking advantage of preferential tariff when accessing to internal-group markets.

b) Eliminate most tariffs and most immediate benefit from TPP joining of Vietnam.

In fact, any negotiations on the free trade agreement always discuss tariffs. However, TPP sets a high requirement of import duties elimination immediately after the agreement comes into force (excluding goods of 3, 5 or 10-year roadmap). This requirement has poses both opportunities and challenges for Vietnamese enterprises. According to statistics given by the Ministry of Industry and Trade, the US is the second largest trade partner of Vietnam, following after the EU, with imports from Vietnam reaching $ 19.6 billion in 2012, accounting for 17.1% of total Vietnamese exports. Japan ranks the 4th, with $ 13.1 billion, accounting for 11.4%. Some of Vietnam's export items including textiles, footwear, seafood and furniture are believed to have many advantages.

In fact, as some major export goods of Vietnam such as seafood: fish, shrimp, crab ... exported to Australia outside markets (New Zealand and Peru) have been applied duty rate of 0%; unprocessed seafood or furniture (mainly exported to the US market) have enjoyed tax rate of nearly 0% so benefits from these above groups will not be shown clearly when Vietnam signs TPP agreement.

However, TPP is expected to bring tariff incentives to major export products

of Vietnam such as textiles, footwear, especially to the US market. For years, US, EU, Japan have played as traditional and important markets in Vietnam's textiles exports (in which US is the largest export market). In 2014, Vietnam's textile export turnover to the US reached $ 9.96 billion, accounting for nearly 36% of total textile exports of the country ($ 29.3 billion) and accounted for approximately 9.26% of the US textile market. So far, most of Vietnam's garment exported to the US have been imposed the average tax rate of 17.3%, the highest rate of 32%, so TPP offers greater expectations, because that time Vietnam's textiles will have the opportunity to enjoy the tax rate of 0%, exports could rise 12-13% per year, instead of 7% per year currently.

Currently, Vietnam ranks second after China in footwear exports to the US market. In 2012, Vietnam's footwear exports to the US market reached $ 2.24 billion. However, in the US, Vietnam's footwear only accounted for 6% in the quantity and 8% in the values. At the signing of TPP, the average import tariff of 14.3% currently (in the US market) will be reduced to 0%. It will be a great opportunity for Vietnam to approach world's big footwear, handbags brands. However, to get this opportunity, Vietnam's footwear, handbags sectors may encounter many challenges, competititiveness with foreign investment enterprises, serious requirements on delivery quality and technical barriers, domestic market mastering capability, raw material localization ratio to ensure the eligibility for preferential tax ...

Besides, there will also be some benefits from import tax reduction from TPP countries,

specifically, consumers and production sectors using raw materials imported from these countries as input materials will benefit from goods, cheap raw materials, reduce the cost of living and production, which can improve competitiveness of these industries ...

c) TPP will create great opportunity for Vietnam to attract Foreign Direct Investment (FDI).

Among TPP participating countries, Asia only includes Malaysia, Singapore, Brunei and may be Japan. Thus, viewing from a certain aspect, Vietnam will only have to compete with Malaysia to attract FDI. In relation to the regional "rivals" today as Thailand, Indonesia, Myanmar, as a TPP member state, Vietnam will more or less advantageous in the race of FDI attraction. Currently, Japan, Singapore, Malaysia, US- countries participating in the TPP negotiations- are the leading investors in Vietnam and probably enterprises of these countries will continue to ramp capital in Vietnam to take advantage of cheap labor, open export markets. Of course, not only investors from TPP members, but also from others countries and regions will also be more interested to Vietnam because of advantages brought by TPP, including Korea, China.

Foreign investors will look at the opportunities generated by open export markets open, low tariff, to come to Vietnam. Additionally, cheap, diligent, clever labor, Vietnam will attract more FDI. Recently, many foreign investors have come to Vietnam for investment promotion or expansion with a view to catching opportunities of recovery economy and Vietnam's TPP membership. In 2013, there have been $ 453 million of FDI capital invested in textile and fiber sectors. It is expected to be about $ 1 billion invested in this sector in the future. In fact, investors shall pay attention to sectors with many exports advantages, especially textiles and footwear.

Mr. Chris Freund, CEO of Mekong Capital also said that an increasing number of foreign investors shall come to Vietnam to benefit tax when exporting goods to TPP countries,

especially the US and Japan - two world's big import markets, ranking the top and the fourth respectively. To take advantage of this opportunity in the shortest time, foreign investors will take Mergers and Acquisitions (M&A) to save time. So, M & A activities in Vietnam shall boom with the TPP participation of Vietnam.

d) With the opening of Vietnam market for goods and services from TPP countries, it is expected to have a more competitive business environment making goods and services

cheaper with better quality. With more technology, machinery, materials at lower prices, as well as new management models, and methods, enterprises will do business more efficiently. Moreover, there is expectation about benefits from foreign investment expansion, including the generation of production, jobs, revenues from taxes ...

đ) From the perspective of state management, following advantages brought by WTO,

TPP may offer a effective wave of institutional and administrative reform matching with international common practice. According to Le Dang Doanh, "Joining TPP will promote reform in Vietnam". One of the reforms will be on the rights of employees. With TPP, employees will be free to form unions, free to negotiate labor contract with employers. This may conflict with Vietnam's Trade Union Law, and force Vietnam to adjust to suit with international commitments. Joining TPP also requires Vietnamese policy makers to complete the legal framework to attract foreign investment. It is also required to determine incentives rights of state-owned enterprises to comply with the fair play rules among enterprises, to change government's expenditure policy, transparentize information.

e) In addition, Vietnam’s TPP joining is also an opportunity to balance trade exchange

with powerful markets, including solving the high deficit in business relationship with China. Considering overall benefits to the Vietnamese economy when joining TPP in spite of some certain disadvantages as described below, the benefits (in theory at least) are still greater compared to TPP non-participation.

4.2. Negative impacts of TPP

Besides said above favorable factors, Vietnem's TPP participation could impose some certain negative impacts that Vietnam should consider to proactively offer measures to deal with.

a) According to the reciprocity the principle in the international trade, Vietnam's exports benefiting from the tax reduction in TPP also means that goods from TPP partner countries imported into Vietnam will also enjoy corresponding benefits. As a result:

b) Budget revenues received from import duty will reduce because the import duty will

reduce to 0%. However, revenue reduction is expected not to be at large quantity as many countries within TPP have got FTA with Vietnam;

c) Domestic competition will be more fierce thanks to an increase in imports from TPP

members countries in Vietnam because of the removal of the average tax rate of 11.7% at present, and the price and quality will be more competitive as well. This will have certain impact on domestic market, demanding Vietnamese enterprises to actively adapt enhance business production capacity and improve product quality and competitiveness.

It is worth noting that according to a representative from Vietnam Textile (Vinatex), in the future, there will be a Chinese investment wave into Vietnam's textile sector, mainly garment sector. So, it will make it more difficult for Vietnamese enterprises to compete with TPP agreement. Meanwhile, Vietnam's garment enterprises have currently shown poor competition, mostly due to made-by-hand process and their over-dependence on raw materials imported from China.

Partner countries use technical barriers to protect domestic production.

Anti-dumping lawsuits occurring in recent years show that this is a great threat to

Vietnam manufacturers in competing on the international market. Domestic business community shows their high concerned about the high and complex demand of origin in TPP while export raw materials of Vietnam, especially garments, footwear, mainly are mainly imported from non-TPP member countries. In addition, intellectual property protection highly emphasized by the US also poses concerns to the Vietnamese's access to medicines, knowledge, science, cultural and spiritual property.

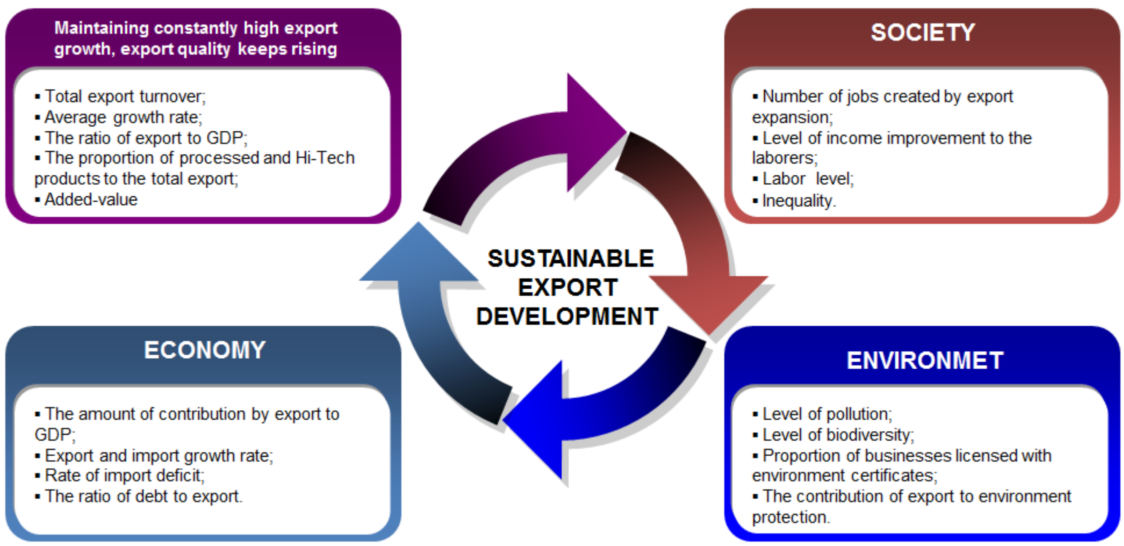
5. Sustainable Export Development in Vietnam's Enterprises

5.1. Summary of sustainable export

Sustainable development has become an inevitable global trend. It is also the goal of nations worldwide. Generally speaking, sustainable development indicates development meeting the demands of the existing generation without having any impacts on demand satisfaction of future generations. In other words, sustainable development ensures the quality of development, harmonizing economic goals with social and environment ones.

Ensuring sustainable development of an economy requires sustainable development in all sectors, in which trade in general, export in particular, are parts of the whole process. For countries having export-oriented economy, sustainable export contributes to the overall sustainable development of the economy. Sustainable export is maintaining high and steadfast export growth with constantly improved export quality, thus contributing to economic growth and stability, social order and environment protection. Sustainable export is the combination of these two factors. Firstly, maintaining high and steadfast export growth with constantly improved export quality. Secondly, harmonizing the different elements of sustainable development, namely the economic, social and environment (Figure 3).

Figure 3: Sustainable Export Development



Source: Compiled from multiple authors

Export is an economic activity, part of the overall economic activities, therefore, sustainable export is quite similar to economic sustainable development, meaning that maintaining constantly high growth, ensuring growth quality on the basis of increasing export added value, shifting export structure towards modernity, ever-rising competitiveness of export products. Inconsistent export growth poses many risks especially when there are sharp fluctuations due to inappropriate structure, low competitiveness of export products, decline in export growth, thus destabilizing the macro-economy. Therefore, inconsistent export growth cannot be seen as sustainable export.

Sustainable export should also meet the requirements of sustainable development for harmonization among economic, social and environment elements. Constantly high export growth with increasing quality but heavily relies on exploiting natural resources and causes much pollution, in other words, trading off the environment for high export growth, should not be seen as sustainable export. Or export only serves the interests of a particular group of people, especially in exploiting natural resources. This situation happens mostly in countries where there is low democracy, dictatorship, centralization of power. In this case, unfair benefit sharing exits, therefore it should not be considered sustainable export.

In Vietnam, export is a strategic orientation in economic development. During the years of the Renewal Policy, export is among the major motivators of economic growth, helping solve some social issues and protect the environment. However, export in Vietnam during the past years has not been sustainable. The quality of export growth has been insubstantial, risky and export has not presented the cause of industrialization and modernization. Export has been overusing natural resources, causing environmental pollution and ecological imbalance. Current export also raises social issues, such as unfair distribution of benefits from export. The Government has established Decision 432/QĐ-TTg dated April, 12, 2012 of the Prime Minister on ratifying Sustainable Development Strategy for Vietnam, period 2011 – 2020.

During the negotiation of TPP and RCEP, etc., the export orientation of Vietnam is to adopt policies enhancing export quality, supporting export structure shifting towards adding value, restricting exploitation of natural resources and environmental pollution. Export should also be part of the solution to social issues, such as creating jobs, increasing income and reducing inequality in income distributions, etc.

In order to ensure sustainable export, sound and appropriate policies grounded in science research should be in place. These policies take the harmonization of the economic, social and environment goals into consideration. However, over the past years, the formulation of sustainable export policies has not been grounded in the theoretical basis and reality of sustainable development. Therefore, it is important to establish scientific criteria as the basis for managers to develop policies ensuring sustainable export. The main purpose of this article is to clarify the concept, contents and criteria for sustainable export, to access export activities of Vietnam in accordance with the criteria for sustainable development and to propose some solutions to foster sustainable export in Vietnam in the coming years.

5.2. Criteria for sustainable export

5.2.1. Criteria for stability and quality of export growth

- The scale and average growth rate of export turnover at a certain time. This criteria indicates the maintenance of the export scale and growth, which is the annual export turnover and the average export growth. The scale of the export turnover is demonstrated by the ratio of a country's export turnover to the total export turnover of the world or a particular region. The average growth rate of export should be compared to GDP growth rate.

- The ratio of export to GDP is also an indicator for the sustainability of export activities on the economic terms. Accordingly, the rapid growth of the ratio of export to GDP shows the openness of an economy within the context of international economic integration.

- The quality of export growth is demonstrated by the structure of export in terms of commodities' categories as well as the processing level. For example, the ratio of export turnover for high-technology goods to the total export revenue of a country shows the industrialization level of that country as well as the value-added rate of the export goods.

- The increase of the value of export goods. This is a very important index to evaluate the efficiency of exporting activities as well as the competitiveness of export goods.

The sustainability of exporting activities is also indicated by other elements, for example the quality of operation of the financial and banking system, export-facilitating services, socio-economic infrastructure and the distribution channel, etc.

5.2.2. Criteria for economic sustainability

- The contribution of export to GDP growth is shown by the percentage of export on GDP growth or the percentage point of export on GDP growth.

- Index of debt over export. Actually, this index demonstrates the safety level in terms of financial capabilities of a country, i.e. the contribution of export to the foreign reserve and balance of payments. If the index of debt over export increases constantly during a long period, it means that both debt and deficit in the balance of payments have gone over the limit. Otherwise, if this index has a tendency to decrease, it means that the current debts are within limits and the country is able to pay her debts.

- The ratio of export growth to import growth also displays the macro-stability of the economy. If this ratio is greater than 1, it reflects the healthiness of the balance of trade thanks to export growth. This ratio also indicates the healthiness of the current account balance.

5.2.3. Criteria for environment sustainability

- The level of environmental pollution is calculated by the concentration of environment elements such as air, water, land and solid waste, etc, for example, the connection between export growth and level of environmental pollution or the level of environmental improvement. Sectors having great impacts on the environment include agriculture, textile, footwear, chemicals, steel, cement, etc.

- The level of maintaining renewable resources and the level of using non-renewable resources. For example, deterioration of biodiversity or improving it under the impact of export expansion, such as aquaculture export and narrowing mangrove forests, export growth in forestry products and narrowing primary forests, affecting the number of sacred plants and animals, etc.

- The proportion of businesses licensed with environment-friendly certificates. For example, the proportion of businesses licensed with International Organization for Standardization (ISO) 14000 certificate.

-The amount of contribution by export to environment protection expenses. In reality, it is unfeasible to separate the contribution by export to environment protection activities. However, we can see this contribution through export's contribution to economic growth.

- The ability of the administration to manage export activities, which can eliminate the negative impacts on the environment, as well as the awareness of the people to protect the environment. This criteria is reflected in policies aimed at boosting exports, at the same time protecting the environment.

5.2.4 Criteria for evaluating social sustainability

- The level of new jobs being created brought by export expansion. This can be seen through analyzing the relationship between export expansion and labor attraction, thus creating new jobs.

- The improvement level of people's income brought by export activities. Index of income, the rate of poverty can be used to evaluate social sustainability regarding export.

- The proportion of export businesses adopting measures to improve the working environment and conditions, for example the application of Social Accountability (SA) 8000.

- Social sustainability regarding export can be evaluated through analyzing mechanisms of sharing benefits from export, for example demonstrations, strikes by the workers, surveys on income inequality, etc.

- The sustainability of export can be accessed through policies in favor of export, for example export subsidies, export tax return, export insurance, etc.

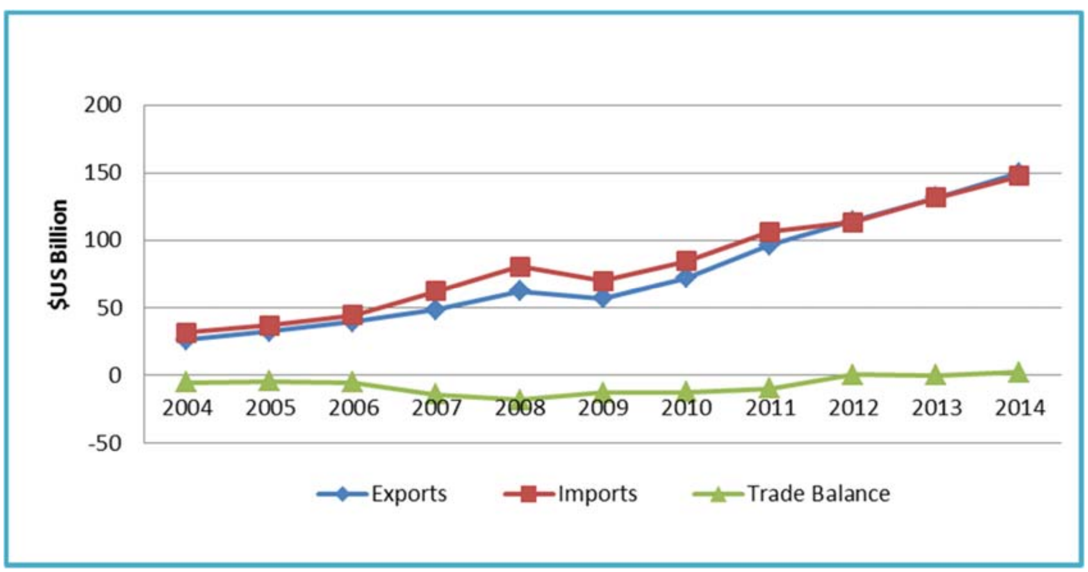
5.3. Accessing Vietnam's export activities in accordance with the criteria for sustainable development

5.3.1. The scale and export growth of Vietnam period 2004 – 2014

Export growth of Vietnam period 2004 - 2014

Accessing export turnover of Vietnam period 2004 – 2014: Export fluctuated more sharply than ever before. In 2008, export rose dramatically, at 29.1%. However, in 2009, under the impact of the global financial crisis, export declined at 8.9%, but in 2010, rose again at 26.5% and continued rising to 34.2% in 2011; rose at 18.2%; 15.3%; 13.7% in 2012, 2013, 2014 respectively (Table 2).

Figure 4: Imports-Exports value and Trade balance 2004-2014



Source: Author's calculations from General Department of Vietnam Customs data

Table 2: Import-Export value , GDP and Trade Balance

Year	Exports ($US Bill.)	Exports growth rate (%)	Imports ($US Bill.)	Imports growth rate (%)	Trade Balance ($US Bill.)	GDP growth rate (%)	Exports /GDP (%)

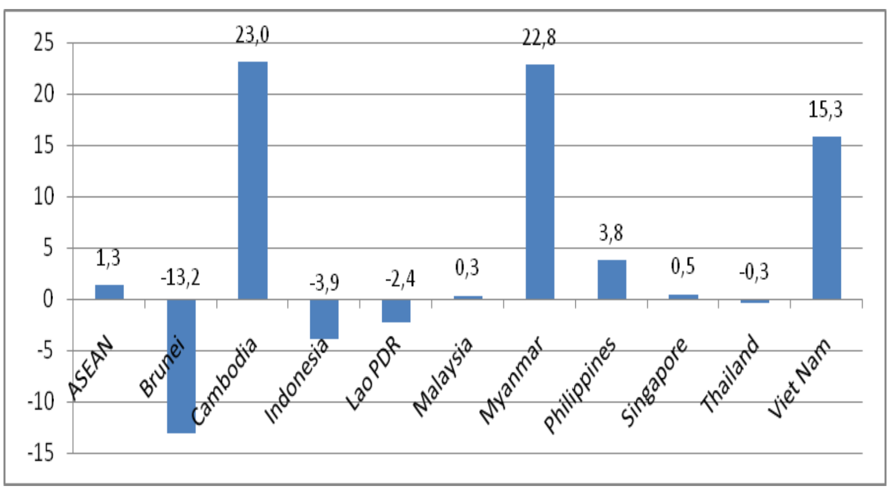
Năm 2014	150,19	13,7	148,05	12,1	2,14	5,42	80,2

Source: Calculated from GSO data of Vietnam.

According to the GSO and ASEAN Community in Figures (ACIF) SE 2014, commodity export turnover of Vietnam reached US$132 billion, 15.3% higher than 2012 (Figure 5). In comparison with other Association of ASEAN countries, Vietnam's exports in 2013 continued to maintain relatively stable growth rate and much higher than that of ASEAN as the whole.

Figure 5: Export Growth Rate of ASEAN Countries in 2013 (Percentage)



Source: GSO and ACIF SE 2014

In 2013, three exporting items valued over US$10 billion, making up 37.7% of total export value. The highest item was phones and parts with US$21.2 billion, followed by textile US$17.9 billion and computers, electronic goods and parts with US$10.6 billion. The exporting group which valued from US$5 billion to US$10 billion, accounted for 25.7% of total export value, including 5 items, i.e. footwear, crude oil, seafood, machinery, equipment and their components, wood and wooden products. Group which valued from US$1 billion to 5 billion comprised of 14 items, making up 22.0%. The rest under US$1 billion accounted for 14.6%. Most of the major exporting items of Vietnam in 2013 gained relatively high growth rate, in which phones and parts increased by 67.1% against 2012; computers, electronic goods and parts increased by 35.3%; textiles, footwear maintained high and stable growth of 18.8% and 15.6% respectively; seafood products rose by 10.2%. Particularly, coffee exports decreased by 26%; rice by 20.4%; rubber by 12.8%.

According to statistics from the Ministry of Industry and Trade; and Dr. Tran Du Lich, Member of the National Assembly's Economic Commission, in the 2011 - 2014 period, Vietnam's export growth rate is always three times higher than its GDP growth rate and higher than its import growth rate. Merchandise export growth was 19.4 percent a year on average. Export value jumped from US$96.9 billion in 2011 to estimated US$150,19 billion in 2014. Export structure was shifted in a positive direction, featured by a lower proportion of crude exports and a higher proportion of processed products and industrial products. Export scale was expanded, focusing on key exports. More exports brought in over US$1 billion a year for the country year after year. In 2014, Vietnam is expected to have 24 exports each generating over US$1 billion of income, accounting for 86 percent of total export items. Export markets are being expanded and have reached most markets around the world. Many products have established strong standings and competitiveness in demanding markets like the EU, Japan and the US.

Regarding the ratio of export commodities to GDP, it stood at 64.3% in 2008, after joining the WTO; at 77% in 2013; at 80,2% in 2014, which was much higher than the period prior to the Renewal Policy and integration process. Vietnam's ratio is quite high regionally and globally. It is hopeful that this ratio will be even higher when the TPP is concluded and Vietnam utilizes the export opportunities offered by TPP members.

At the end of December, 2014, the balance of trade by commodity enjoyed surplus at US$ 2.14 billion, therefore it is quite obvious that Vietnam will continue getting export surplus, or even the surplus of the balance of trade will double or triple those of 2012 and 2013. After two decades of constant deficit in the balance of trade, the spectacular reverse during the past three years has performed an export miracle for Vietnam with the annual growth rate at 14%, setting a record of US$ 150.19 billion.

Export markets of Vietnam

EU continued being the largest export market of Vietnam with export turnover at US$ 24.3 billion in 2013, accounting for 18.4% of the total export turnover and rising by 19.8% (approximately US$ 4 billion) compared to 2012. The major export commodities to EU included: variations of telephone and components valued at US$ 8.1 billion; sandals at US$ 2.9 billion; textile at US$ 2.7 billion; computers and components at US$ 2.2 billion. The U.S. got the second position with export turnover at US$ 23.8 billion, accounting for 18% and rising by 21.2% compared to 2012. The U.S. was also a major market for Vietnam's main export commodities, such as textile valued at US$ 8.6 billion, sandals at US$ 2.6 billion, timber and wooden products at US$ 2 billion. Vietnam' export to Japan in 2013 reached US$ 13.6 billion, accounting for 10.3%, up 4.3% against 2012. ASEAN was among the most significant trading partners of Vietnam and the motivator helping Vietnam maintain economic and export growth over the past years. In 2013, ASEAN – Vietnam two-way trade reached US$ 39.7 billion, increased by 3.9% compared to 2012 and taking up 15% of Vietnam's total import-export turnover. Currently, Vietnam ranked 5th in terms of import-export turnover with ASEAN, behind Singapore (US$ 206.7 billion), Malaysia (US$ 119.1 billion), Thailand (US$ 103.7 billion), Indonesia (94.7 billion).

5.3.2. The quality of export growth

The quality of export growth from the perspective of export structure shifting

Main export products include outsourced commodities and raw materials. Particularly in 2012, the proportion of export turnover for raw material was still large (Crude oil, coal, ores and minerals alone reached US$ 9.65 billion, accounting for 8.4%). Agricultural, forestry and aquaculture, unprocessed or preliminarily processed products still kept high proportion (valued at US$ 27 billion, accounting for 23.6%). Outsourced and assembled products also took the large share (the turnover of textile, sandals, textile fiber and materials, footwear, computers, electronic components and others was over US$ 33 billion, accounting for 29%). The above three categories of commodities had already took up more than 60% of national export turnover.

According to Deputy Minister Le Danh Vinh and economic experts, Vietnam's export structure over the past years had significantly changed, for example, the proportion of processed commodities increased while that of raw materials declined, export markets were diversified and both the private sectors and foreign direct investment enterprises took the bigger roles. Despite growth, export in Vietnam had not been sustainable. Export scale was still small and incommensurate with the potentials. Most of the export commodities were produced by foreign direct investment enterprises and mostly based on cheap labor and outsourcing, rather than commodities with high technology contents. Vietnam only made use of available comparative advantages to develop export and she had not fully utilized competitive advantages to produce commodities with high technology contents and added value. Export products were still low in value and had not been present in the manufacturing and circulation chains of regional and global Transnational Corporations. Moreover, the shifting of export structure in Vietnam lately had not clearly demonstrated the industrialization and modernization trend, evidenced by the proportion of raw, preliminarily processed commodities and products of low value was still large.

The added value of export

Although the growth rate of Vietnam's export is very high, the added value by export commodities is still modest compared to the total export turnover. The reason for low added value is the fact that export is mostly based on natural resources exploitation, cheap labor, low-technology manufacturing requiring intensive labor to produce mid-tech components. The export policies over the past years mainly focused on quantity targets and did not pay enough attention to export quality and efficiency.

Many of the export products, including those with large turnover, do not have their own brands, normally export of these products are made through another partner, therefore prices are often lower than other countries' products of the same type.

The competitiveness of export commodities

Lately, there has been improvement in the competitiveness of Vietnam's export products, but, basically, this competitiveness is still low compared to other countries in the region, particularly China and ASEAN members. Vietnam is highly competitive in sectors engaging natural resources and cheap labor. However, when compared to Thailand, China, Vietnam's competitiveness in labor-intensive sectors, such as textile, footwear, assembling, etc., is still low.

The possibility to join the global value chain

Vietnam has only joined segments that create the least value in the global value chain. These segments include outsourcing, assembling, providing raw input materials. If Vietnam's competitiveness is not improved adequately, her capacity to join segments creating high added value will be restricted, thus preventing constantly rapid export growth.

5.3.3. The contribution by export to macroeconomic growth and stability

Contribution to GDP growth

Export growth has contributed greatly to GDP growth, by creating more jobs, consuming farm produce and cutting inventory. This outcome confirms the gradual efficiency of the export guidelines over the past years, also reflects the ever-expanding export production ability. Furthermore, export growth has significantly helped with controlling import surplus. Trade surplus in 2014 was maintained at US$ 2 billion.

During the recent years, foreign direct investment enterprises have also contributed substantially to economic and export growth. In 2014, foreign direct investment sector keeps on with holding a high position in creating value and driving export growth. In 2014, the export turnover of foreign direct investment enterprises was estimated to be US$ 101.8 billion, up 15.4% against 2013, accounting for 67.9% of the national export turnover.

Ensuring macroeconomic stability

Besides strengthening the balance of payments, export increases the foreign reserve. The currents debts of Vietnam are still within the safety limits. The ratio of debts to GDP is about 40% and the ratio of debts to export is on the decrease and lower than the alarming rate. However, export still poses potential risks to the economy's stability. Firstly, the structure of export commodities is holding risks to the national budget revenue and export development in the context of free trade. Secondly, the high protectionist trade policy for capital intensive sectors but employing just a few people and towards replacing importation, thus distorting investment and bringing about unsustainable GDP growth, as well as burdening the country with foreign debts in the upcoming context of free trade. Thirdly, given the current high level of openness, the national economy heavily depends on the global economy. Hence, if reforms and improvement of competitiveness do not accelerate, fluctuations on the global market will surely radically affect macroeconomic stability and social safety. Fourth, safety for the laborers in the export-oriented sectors is not high, therefore, it is very likely that the laborers will lose their jobs and receive less payment when there are sharp market fluctuations.

5.3.4. Export and environment issues

Export in connection with the maintenance and improvement of resources and biodiversity

The considerable economic benefits brought by agricultural, aquaculture commodities stimulates the producers to preserve and further develop them. Science-based farming techniques restricting chemical fertilizers while promoting organic ones and crop rotation have positive effects in enriching soil fertility, etc. The development of plants' varieties with high economic value by utilizing traditional sacred genes, such as lychees, bananas, forest specialities, has helped maintain and further develop resources and biodiversity, thus ensuring ecological balance.

However, export activities of the country over the recent years have disturbed biodiversity, most notably the promotion of agricultural and aquaculture exports based on width has narrowed the forests, affecting terrestrial and coastline ecological balance due to expansion of cultivated area. Fry and many aquatic species are disappearing due to destructive fishing methods by dynamite and small meshes. Natural forests of our country are being narrowed by the expansion of farmland for growing high export value plants, such as rubber, coffee and cashew nuts. Illegal timber harvesting is also leading to narrowing the primary forests. Wildlife trafficking is the main reason for biodiversity decline, only behind forest fires and deforestation. Therefore, if Vietnam's export continues to be grounded into the width-oriented model on the basis of mobilizing the available comparative advantages, it will be challenging for Vietnam's export growth to remain high. Besides, increasing competitiveness worldwide under the impact of the global economic recession is putting pressure on Vietnam to rapidly shift to a new model of growth.

Export in connection with environmental pollution and improvement

Export-oriented economic development has created favorable conditions for Vietnam to garner high technologies causing low or zero pollution and saving materials. Applying innovative, clean technologies, environment-friendly production methods and outstanding breeds and seeds has facilitated crop yields and livestock, thus decreasing the expansion of farm land and positively affects biodiversity preservation.

However, national export still holds potential risks of environmental pollution. Improper and excessive usage of fertilizers, crop protection chemicals aiming at producing good crop yields and livestock, is among the factors causing environmental pollution, especially facilities for agricultural, aquaculture products, textile, footwear, craft, wooden furniture, etc. Exploiting minerals for export, particularly coal and other minerals by artisanal mining, causing soil, water and air pollution and declining biodiversity.

Capacity to meet environment requirements and standards

Many businesses have applied new production methods, renovated technologies, saved input materials, changed fishing and farming methods in order to better utilize resources and biodiversity, such as aquaculture, agricultural and forestry products. By doing so, it has enhanced the competitiveness of Vietnam's products and restricting environmental pollution within the country.

However, it is still challenging for the businesses to meet environment requirements for export commodities. Due to limited awareness, obsolete processing technologies, lack of information about importing countries' regulations, it is common that Vietnamese exporters do not comply with environment and hygiene requirements by the importers.

Therefore, the new model of growth should be based on in-depth development, making use of mobile competitive advantages to boost export productivity, quality and efficiency, by means of institutional reform, innovative technology application, human resource improvement, modern infrastructure development. Shifting from export development based on width to depth, from relying mostly on available comparative advantages to mobile competitive ones is the decisive factor for the quality of export growth, maintaining high growth, improving economic efficiency, enhancing the competiveness of export commodities, in tandem with the dramatic market changes, thus minimizing risks by adverse global fluctuations.

5.3.5. Export in connection with social issues

Export in connection with jobs and income

Export has helped stimulate GDP growth, thus increasing per capita income. Per capita export turnover of our country rose from US$ 31 billion by 1991 to US$ 1,290 and US$ 1,435 by 2012 and 2013 respectively, and increased greatly compared to US$ 830.5 by 2010. Export expansion of intensive-labor sectors, such as footwear, textile, craft, aquaculture and agricultural products, wooden furniture, has created a great number of jobs and increased income for part of the low-income population, especially those working in agriculture. However, Vietnam's export is still based on width, thus the skills of the laborers are still modest and their incomes are unstable.

Export in connection with social equality

First of all, trade liberalization has deepened the gap between the rich and the poor and increasing inequality among regions and people of different social strata. Various trade opportunities lead to various incomes. Above all, unsuitable trade policies also bring about unequal distribution of economic benefits among people of different social strata. The low-income population and those working in agriculture are disadvantaged in sharing added value brought by integration and free trade.

Export in connection with labor quality and skills

Export development by transferring and creating new technologies and advanced management methods has contributed to training managers and business persons. The integration process has also been instrumental in strengthening human resources in all aspects of modern life. However, as export quality is slow in getting improved and export growth is mostly driven by cheap labor, therefore, it takes quite some time to fully strengthen export growth. This will affect the shifting among sectors to shield against sharp market fluctuations.

6. Policy Recommendations to sustainable export in Vietnam

6.1. Improving the quality of export growth

Enhancing business climate, creating a fair and healthy business climate for all the enterprises

First of all, it is necessary to improve the legal system to enhance the business climate in Vietnam in the direction of ensuring the legal basis and equal business conditions, applying “common rules” of the domestic and international market. In order to do this, timely and flexible policy response is required so that protective measures, incentives to domestic manufacturing can be applied if necessary, in accordance with commitments to opening the markets and international economy integration as stipulated in regional free trade agreements and international agreements Vietnam has signed (WTO, FTAs, AFTA, RTAs, ...) as well as agreements Vietnam are currently negotiating, namely TPP, RCEP.

Next, it is necessary to formulate a policy on competitiveness in order to foster and promote fair and healthy competition, thus contributing to the overall business climate and maintaining sustainable economic growth. This policy should avoid discrimination among economic sectors and types of businesses (State-owned, private or foreign) and the disguise of inappropriate subsidy, monopoly, which are major barriers to national development. A sound policy of competitiveness will also help increase social productivity and bring significant economic reforms.

Building a strategy for enhancing the competitiveness for Vietnamese export products

The competitiveness enhancement of the export products is mainly based on increasing the high technology contents, quality of the labor in order to raise the added-value of export products, heading towards ingenious and high value-added orders. Given the reality of Vietnam at the moment, we cannot immediately join fully the Research and Development and the Design, but we can absolutely be part of the two following segments, namely Branding and Distribution. Therefore, the strategy for competitiveness enhancement of Vietnamese export should focus on these segments.

Along with enhancing the competitiveness of export products, at each of a specific period, the Government should approve and enforce the Program specifying key export products of each of the sector. The businesses are also oriented by the Government towards developing strategies for doing business, export products for both short and long term, concurrently, making wise choice of “strategic product lines”, thus having focal investment and diminishing risks. Besides, it is required to continue diversifying the export structure and the comparative advantages of Vietnam towards: firstly, developing new major exported products; secondly, shifting towards products with high added value and high technology contents.

Shifting the structure of comparative advantages and export products

Moving towards terminating exporting products in the form of raw material, preliminarily processed products, gradually increasing exporting processed ones; rapidly moving away from outsourcing light-industry products and crafting, instead enhancing exporting hi-tech products, thus increasing export values and achieving sustainable export.

In order to raise the value of export, the solution is to refrain from increasing exporting raw material or preliminarily processed products which has low added-value (moreover, currently the export volume of raw material is already high while resources are depleted). Instead, the solution is to shift the comparative advantages structure towards exporting processed products, cutting-edge products with high added value. Moreover, guidelines are needed to foster rapid advancing from outsourcing and assembling towards higher segments in the global value-added chain.

The focal measures include:

- Developing high-quality human resources and boosting Research and Development (R&D), advancing Design and Manufacturing with a view to rapidly shifting the export growth model from primarily relying on available advantages of resources, abundant and cheap labor, towards getting mobile advantages of skilled labor, science and technology.

Besides developing skilled labor, attracting R&D, Design and Manufacturing activities by Transnational Corporation (TNC) is considered as top priority. This is a shortcut to develop R&D in Vietnam. In order to achieve this, Vietnam should improve technology development and transfer policy in the direction that encouraging R&D activates right in Vietnam by TNCs and enhancing protection of intellectual property, industrial patents on science and technology and industrial products. Protection of intellectual property has always been the concern of TNCs upon their investment in a particular country. If TNCs' intellectual property is well protected in Vietnam, they will not hesitate to invest capital and transfer technology to partner businesses in Vietnam. This will offer an opportunity for Vietnamese businesses to approach new technology and know-hows, getting more investment in R&D, thus enabling them to join more important segments of the global value chains created by TNCs.

- Creating a business climate conducive to attracting foreign direct investment, thus increasing investment capital, transferring innovative technologies and management skills by TNCs.

First of all, the Government should adopt policies encouraging all economic sectors to invest in export. The investment by the State Budget should prioritize creating infrastructure, training human resources, R&D and promoting trade and investment.

Besides the maximum mobilizing of all the internal resources for export development, it is necessary to create favorable business climate, carry out administration reforms, aiming at attracting foreign direct investment to increase the overall investment capital. Particularly, the focus is on stimulating investment from foreign businesses who are already operating in Vietnam, especially Multinational Corporation (MNC)/TNCs and their transfer of innovative technologies and management skills in high technology, intellectual work, thus adding value to export.

- Upgrading the infrastructure and further developing industrial zones and clusters, calling for the investment from the private sector, including from foreign companies, in commensurate with the potentials and the demands of such a dynamic region, thus developing the overall infrastructure in general and the industrial zone's infrastructure in particularly, heading for export-designated industrial zones, clusters.

- Fostering the development of supporting industry, attracting foreign investment and encouraging businesses of all sectors to join in developing supporting industry, thus increasing the proportion of localization in export products.

The Government should create a stable climate for FDI businesses and adopt specific, long-term policies and mechanisms facilitating supporting industry, thus providing components and accessories for export. In reality, the localization of components and accessories should begin with attracting foreign direct investment from international providers, after that, gradually improving the capacity of domestic providers. At the initial stage of industrialization process of Vietnam, foreign direct investment businesses play the leading role and make up the majority in the supporting industry.

In addition to attracting foreign investment in supporting industry, the Government should implement policies encouraging businesses of all economic sectors to join in the development of supporting industry, particularly small and medium ones, also consolidating the linkages and the bonds among state-owned businesses with the private and the foreign ones.

- Making choice of active participation into the global value chain, selecting a specific field, focusing on products of strength, thus generating high competitiveness, moving towards becoming an important part in the global value chain regarding major exported products.

The businesses should be oriented by the Government to develop domestic chains of export products in the direction that taking shortcut is possible, not necessarily taking step by step of the value-added chain, thus setting a precedent for participating the global chain. On that note, businesses should be proactive in joining the above chains, wisely selecting prioritized segments to make good use of the comparative advantages, enhancing management and leadership capacity of the chains.

Seeking for niche markets and enhancing trade promotion activities, expanding export markets

Capture niche markets. In order to expand export markets, besides capturing and maintaining traditional markets by raising the quality of products and offering competitive prices, it is crucial to seek for niche markets ands offer suitable export products that can meet the demands of these markets.

Strengthening trade promotion. Information collection and dissemination as well as forecasting tasks should be strongly promoted to direct manufacturing and export activities. Research on establishing a Trade Promotion Fund should be carried out with the participation of businesses. This Fund will support businesses in trade fairs, exhibitions and expos, etc. Major export promotion programs should also be effectively conducted. The role of diplomatic, trade representative agencies overseas needs to be consolidated. The Government should encourage and facilitate businesses to open branches, representative offices or trade centers overseas, so that businesses are able to capture the demands, tastes of the market, as well as promote products, brands and sign contracts for product consumption.

6.2.Harmonize export growth with environment protection

- Raising the awareness of competent agencies and businesses of environment protection: The measures include launching training programs about environment protection and sustainable development and enhancing information dissemination.

- Integrating environment protection right into the process of strategy developing and investment project planning: Resolutely refusing to put facilities below environment protection standards into operation. Firstly, adjusting export development strategy under consideration of environment issues. There should be a scientific analysis of the interaction between targeted export growth and the environment impacts by export growth.

- Assisting businesses with the application of environment-friendly manufacturing processes and technologies: Stimulating the development of science and technology, especially environment-friendly ones. There should be incentives for importing innovative, green machinery and technologies, particularly pollution tackling and treatment ones. Researches on environment-friendly manufacturing processes and application at businesses are strongly encouraged, such as safe vegetable, meat, aquaculture, etc production processes. The businesses are also supported to get environment certificates for export products for example inspection centers, technology consultation and assistance centers. They are also financially supported when it comes to getting environment certificates through environment or export supporting funds. Moreover, businesses are also supported with information, technologies, for example developing environment-friendly business strategies; increasing the availability of input materials; strengthening the cooperative ties between small and medium enterprises with other businesses which are experienced in applying environment standards and regulations; assisting businesses in applying advanced environment management models, namely ISO 9000,ISO 14000, Hazard Analysis & Critical Control Points (HACCP), etc.

- Building national standards in commensurate with international ones:

+ Disseminating international environment regulations and standards to the managers and businesses, for example, the ones relating to WTO: Technical Barriers to Trade (TBT), Sanitary and Phytosanitray (SPS), Trade-Related Aspects of Intellectual Property Rights (TRIPS), ASEAN; multilateral environment agreements concerning trade: Biological Diversity (CBD), Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), Basel Convention, etc.; environment regulations and standards of other countries and of markets, such as the US, EU, Japan, etc. The purpose is to make businesses realize the importance of such regulations and standards when they export their products.

+ Building national standards: The building of national standards is very crucial in encouraging businesses to operate accordingly to domestic environment requirements as well as enhancing their competitiveness, reputation when integrating internationally.

- Improving policies and guidelines regarding the environment and export: Constant researches and specifically adding the List of commodities restricted or banned from export or commodities presenting hazards to the environment are required. There should also be constant modifying and adding categories of tax or export tariffs to stimulate export, concurrently, eliminating over-exploitation of natural resources.

- Applying rules and regulations, economic tools in environment management, enhancing examination and inspection: It is necessary to establish criteria for sustainable development under consideration of environment protection. It is also required to improve and establish national environment standards, or even standards for a particular sector, in line with international standards. Environment management is heightened, violations against environment protection are strictly and promptly dealt with. Information dissemination mechanisms on environment issues to export-related bodies and agencies are greatly enhanced, including managers, manufacturers, exporters and local communities.

- Encouraging the participation by the community into environment protection, promoting international cooperation in environment protection, i.e. making environment protection a communal task. There are supporting policies and incentives for communities at regions with high biodiversity in order to help them utilize, at the same time, preserve and further develop these regions. It is also important to make good use of international technical assistance in building and applying environment-friendly manufacturing models.

- There should be supporting polices as well as special inspection and control over sectors that have direct impacts on the environment, for example agriculture, aquaculture raising and exports, forestry products or minerals, etc.

6.3. Harmonizing growing export and solving social issues

- Creating mechanisms of equally sharing benefits in trade. Above all is the benefit sharing mechanism in using natural resources.

- Creating widespread social welfares to cope with inequalities in income, unemployment, bankruptcy, trade risks.

- Extending support to labor-intensive sectors, such as aquaculture, agricultural products, textile, footwear, craft, wooden furniture, in case when there are sharp fluctuations adversely affecting export, thus making farmers and laborers loose their livelihood and work.

- Applying measures that help with improving the working environment for the workers, also meeting the requirements of importers, particularly in textile, footwear (the application of SA 8000 standards).

- The Government, along with competent bodies and agencies, should further strengthen market forecast, thus minimizing adverse impacts on the producers.

7. Conclusion

Vietnam is getting more and more fully integrated into the region and the world. Moreover, global competition is becoming more intense. This context requires Vietnam to urgently adopt a new model of growth. The structure shifting of comparative advantages and export aiming at advancing the competitiveness of manufacturing and export sectors in general, national major export commodities in particular, has become an urgent requirement for Vietnam on her pathway of new growth towards 2020. For Vietnam, this requirement could be satisfied by working out a strategy for strengthening the competitiveness of export commodities, further diversifying and shifting structures of export and comparative advantages on the basis of gradually reducing the export proportion of raw and preliminarily processed commodities and natural resources while increasing that of processed and hi-tech products, prioritizing utilizing competitive advantages based on: Adopting policies facilitating innovating technologies; Strengthening human resources; Stimulating foreign investment, thus promoting R&D, Design and Manufacturing; Upgrading infrastructure at industrial zones and clusters as well as developing supporting industry; moving to higher segments of the global production chain.

The main purposes of this paper are: i) to review finance literature used in simultaneous equations method, ii) to show that both two-stage least squares (2SLS) and three-stage least squares (3SLS) are special cases of generalized method of moments (GMM) estimator in estimating simultaneous equations and iii) to investigate the interrelationship among investment, financing, and dividend decisions. We review studies that apply the simultaneous equation estimation on capital structure, corporate investment, payout decisions, ownership structure, corporate governance, stock return, firm performance and/or other corporate issues. Detailed descriptions about the concept of 2SLS, 3SLS, and GMM estimation are introduced. We also investigate the interrelationship among investment, financing and dividend decisions using 2SLS, 3SLS, and GMM methods based on the U.S. listed firm annual data between 1965 and 2012. Our results are consistent with Lambrecht and Myers's (2012) theory that dividend and investment decisions are jointly determined. In addition, these three corporate decisions are co-determined and the interaction among them should be taken into account in a simultaneous equation framework.

Keywords 2SLS • 3SLS • GMM • Investment decision • Financing decision •Dividend decision

1 Introduction

Simultaneous equations models have been widely adopted to mitigate econometric problem in finance literature. It is suggested that the relation, particularly the interaction, among corporate decisions, firm characteristics, and firm performance should be contemporaneously determined. For example, Anderson and Reeb (2003) investigate the relation between founding-family ownership and firm performance by considering the reversed causality issue. Gong et al. (2008) decipher the cause-consequence relationship between repurchase and earnings management activities in system equations. Harford et al. (2014) consider the interdependence of a firm's cash holdings and the maturity of its debt. Therefore, to understand the application of simultaneous equations models, we survey the methodologies and review papers that use these methods. We also illustrate how to implement the estimation of simultaneous equations with a test on corporate investment, leverage, and payout.

The utilization of ordinary least squares (OLS) estimation on simultaneous equations yields biased and inconsistent estimates since the assumption of uncorrelation between the regressors and the disturbance terms is violated in empirical data. The instrumental variable (IV) methods are commonly used to deal with this endogeneity problem, and both two-stage least squares (2SLS) and three-stage least squares (3SLS) estimations belong to IV class estimators.[1] The generalized method of moments (GMM) estimator proposed by Hansen (1982) further generalizes Sargan's (1958, 1959) linear and nonlinear IV estimators based on optimal weighting matrix for the moment conditions. In contrast to traditional IV class estimators, the GMM estimator uses a weighting matrix taking account of temporal

---

[1] Wang (2015) reviews instrumental variables approach to correct for endogeneity in finance.

dependence, heteroskedasticity or autocorrelation. In this paper, we give a detailed description about the concept of GMM estimation and also show that both 2SLS and 3SLS estimators are special cases of GMM estimator in estimating a simultaneous equations model.

The applications of simultaneous equations models in finance research are abundant. Some papers study the interrelationship among a firm's capital structure, investment, and payout policy (e.g., Grabowski and Mueller 1972; Higgins 1972; McCabe 1979; Petersen and Benesh 1983; Switzer 1984; Gugler 2003; MacKay and Phillips 2005; Chava and Roberts 2008; Aggarwal and Kyaw 2010; Harford et al. 2014), given the fact that these decisions are simultaneously determined. For example, an increase in debt financing may enhance the funds available to outlays for investment; meanwhile the increase in investment may change the supply-side debt capacity. Firms may adjust their major policies by taking into account the interdependencies among them. In addition, the interrelationship between board composition (or ownership) and firm performance is often investigated in simultaneous equations (e.g. Loderer and Martin 1997; Bhagat and Black 2002; Demsetz and Villalonga 2001; Prevost et al. 2002; Anderson and Reeb 2003). On one hand, insider (manager or director) holdings affect the insider's incentive to work and accordingly positively influence firm performance upon the agency theory; however, firm performance, which is usually proxied by Tobin's Q, also affects whether or not the insider is willing to sell their shares, leading to changes in the ownership structure. In addition to the above-mentioned studies, many other issues of research also apply the simultaneous equations model in their papers because firm decisions, characteristics, and performance may be jointly determined.[2]

[2] For example, capital structure and firm performance (Berger and Bonaccorsi di Patti 2006), financial

In an attempt to illustrate the application of simultaneous equations models, we also examine the interrelationship among a firm's investment, financing and dividend decisions using the 2SLS, 3SLS, and GMM estimations. We collect U.S. listed dividend-paying firms from 1965 to 2012.[3] Our results are consistent with Lambrecht and Myers's (2012) theory that dividend and investment decisions are jointly determined. Moreover, we find that firms with higher investment changes have higher debt financing changes and vice versa. The impact of changes of dividend on changes of debt financing is significantly negative, showing that firms need less debt financing when they are capable of paying more dividend. This finding is consistent with the economic intuition that the firms with a higher dividend payout usually have greater earnings (e.g., Lintner 1956; Skinner 2008) and thus have less incentive to issue debt financing. In addition, the increases in debt financing seem to enhance the funds available to outlays for dividend payout, implying that there is a wealth transfer effect between bondholders and shareholders.

Our research offers two contributions to the literature. First, this paper reviews applications of simultaneous equations models in the financial research and their econometric estimation methods. The endogeneity problem in empirical studies is extensively noted and the appropriate estimation methods should be adopted. Second, we employ 2SLS, 3SLS, and GMM estimations in examining the interrelationship among a firm's investment, dividend payout and debt financing policies. We find these major decisions of firms correlate to each other and should be considered simultaneously.

---

policies and ownership (Jensen et al. 1992; Setia-Atmaja et al. 2009), agency problem and firm performance (Agrawal and Knoeber 1996), corporate governance and liquidity (Chen et al. 2007), repurchase and firm performance (Gong et al. 2008), governance in banking industry (Aggarwal and Jacques 2001; Chen et al. 2006), and capital asset pricing models (Simkowitz and Logue 1973; Lee 1976) are the issues of research applying simultaneous equations model in the papers.

[3] Smirlock and Marshall (1983) and Fama and French (2002) also only consider the firms paying dividend.

The paper proceeds as follows. Section 2 presents the literature reviews about the application of simultaneous equations models in finance research. Section 3 discusses the econometric methodologies applied in estimating simultaneous equations model. Section 4 illustrates the application of simultaneous equations to investigate the interaction among investment, financing and dividend decisions. Conclusions are presented in Section 5.

2 Literature review

Simultaneous equations models are intensively applied in studies considering the interrelationship among a firm's major policies. Higgins (1972), Fama (1974), and Morgan and Saint-Pierre (1978) investigate the relationship between investment decision and dividend decision. Grabowski and Mueller (1972) examine the interrelationship among investment, dividend and research and development (R&D). Fama and French (2002) consider the interaction between dividend and financing decisions. Dhrymes and Kurz (1967), McDonald et al. (1975), McCabe (1979), Peterson and Benesh (1983), and Switzer (1984) argue that the investment decision is related to financing decision and dividend decision. Chava and Roberts (2008) show how financing impacts corporate investment via debt covenants. Harford et al. (2014) consider the interdependence of a firm's cash holdings and the maturity of its debt by using a simultaneous equation framework and performing a 2SLS estimation.

The interrelationship between board composition (or ownership) and firm performance is often investigated in simultaneous equations. Agrawal and Knoeber (1996) use seven mechanisms to control agency problems between managers and shareholders.[4] By using 2SLS procedure, Agrawal and Knoeber (1996) find the

[4] These control mechanisms include insider shareholdings, institutional shareholdings, blockholders'

interdependence among these mechanisms and suggest the regression on any single mechanism for firm performance is misleading. Loderer and Martin (1997) examine the executive ownership and firm performance, and find that better performance leads to larger stockholdings of a manager, but not vice versa. Demsetz and Villalonga (2001) suggest that the ownership structure should be modeled as an endogenous variable and should be considered separately for the fractions of shares owned by outside shareholders and management. They run 2SLS regression to mitigate the endogeneity and find no statistically significant relation between ownership structure and firm performance. Anderson and Reeb (2003) also apply 2SLS on the relation between founding-family ownership and firm performance; however, they find family firms perform better than nonfamily firms. In addition to 2SLS, a 3SLS approach is also adopted in this issue. Prevost et al. (2002) set up a simultaneous equations model to control potential endogeneity between board composition and firm performance by using a 3SLS system approach methodology. They find evidence that board composition and firm performance jointly determine and influence each other in a positive manner for the sample of New Zealand firms. Bhagat and Black (2002) also use a 3SLS approach to investigate the similar issue for large American firms. However, they find that low-profitability firms increase the independence of their boards of directors, and firms with more independent boards do not perform better than other firms.

The simultaneous equations model is also used to examine the interaction between financial policies and firm ownership. Jensen et al. (1992) examine the determinants of insider ownership, debt, and dividend policies within a system of equations and apply 3SLS estimation. They find that high insider ownership firms

---

shareholdings, use of outsiders on the board of directors, debt financing, the labor market, and the market for corporate control.

choose lower levels of both debt and dividends. By using Austrian data, Gugler (2003) investigates the interrelation among dividends, R&D, and capital investment, and compare the dividend payout policy of different ownership and control structure of firms. He finds the evidence that the investment, R&D , and dividends are jointly determined and thereby estimate the simultaneous equations system by 3SLS. By comparing family-controlled firms, Gugler (2003) finds that state-controlled firms smooth dividends, have large payout ratios, and are most reluctant to cut dividends. Setia-Atmaja et al. (2009) examine the interrelationship among dividends, debt, and boards of directors of family controlled firms in the Australian capital market. By using 3SLS for a system of four equations they show that family controlled firms employ higher dividend payout ratios, higher debt levels, and lower levels of board independence than non-family firms.

The simultaneous equations model is applied in the capital structure literature. Berger and Bonaccorsi di Patti (2006) ague that an agency costs hypothesis predicts that leverage affects firm performance, yet firm performance also affects the choice of capital structure. To address this problem of reverse causality between firm performance and capital structure, they use 2SLS to estimate the simultaneous equations model. They also estimate by 3SLS and do not change the main findings that higher leverage is associated with higher profit efficiency. Aggarwal and Kyaw (2010) examine the impact of multinationality on capital structure and dividend policy using a simultaneous equations model. By recognizing the interdependence between capital structure and dividend payout policy and using 2SLS, they find that compared to domestic companies, multinational companies have significantly lower debt ratios and pay higher dividends. MacKay and Phillips (2005) estimate a system of simultaneous equations using GMM and find that financial structure, technology, and risk are jointly determined within industries.

In addition to the above-mentioned papers, simultaneous equations model is also applied in other issues of finance studies. Simkowitz and Logue (1973) propose a simultaneous equation capital asset pricing model (CAPM) to offer a robust test for the interdependent assumption of the Sharp model. But the effect of multicollinearity in their 2SLS estimation was challenged by Lee (1976). Instead of 2SLS, Lee (1976) shows that the modified 2SLS is more appropriate in estimation of Simkowitz and Logue's (1973) model. Aggarwal and Jacques (2001) estimate a 3SLS model to examine the simultaneous impact of prompt corrective action (PCA) on both bank capital and credit risk. They show that PCA has a significant impact both in terms of raising capital ratios and reducing credit risk for banks. Chen et al. (2006) employ a two-equation model and estimate by 2SLS to examine the relationship between executives' incentive compensation and firm risk for the banking industry. Gong et al. (2008) investigate the earnings management problem of share repurchase. They consider the possible interaction between post-repurchase abnormal accruals and the percentage of share outstanding repurchased using 3SLS. Chen et al. (2007) adopt simultaneous equations system using both 3SLS and GMM to control the possible simultaneity in the determination of a bid-ask spread and a firm's disclosure policy. They find that firms with poor information transparency and disclosure practices tend to have higher cost of equity liquidity.

3 GMM Methodology

Suppose that a set of observations on a variable y is drawn independently from probability distribution depends on an unknown vector of parameters $\boldsymbol{\beta}$ of interest. One general approach for estimating parameters $\boldsymbol{\beta}$ is based on maximum likelihood

(ML) estimation. The intuition behind ML estimation is to specify a probability distribution for it, and then find an estimate $\hat{\boldsymbol{\beta}}$ in which the data would be most likely to have been observed. The drawback with maximum likelihood methods is that we have to specify a full probability distribution for the data. Here, we introduce an alternative approach for parameter estimation known as generalized method of moments (GMM). The GMM estimation was formalized by Hansen (1982), and has since become one of the most widely used methods of estimation in economics and finance. Hansen won his Nobel Prize in 2013 in economics for deriving the GMM estimation. In contrast to ML estimation, the GMM estimation only requires the specification of certain moment conditions rather than the form of likelihood function.

The idea behind GMM estimation is to choose a parameter estimate so as to make the sample moment conditions as close as possible to the population moment of zero according to the measure of Euclidean distance. The GMM estimation proposed a weighting matrix reflecting the importance given to matching each of the moments. Alternative weighting matrix is associated with alternative estimator. Many standard estimators, including ordinary least squares (OLS), method of moments (MM), ML, instrumental variable (IV), two-stage least squares (2SLS), and three-stage least squares (3SLS) can be seen as special cases of GMM estimators. For example, when the number of moment conditions and unknown parameters are the same, solving the quadratic criterion yields the GMM estimator, which is the same as the method of moment (MM) estimator that sets the sample moment condition exactly equal to zero. The weighting matrix does not matter in this case. In particular, in models for which there are more moment conditions than model parameters, GMM estimation provides a straightforward way to test the specification of the proposed model. This is an important feature that is unique to GMM estimation.

Recently, the endogeneity concern has received much attention in empirical corporate finance research. There are at least three generally recognized sources of endogeneity: omitted explanatory variables, simultaneity bias, and errors in variables. Whenever there is endogeneity, the application of ordinary least squares (OLS) estimation yields biased and inconsistent estimates. In literature, the instrumental variable (IV) methods are commonly used to deal with this endogeneity problem. The basic motivation for the instrumental variable method was to deal with equations that exhibited both simultaneity and measurement errors in exogenous variables. The idea behind IV estimation is to select suitable instruments that are orthogonal to the disturbance while sufficiently correlated with the regressors. The IV estimator makes the linear combinations of sample orthogonality conditions close to zeros. Sargan (1958, 1959) established a fully developed theory of IV estimation. The GMM estimator proposed by Hansen (1982) is also based on orthogonality conditions and provides an alternative solution. Hansen's (1982) GMM estimator generalized Sargan's (1958, 1959) linear and nonlinear IV estimators based on optimal weighting matrix for the moment conditions. In contrast to traditional IV class estimators such as 2SLS and 3SLS estimators, the GMM estimator uses a weighting matrix takes into account temporal dependence, heteroskedasticity or autocorrelation.

3.1 Application of GMM estimation in the linear regression model

Consider the following linear regression model:

$$y_t = \mathbf{x}_t\boldsymbol{\beta} + \varepsilon_t, \quad t = 1, \ldots, T \tag{1}$$

where y is the endogenous variable, $\mathbf{x}_t$ is a $1 \times K$ regressor vector which includes constant term, and ε_t is the error term. Here, $\boldsymbol{\beta}$ denotes a $K \times 1$ parameter vector of interest. The critical assumption made for the OLS estimation is that the disturbance ε_t is uncorrelated with the regressors $\mathbf{x}_t$, $E(\mathbf{x}_t'\varepsilon_t) = \mathbf{0}$. The T observations in model (1) can be written in matrix form as

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon} \tag{2}$$

here $\mathbf{Y}$ denotes the $T \times 1$ data vector for the endogenous variable and $\mathbf{X}$ is a $T \times K$ data matrix for all regressors. In this matrix notation, we have the OLS estimator for $\boldsymbol{\beta}$ as follows:

$$\boldsymbol{\beta}_{\mathrm{OLS}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Y} \tag{3}$$

If the disturbance term is correlated with at least some components of regressors, we say that the regressors are endogenous. Whenever there is endogeneity, the application of ordinary least squares (OLS) estimation to equation (2) yields biased and inconsistent estimates. The instrumental variable (IV) methods are commonly used to deal with this endogeneity problem. In a typical IV application, the researcher first chooses a set of variables as instruments that are exogenous and applies 2SLS method to estimate the parameter $\boldsymbol{\beta}$. A good instrument should be highly correlated with the endogenous regressors while uncorrelated with the disturbance in the structural equation. The IV estimator for $\boldsymbol{\beta}$ can be regarded as the solution to the following moment conditions of the form

$$E[\mathbf{z}_t'\varepsilon_t] = E[\mathbf{z}_t'(y_t - \mathbf{x}_t'\boldsymbol{\beta})] = \mathbf{0} \tag{4}$$

where $\mathbf{z}_t$ is a $1 \times L$ vector of instrumental variables which are uncorrelated with a disturbance, but correlated with $\mathbf{x}_t$, and the sample moment conditions are

$$\frac{1}{T}\sum_{t=1}^{T}\mathbf{z}_t'(y_t - \mathbf{x}_t\boldsymbol{\beta}) = \mathbf{0} \tag{5}$$

Assume $\mathbf{Z}$ denotes a $T \times L$ instruments matrix. If the system is just identified

($L = K$) and $\mathbf{Z'X}$ is invertible, the system of sample moment conditions in (5) has a unique solution. We have an IV estimator $\boldsymbol{\beta}_{IV}$ as follows:

$$\boldsymbol{\beta}_{\mathrm{IV}} = (\mathbf{Z'X})^{-1}\mathbf{Z'Y} \tag{6}$$

Suppose that the number of instruments exceeds the number of explanatory variables ($L > K$). The system in (5) is over-identified. Then the question arises how to select or combine more than enough moment conditions to get K equations. Here, the 2SLS estimator, which is the most efficient IV estimator out of all possible linear combinations of the valid instruments under homoscedasticity, is employed in this case. The first stage of the 2SLS estimator is regressing each endogenous regressor on all instruments to get its OLS prediction, expressed in matrix notation as $\mathbf{X} = \mathbf{Z}(\mathbf{Z'Z})^{-1}\mathbf{Z'X}$. The second stage is regressing dependent variable on $\mathbf{X}$ to obtain the 2SLS estimator for $\boldsymbol{\beta}$, $\boldsymbol{\beta}_{2\mathrm{SLS}} = (\mathbf{X'X})^{-1}\mathbf{X'Y}$. Substitute $\mathbf{Z}(\mathbf{Z'Z})^{-1}\mathbf{Z'X}$ for $\mathbf{X}$, the 2SLS estimator $\boldsymbol{\beta}_{2\mathrm{SLS}}$ can be written as

$$\boldsymbol{\beta}_{2\mathrm{SLS}} = \left[(\mathbf{X'Z})(\mathbf{Z'Z})^{-1}\mathbf{Z'X}\right]^{-1}(\mathbf{X'Z})(\mathbf{Z'Z})^{-1}\mathbf{Z'Y} \tag{7}$$

Hansen's (1982) GMM estimation provides an alternative approach for parameter estimation in this over-identified model. The idea behind GMM estimation is to choose parameter estimate so as to make the sample moment conditions in (5) as close as possible to the population moment of zero. The GMM estimator is constructed based on the moment conditions (5) minimizes the following quadratic function:

$$\left[\sum_{t=1}^{T}\mathbf{z}_t{}'(y_t - \mathbf{x}_t\boldsymbol{\beta})\right]' \mathbf{W}_T^{-1}\left[\sum_{t=1}^{T}\mathbf{z}_t{}'(y_t - \mathbf{x}_t\boldsymbol{\beta})\right] \tag{8}$$

for some $L \times L$ positive definite weighting matrix $\mathbf{W}_T^{-1}$. If the system is just identified and $\mathbf{Z'X}$ is invertible, we can solve for the parameter vector, which makes the sample moment conditions of zero in (5). In this case, the weighting matrix is irrelevant. The corresponding GMM estimator is just as the IV estimator $\boldsymbol{\beta}_{IV}$ in (6). If the model is over-identified, we cannot set the sample moment conditions in (5) exactly equal to zero. The GMM estimator for $\boldsymbol{\beta}$ can be obtained by minimizing the quadratic function in (8) as follows:

$$\boldsymbol{\beta}_{\text{GMM}} = \left[(\mathbf{X'Z})\mathbf{W}_T^{-1}\mathbf{Z'X}\right]^{-1}(\mathbf{X'Z})\mathbf{W}_T^{-1}\mathbf{Z'Y} \tag{9}$$

Alternative weighting matrices $\mathbf{W}_T$ are associated with alternative estimators. The question in GMM estimation is which $\mathbf{W}_T$ to use in (8). Hansen (1982) shows that the optimal weighting matrix $\mathbf{W}_T$ for the resulting estimator is

$$\mathbf{W}_T = \text{Var}[\mathbf{z}'\varepsilon] \equiv E[\mathbf{zz}'\varepsilon^2] = E_{\mathbf{z}}\left\{\mathbf{zz}'[E(\varepsilon^2 \mid \mathbf{z})]\right\} \tag{10}$$

Under conditional homoscedasticity $E(\varepsilon^2 \mid \mathbf{z}) = \sigma^2$, the optimal weighting matrix in which case is

$$\mathbf{W}_T = \left(\frac{\mathbf{Z'Z}}{T}\right)\sigma^2 \tag{11}$$

Hence, any scalar in $\mathbf{W}_T$ will be canceled in this case yields

$$\boldsymbol{\beta}_{\text{GMM}} = \left[(\mathbf{X'Z})(\mathbf{Z'Z})^{-1}\mathbf{Z'X}\right]^{-1}(\mathbf{X'Z})(\mathbf{Z'Z})^{-1}\mathbf{Z'Y} \tag{12}$$

Thus, the GMM estimator is simply the 2SLS estimator under conditional homoscedasticity. However, if the conditional variance of ε_t given $\mathbf{z}_t$ depends on $\mathbf{z}_t$, the optimal weighting matrix $\mathbf{W}_T$ should be estimated by

$$\mathbf{W}_T = \frac{1}{T}\sum_{t=1}^{T}\mathbf{z}_t'\mathbf{z}_t\hat{\varepsilon}_t^2 = \frac{1}{T}\mathbf{Z'DZ} \tag{13}$$

where $\hat{\varepsilon}_t$ is sample residuals and $\mathbf{D} = \text{diag}(\hat{\varepsilon}_1^2, \ldots, \hat{\varepsilon}_T^2)$. Here, we can apply the two-stage least-squares (2SLS) estimator in equation (7) to obtain the sample residuals by $\hat{\varepsilon}_t = y_t - \mathbf{x}_t \boldsymbol{\beta}_{2SLS}$, then the GMM estimator $\boldsymbol{\beta}_{GMM}$ is

$$\boldsymbol{\beta}_{GMM} = \left[(\mathbf{X}'\mathbf{Z})(\mathbf{Z}'\mathbf{D}\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{X} \right]^{-1} (\mathbf{X}'\mathbf{Z})(\mathbf{Z}'\mathbf{D}\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{Y} \tag{14}$$

Note that the GMM estimator is obtained by two-step procedure under heteroskedasticity. First use the 2SLS estimator as an initial estimator since it is consistent to get the residuals by $\hat{\varepsilon}_t = y_t - \mathbf{x}_t \boldsymbol{\beta}_{2SLS}$. Then substitute $\sum_{t=1}^{T} \mathbf{z}_t{}'\mathbf{z}_t \hat{\varepsilon}_t^2$ into $\mathbf{W}_T$ as the weighting matrix to obtain the GMM estimator. For this reason, the GMM estimator sometimes called a two-stage instrumental variables estimator.

3.2 Application of GMM estimation in the simultaneous equations model

Consider the following linear simultaneous equations model:

$$\begin{aligned} y_{1t} &= \delta_{12} y_{2t} + \delta_{13} y_{3t} + \cdots + \delta_{1J} y_{Jt} + \mathbf{x}_{1t} \boldsymbol{\gamma}_1 + \varepsilon_{1t} \\ y_{2t} &= \delta_{21} y_{1t} + \delta_{23} y_{3t} + \cdots + \delta_{2J} y_{Jt} + \mathbf{x}_{2t} \boldsymbol{\gamma}_2 + \varepsilon_{2t} \\ &\vdots \\ y_{Jt} &= \delta_{J1} y_{1t} + \delta_{J2} y_{2t} + \cdots + \delta_{J(J-1)} y_{(J-1)t} + \mathbf{x}_{Jt} \boldsymbol{\gamma}_J + \varepsilon_{Jt} \end{aligned} \tag{15}$$

Here $t = 1, 2, \ldots, T$. Define that $\mathbf{y}_t = [y_{1t} \quad y_{2t} \quad \cdots \quad y_{Jt}]'$ is an $J \times 1$ vector for endogenous variables, $\mathbf{x}_t = [\mathbf{x}_{1t} \quad \mathbf{x}_{2t} \quad \cdots \quad \mathbf{x}_{Jt}]'$ is a vectors for all exogenous variables in this system includes constant term. $\boldsymbol{\varepsilon}_t = [\varepsilon_{1t} \quad \varepsilon_{2t} \quad \cdots \quad \varepsilon_{Jt}]$ is an $J \times 1$ vector for the disturbances. Here, $\boldsymbol{\delta}$ and $\boldsymbol{\gamma}$ are the parameters matrices of interest defined as

$$\boldsymbol{\delta} = \begin{bmatrix} \delta_{12} & \delta_{13} & \cdots & \delta_{1J} \\ \delta_{21} & \delta_{23} & \cdots & \delta_{2J} \\ \vdots & \vdots & \vdots & \vdots \\ \delta_{J1} & \delta_{J2} & \cdots & \delta_{J(J-1)} \end{bmatrix} = \begin{bmatrix} \boldsymbol{\delta}_1 \\ \boldsymbol{\delta}_2 \\ \vdots \\ \boldsymbol{\delta}_J \end{bmatrix} \text{ and } \boldsymbol{\gamma} = \begin{bmatrix} \boldsymbol{\gamma}_1 \\ \boldsymbol{\gamma}_2 \\ \vdots \\ \boldsymbol{\gamma}_J \end{bmatrix} \tag{16}$$

There are two approaches to estimate the structural parameters $\boldsymbol{\delta}$ and $\boldsymbol{\gamma}$ of the system, one is the single equation estimation and the other is the system estimation. First, we introduce the single equation estimation shown below. We can rewrite the j-th equation in our simultaneous equation model in terms of the full set of T observations:

$$\mathbf{y}_j = \mathbf{Y}_j\boldsymbol{\delta}_j + \mathbf{X}_j\boldsymbol{\gamma}_j + \boldsymbol{\varepsilon}_j = \mathbf{Z}_j\boldsymbol{\beta}_j + \boldsymbol{\varepsilon}_j, \quad j = 1,\ldots,J \tag{17}$$

where $\mathbf{y}_j$ denotes the $T \times 1$ vector of observations for the endogenous variables on left-hand side of j-th equation. $\mathbf{Y}_j$ denotes the $T \times (J-1)$ data matrix for the endogenous variables on right-hand side of this equation. $\mathbf{X}_j$ is a data matrix for all exogenous variables in this equation. Since these jointly determined variables $\mathbf{y}_j$ and $\mathbf{Y}_j$ are determined within the system, they are correlated with the disturbance terms. This correlation usually creates estimation difficulties because the OLS estimator would be biased and inconsistent (e.g. Johnston and DiNardo 1997; Greene 2011).

As discussed above, the application of OLS estimation to equation (17) yields biased and inconsistent estimates because of the correlation of $\mathbf{Z}_j$ and $\boldsymbol{\varepsilon}_j$. The two-stage least squares (2SLS) approach is the most common method used to deal with this endogeneity problem resulting from the correlation of $\mathbf{Z}_j$ and $\boldsymbol{\varepsilon}_j$. The 2SLS estimation uses all the exogenous variables in this system as instruments to obtain the predictions of $\mathbf{Y}_j$. In the first stage, we regress $\mathbf{Y}_j$ on all exogenous variables in the system to receive the predictions of the endogenous variables on right-hand side of this equation, $\hat{\mathbf{Y}}_j$. In the second stage, we regress $\mathbf{y}_j$ on $\hat{\mathbf{Y}}_j$ and $\mathbf{X}_j$ to obtain the estimator of $\boldsymbol{\beta}_j$ in equation (17). Thus, the 2SLS estimator for $\boldsymbol{\beta}_j$ in Equation (17) is,

$$\boldsymbol{\beta}_{j,2SLS} = \left[(\mathbf{Z}_j^{'}\mathbf{X})\left(\mathbf{X}^{'}\mathbf{X}\right)^{-1}\mathbf{X}^{'}\mathbf{Z}_j \right]^{-1} (\mathbf{Z}_j^{'}\mathbf{X})\left(\mathbf{X}^{'}\mathbf{X}\right)^{-1}\mathbf{X}^{'}\mathbf{y}_j \tag{18}$$

where $\mathbf{X} = [\mathbf{X}_1 \ \ \mathbf{X}_2 \ \ \cdots \ \ \mathbf{X}_J \ ]$ is a matrix for all exogenous variables in this system.

The GMM estimation provides an alternative approach to deal with this simultaneity bias problem. As for the GMM estimator with instruments $\mathbf{X}$, the moment conditions in the equation (17) is,

$$E_t\left(\mathbf{x}_t^{'}\varepsilon_{jt}\right) = E_t\left[\mathbf{x}_t^{'}(y_{jt} - \mathbf{Z}_{jt}\boldsymbol{\beta}_j)\right] = \mathbf{0} \tag{19}$$

We can apply the 2SLS estimator in equation (18) with instruments $\mathbf{X}$ to estimate $\boldsymbol{\beta}_j$ and obtain the sample residuals $\hat{\boldsymbol{\varepsilon}}_j = \mathbf{y}_j - \mathbf{Z}_j\hat{\boldsymbol{\beta}}_{j,2SLS}$. Then, compute the weight matrix $\mathbf{W}_j$ for GMM estimator based on those residuals as follows:

$$\mathbf{W}_j = \left[\frac{1}{T^2}\left(\sum_{t=1}^{T}\mathbf{x}_t^{'}\varepsilon_{jt}\varepsilon_{jt}^{'}\mathbf{x}_t\right)\right] \tag{20}$$

The GMM estimator based on the moment conditions (19) minimizes the following quadratic function:

$$\left[\sum_{t=1}^{T}\mathbf{x}_t^{'}(y_{jt} - \mathbf{Z}_{jt}\boldsymbol{\beta}_j)\right]\mathbf{W}_j^{-1}\left[\sum_{t=1}^{T}\mathbf{x}_t^{'}(y_{jt} - \mathbf{Z}_{jt}\boldsymbol{\beta}_j)\right] \tag{21}$$

The GMM estimator that minimizes this quadratic function (21) is obtained as

$$\hat{\boldsymbol{\beta}}_{GMM} = \left[\left(\mathbf{Z}_j^{'}\mathbf{X}\right)\mathbf{W}_j^{-1}\left(\mathbf{X}^{'}\mathbf{Z}_j\right)\right]^{-1}\left[\left(\mathbf{Z}_i^{'}\mathbf{X}\right)\mathbf{W}_j^{-1}\left(\mathbf{X}^{'}\mathbf{y}_j\right)\right] \tag{22}$$

In the homoscedastic and serially independent case, a good estimate of the weight matrix $\mathbf{W}_j$ would be

$$\mathbf{W} = \left[\frac{\sigma^2}{T}\left(\mathbf{X}^{'}\mathbf{X}\right)\right]$$

Given the estimate of σ^2 is obtained, then rearrange terms in equation (22), which yields

$$\hat{\boldsymbol{\beta}}_{GMM} = \left[(\mathbf{Z}_j'\mathbf{X})\left(\mathbf{X}'\mathbf{X}\right)^{-1}\mathbf{X}'\mathbf{Z}_j \right]^{-1} (\mathbf{Z}_j'\mathbf{X})\left(\mathbf{X}'\mathbf{X}\right)^{-1}(\mathbf{X}'\mathbf{y}_j) \tag{24}$$

Thus the 2SLS estimator is a special case of GMM estimator.

As Chen and Lee (2010) pointed out the 2SLS estimation is a limited information method. The 3SLS estimation is a full information method. The 3SLS estimation takes into account the information from a full system of equations. Thus, it is more efficient than the 2SLS estimation. The 3SLS method estimates all structural parameters of this system jointly. This allows the possibility of contemporaneous correlation between the disturbances in different structural equation. We introduce the 3SLS estimation below. We rewrite our full system of equations in equation (18) as

$$\mathbf{Y} = \mathbf{Z}\boldsymbol{\beta} + \boldsymbol{\varepsilon} \tag{25}$$

where $\mathbf{Y}$ is a vector defined as $\left[\mathbf{y}_1 \quad \mathbf{y}_2 \quad \cdots \quad \mathbf{y}_J\right]'$. $\mathbf{Z} = \text{diag}\left[\mathbf{Z}_1 \quad \mathbf{Z}_2 \quad \cdots \quad \mathbf{Z}_J\right]$ is a block diagonal data matrix for all variables on right-hand side of this system with the form $\mathbf{Z}_j = [\mathbf{Y}_j \ \ \mathbf{X}_j]$ as defined in equation (18). $\boldsymbol{\beta}$ is a vector of interest parameters defined as $\left[\boldsymbol{\beta}_1 \quad \boldsymbol{\beta}_2 \quad \cdots \quad \boldsymbol{\beta}_J\right]'$. $\boldsymbol{\varepsilon}$ is a vector of disturbances defined as $\left[\boldsymbol{\varepsilon}_1 \quad \boldsymbol{\varepsilon}_2 \quad \cdots \quad \boldsymbol{\varepsilon}_J\right]'$ with $\text{E}(\boldsymbol{\varepsilon}) = \mathbf{0}$ and $\text{E}(\boldsymbol{\varepsilon}\boldsymbol{\varepsilon}') = \boldsymbol{\Sigma} \otimes \mathbf{I}_T$ where $\otimes$ signifies the Kroneker product. Here, $\boldsymbol{\Sigma}$ is defined as

$$\boldsymbol{\Sigma} = \begin{bmatrix} \sigma_{11} & \sigma_{12} & \cdots & \sigma_{1J} \\ \sigma_{21} & \sigma_{22} & \cdots & \sigma_{2J} \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{J1} & \sigma_{J2} & \cdots & \sigma_{JJ} \end{bmatrix} \tag{26}$$

The 3SLS approach is the most common method used to estimate the structural parameters of this system simultaneously. Basically, the 3SLS estimator is a generalized least square (GLS) estimator in the entire system taking account of the covariance matrix in equation (26). The 3SLS estimator is equivalent to using the all exogenous variables as instruments and estimating the entire system using GLS estimation (Intriligator, Bodkin, and Hsiao; 1996). The 3SLS estimation uses all exogenous variables $\mathbf{X}=[\mathbf{X}_1\ \ \mathbf{X}_2\ \ \cdots\ \ \mathbf{X}_J\ ]$ as instruments in each equation of this system, pre-multiplying the model (25) by $\mathbf{X}_I^{'}=\text{diag}[\mathbf{X}^{'}\ \cdots\ \mathbf{X}^{'}]=\mathbf{X}\otimes\mathbf{I}_J$ yields the model

$$\mathbf{X}_I^{'}\mathbf{Y}=\mathbf{X}_I^{'}\mathbf{Z}\boldsymbol{\beta}+\mathbf{X}_I^{'}\mathbf{u} \tag{27}$$

The covariance matrix from (26) is

$$Cov\left(\mathbf{X}_I^{'}\boldsymbol{\varepsilon}\right)=\mathbf{X}_I^{'}Cov\left(\boldsymbol{\varepsilon}\right)\mathbf{X}_I=\mathbf{X}_I^{'}(\boldsymbol{\Sigma}\otimes\mathbf{I}_T)\mathbf{X}_I \tag{28}$$

The GLS estimator of the equation (27) is the 3SLS estimator. Thus the 3SLS estimator is given as follows:

$$\hat{\boldsymbol{\beta}}_{3SLS}=\left\{\mathbf{Z}^{'}\mathbf{X}_I[\mathbf{X}_I^{'}(\boldsymbol{\Sigma}\otimes\mathbf{I}_T)\mathbf{X}_I]^{-1}\mathbf{X}_I^{'}\mathbf{Z}\right\}^{-1}\mathbf{Z}^{'}\mathbf{X}_I[\mathbf{X}_I^{'}(\boldsymbol{\Sigma}\otimes\mathbf{I}_T)\mathbf{X}_I]^{-1}\mathbf{X}_I^{'}\mathbf{Y} \tag{29}$$

In this case, $\boldsymbol{\Sigma}$ is a diagonal matrix, the 3SLS estimator is equivalent to the 2SLS estimator. As discussed above, the GMM estimator with all exogenous variables $\mathbf{X}=[\mathbf{X}_1\ \ \mathbf{X}_2\ \ \cdots\ \ \mathbf{X}_J\ ]$ as instruments, the moment conditions of this system (25) is,

$$\begin{aligned}\mathrm{E}\left(\mathbf{X}_I^{'}\boldsymbol{\varepsilon}\right)&=\mathrm{E}\left[\mathbf{X}_I^{'}(\mathbf{Y}-\mathbf{Z}\boldsymbol{\beta})\right]\\&=\left(\mathrm{E}\left[\mathbf{X}_I^{'}(\mathbf{y}_1-\mathbf{Z}_1\boldsymbol{\beta}_1)\right]\ \mathrm{E}\left[\mathbf{X}_I^{'}(\mathbf{y}_2-\mathbf{Z}_2\boldsymbol{\beta}_2)\right]\ \cdots\mathrm{E}\left[\mathbf{X}_I^{'}(\mathbf{y}_J-\mathbf{Z}_J\boldsymbol{\beta}_J)\right]\right)^{'}=\mathbf{0}\end{aligned} \tag{30}$$

We can apply the 2SLS estimator with instruments $\mathbf{X}$ to estimate $\boldsymbol{\beta}_j$ and obtain the sample residuals $\hat{\boldsymbol{\varepsilon}}_j=\mathbf{y}_j-\mathbf{Z}_j\hat{\boldsymbol{\beta}}_{j,2SLS}$. Then, compute the weight matrix $\mathbf{W}_{jl}$ for GMM estimator based on those residuals as follows:

$$\mathbf{W}_{jl}=\left[\frac{1}{T^2}\left(\sum_{t=1}^{T}\mathbf{x}_{jt}^{'}\varepsilon_{jt}\varepsilon_{lt}^{'}\mathbf{x}_{jt}\right)\right] \tag{31}$$

The system GMM estimator based on the moment conditions (30) minimizes the quadratic function:

$$\begin{bmatrix} \mathbf{X}'\left(\mathbf{y}_1-\mathbf{Z}_1\boldsymbol{\beta}_1\right) \\ \mathbf{X}'\left(\mathbf{y}_2-\mathbf{Z}_2\boldsymbol{\beta}_2\right) \\ \vdots \\ \mathbf{X}'\left(\mathbf{y}_J-\mathbf{Z}_J\boldsymbol{\beta}_J\right) \end{bmatrix}' \begin{bmatrix} \mathbf{W}_{11} & \mathbf{W}_{12} & \cdots & \mathbf{W}_{1J} \\ \mathbf{W}_{21} & \mathbf{W}_{22} & \cdots & \mathbf{W}_{2J} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{W}_{J1} & \mathbf{W}_{J2} & \cdots & \mathbf{W}_{JJ} \end{bmatrix}^{-1} \begin{bmatrix} \mathbf{X}'\left(\mathbf{y}_1-\mathbf{Z}_1\boldsymbol{\beta}_1\right) \\ \mathbf{X}'\left(\mathbf{y}_2-\mathbf{Z}_2\boldsymbol{\beta}_2\right) \\ \vdots \\ \mathbf{X}'\left(\mathbf{y}_J-\mathbf{Z}_J\boldsymbol{\beta}_J\right) \end{bmatrix} \tag{32}$$

The GMM estimator that minimizes this quadratic function (32) is obtained as

$$\begin{bmatrix} \hat{\boldsymbol{\beta}}_{1,\mathrm{GMM}} \\ \hat{\boldsymbol{\beta}}_{2,\mathrm{GMM}} \\ \vdots \\ \hat{\boldsymbol{\beta}}_{J,\mathrm{GMM}} \end{bmatrix} = \begin{bmatrix} \mathbf{Z}_1'\mathbf{X}\mathbf{W}_{11}\mathbf{X}'\mathbf{Z}_1 & \cdots & \mathbf{Z}_1'\mathbf{X}\mathbf{W}_{1J}\mathbf{X}'\mathbf{Z}_J \\ \mathbf{Z}_2'\mathbf{X}\mathbf{W}_{21}\mathbf{X}'\mathbf{Z}_1 & \cdots & \mathbf{Z}_2'\mathbf{X}\mathbf{W}_{2J}\mathbf{X}'\mathbf{Z}_J \\ \vdots & \ddots & \vdots \\ \mathbf{Z}_J'\mathbf{X}\mathbf{W}_{J1}\mathbf{X}'\mathbf{Z}_1 & \cdots & \mathbf{Z}_J'\mathbf{X}\mathbf{W}_{JJ}\mathbf{X}'\mathbf{Z}_J \end{bmatrix}^{-1} \begin{bmatrix} \sum_{l=1}^{J}\mathbf{Z}_1'\mathbf{X}\mathbf{W}_{1l}\mathbf{y}_l \\ \sum_{l=1}^{J}\mathbf{Z}_2'\mathbf{X}\mathbf{W}_{2l}\mathbf{y}_l \\ \vdots \\ \sum_{l=1}^{J}\mathbf{Z}_J'\mathbf{X}\mathbf{W}_{Jl}\mathbf{y}_l \end{bmatrix} \tag{33}$$

The 2SLS and 3SLS estimators are the special cases of system GMM estimator. If the $\mathbf{W}_{jj} = \left[\frac{\sigma_{jj}}{T}\left(\sum_{t=1}^{T}\mathbf{x}_t'\mathbf{x}_t\right)\right]$ and $\mathbf{W}_{jl} = 0$ for $j \neq l$, then the system GMM estimator is equivalent to the 2SLS estimator. In the case, $\mathbf{W}_{jl} = \left[\frac{\sigma_{jl}}{T}\left(\sum_{t=1}^{T}\mathbf{x}_t'\mathbf{x}_t\right)\right]$, the system GMM estimator is equivalent to the 3SLS estimator.

4 Application in investment, financing and dividend policy

4.1 Model and data

The investment, dividend, and debt financing are major decisions of a firm. Past studies argue some relations among investment, dividend and debt financing.[5] To control for the possible endogenous problems among these three decisions, we apply

[5] Higgins (1972), Fama (1974), Morgan and Saint-Pierre (1978), Smirlock and Marshall (1983), Lee et al. (2011) and Chen et al. (2013) investigate the relationship between investment decision and dividend decision. Fama and French (2002) consider the interaction between dividend and financing decisions. Dhrymes and Kurz (1967), McDonald et al. (1975), McCabe (1979), Peterson and Benesh (1983), Switzer (1984), and Pruitt and Gitman (1991) argue that the investment decision is related to financing decision and dividend decision. Chava and Roberts (2008) show how financing impacts corporate investment via debt covenants. Lambrecht and Myers (2012) develop a combined theory of payout, debt, and investment.

2SLS, 3SLS, and GMM methods to estimate the simultaneous-equations model that consider the interaction of the three policies.

There are three equations in our simultaneous-equations system; each equation contains the remaining two endogenous variables as explanatory variables along with other exogenous variables. The three endogenous variables are changes in the investment (ΔInv_{it}), dividend (ΔDiv_{it}), and in debt financing ($\Delta Debt_{it}$) of firm *i* from year *t-1* to year *t*. Inv denotes net property, plant, and equipment. Div denotes dividends. Both Inv and Div are measured on a per share basis. $Debt$ refers to book leverage, defined as the ratio of total liabilities to total assets. The other exogenous variables, which are commonly adopted in the literature, contain lag-terms of the tree policies, sales plus change in inventories (Q_{it}), net income before extraordinary items plus depreciation minus preferred dividends (P_{it}), natural logarithm of lagged total assets ($\ln A_{i,t-1}$), and the lag of earnings before interest and taxes divided by total assets ($E_{i,t-1}/A_{i,t-1}$). The structural equations are estimated as follows:

$$\Delta Inv_{it} = \alpha_{1i} + \alpha_{2i}\Delta Div_{it} + \alpha_{3i}\Delta Debt_{it} + \alpha_{4i}Inv_{i,t-1} + \alpha_{5i}Q_{it} + \epsilon_{it} \ , \tag{34}$$

$$\Delta Div_{it} = \beta_{1i} + \beta_{2i}\Delta Inv_{it} + \beta_{3i}\Delta Debt_{it} + \beta_{4i}Div_{i,t-1} + \beta_{5i}P_{it} + \eta_{it} \ , \tag{35}$$

$$\Delta Debt_{it} = \gamma_{1i} + \gamma_{2i}\Delta Inv_{it} + \gamma_{3i}\Delta Div_{it} + \gamma_{4i}Debt_{i,t-1} + \gamma_{5i}\ln A_{i,t-1} + \gamma_{6i}(E_{i,t-1}/A_{i,t-1}) + \xi_{it} \ . \tag{36}$$

Our sample consists of all dividend-paying U.S. firms listed on NYSE, AMEX, OTC, and NASDAQ stock markets from 1965 to 2012. All of our accounting variables are annual and collected from Compustat Annual Industrial Files. Following previous research (e.g., Fama and Fench 2002; Huang and Ritter 2009; Cook and Tang 2010), we exclude financial firms (SIC 6000-6999) and regulated utilities (SIC 4900-4999) from the sample. We also require firms to have positive total assets and a number of common shares outstanding.[6] To increase the testing power in the regression analysis, we also require firms to survive 30 years or longer. These exclusions leave us with complete information for 564 firms.

Table 1 presents summary statistics on the investment, dividend, and debt financing for different time periods. All of these variables are winsorized at the 1st and 99th percentiles to avoid the influence of extreme observations. Compared with different time periods, the investment during the 1980s is the highest. This result may be from the simulating policies (e.g., the reduction of capital gain tax and the reduction of interest rate), which was promoted by U.S. President Ronald Reagan during the 1980s. Dividend payout is more likely to be reduced after the 1990s. Such finding is consistent with Fama and French (2001), Grullon and Michaely (2002), and Brav et al. (2005), indicating that repurchase is more prevalent to adopt than dividend payout in the recent decades. The average book leverage is 0.494 and the book leverage tends to be higher in later years than in earlier years.

[Insert Table 1 about here]

4.2 Empirical results

Table 2 shows 2SLS regression results for simultaneous-equations model. Averages of individual firms' coefficient estimates of the investment, dividend, and debt financing regressions are presented. The results of relations among these three financial decisions could be directly obtained in this method. First, the significantly positive coefficient of $\Delta Debt_{it}$ (in investment decision), and ΔInv_{it} (in debt financing decision) imply that firms with higher investment changes have higher debt financing changesand vice versa. Ross (1977) and Myers and Majluf (1984) suggest

[6] These variables are used to deflate other variables and the results become difficult to interpret when they have non-positive values.

that debt is preferred to equity for managers to signal the optimistic investment opportunity to investors because the firms are expected to have higher future cash flows to repay the debt. Harris and Raviv (1990) argue that debt is a device to solve the asymmetric information for the investors because it helps to monitor managers and force the firm to liquidation. In addition, our finding that increases in debt financing enhance the funds available to outlays for investment is consistent with McCabe (1979), Peterson and Benesh (1983), John and Nachman (1985), and Froot et al. (1993). Thus, our optimal debt ratio may be the result of a trade-off between the value of information (from more debt) and the cost of monitor.

[Insert Table 2 about here]

Second, the significant coefficients of ΔDiv_{it} and ΔInv_{it} imply that dividend outlays influence investment decisions and vice versa. This finding implies that the firms may use dividend payout to signal the growth opportunity and then these firms increase their investment. The firm with higher investment input may experience the higher earnings and thus could increase the dividend payout. Such finding, that dividend payout responds to investment, confirms the model prediction of Lambrecht and Myers (2012). The relationship between dividend payout and investment is also consistent with the signaling cash flow hypothesis of dividend payout in Yoon and Starks (1995).

Third, the changes of dividend on the change of debt financing are significantly negative, showing that the firms need less debt financing when they are capable of paying more dividend. This finding is consistent with the economics intuition that the firms with higher dividend payout usually have greater earnings (e.g., Lintner, 1956; Skinner, 2008) and thus have less incentive to issue debt financing. In addition, the increases in debt financing seem to enhance the funds available to outlays for dividend payout, implying that firms may transfer the wealth from bondholders to shareholders.

In the investment equation, we find the coefficient of lagged investment is significantly negative, which is the speed of adjustment of investment, indicating that firms adjust its investment toward its target level. The output positively and significantly affects the change of investment, which is consistent with Fama (1974).

In the dividend model, the coefficient of lagged dividend is -0.224 significantly negative, implying that firms adjust the firms' dividends to the targeted levels. The coefficient of P_{it} is significantly positive, implying that firms with high net income tend to increase to pay dividends.

In the debt financing equation, the coefficient of lagged leverage is -0.287 significantly negative. The result is consistent with Jalilvand and Harris (1984), Flannery and Rangan (2006), and Huang and Ritter (2009), which implies firms also tend to adjust toward the target leverage levels. The coefficient of $\ln A_{i,t-1}$ is significantly positive, indicating that large firms leverage more than smaller firms. This finding results from large firms that tend to have a greater reputation and less information asymmetry than small firms and thus large firms can finance at a lower cost. The positive relation between size and leverage is consistent with Fama and French (2002), Flannery and Rangan (2006), and Frank and Goyal (2009).

The coefficient of $(E_{i,t-1}/A_{i,t-1})$ is significantly negative. This result implies that more profitable firms have higher internal funds from their earnings and thus have less incentive to obtain the outside funds by debt issuing. The negative relationship between profitability and leverage is consistent with the findings of Long and Malitz (1985), Rajan and Zingales (1995), Fama and French (2002), and Flannery and Rangan (2006).

Table 3 and Table 4 show results of 3SLS and GMM, respectively. Similarly, we present averages of an individual firm's coefficient estimates of the investment, dividend, and debt financing regressions. All the signs and significance of the estimated coefficients are consistent with the results of 2SLS. We present the detailed process of 2SLS, 3SLS, and GMM estimation by taking IBM's annual data during the period 1966-2012, in Appendix A.

[Insert Table 3 about here]

[Insert Table 4 about here]

By comparing the results from these methods, we find all the coefficients of lagged investment, lagged dividend, and lagged debt financing are significantly negative. This result implies that these three policies tend to be adjusted to the optimal levels. All the exogenous variables have a similar impact in the literature. Our empirical results also can be used to test the joint determination theory of investment, financing, and dividend decisions developed by Lambrecht and Myers (2012).

5 Conclusion

In this paper, we investigate the endogeneity problems related to simultaneous equation system, and introduce how 2SLS, 3SLS, and GMM estimation methods deal with endogeneity. We show that both 2SLS and 3SLS are special cases of the GMM estimator in estimating simultaneous equations. In addition to reviewing applications of simultaneous equation on many finance issues, we also use U.S. listed firms from 1965 to 2012 to examine the interrelationship among corporate investment, leverage, and dividend payout policies in a simultaneous-equation system by employing 2SLS, 3SLS, and GMM.

Our results from 2SLS, 3SLS, and GMM are similar. First, we show that dividend outlays influence investment decisions and vice versa. The fact that dividend payout does not cut back to finance capital investment confirms the model prediction of Lambrecht and Myers (2012). Moreover, investment changes have a positive impact on debt financing changes and vice versa. An increase in debt financing enhances the funds available to outlays for investment, and the increase in investment raises willingness of fund supply by the increase in mortgage of capital investment or investment's future profitability, and thus further improve firm's debt capacity. Changes of dividend have a negative impact on the changes of debt financing, showing that firms need less debt financing when they are capable of paying more dividend. This finding is consistent with the economics intuition that the firms with higher dividend payout usually have greater earnings and thus have less incentive to issue debt financing. In addition, the increases in debt financing enhance the funds available to outlays for dividend payout. Accordingly, our findings suggest that these three corporate decisions are jointly determined and the interaction among them should be taken into account in a simultaneous equation framework.

Appendix A Case study of IBM company

The purpose of this appendix is to use IBM's annual data during the period 1966-2012 as an example to investigate the interrelationship among investment, financing, and dividend decisions. The IBM sample of 47 observations reported in terms of sums of squares and cross products is shown in Table 1. Here, the structural equations of this paper are constructed as follows (34), (35), and (36). As discussed above, we can estimate the structural parameters of this system by one equation at a time through 2SLS estimation and single equation GMM estimation. However, these single estimations ignore the information contained in the other equations. The 3SLS estimation and system GMM estimation provide alternatives to estimate all structural parameters of this system jointly. We illustrate the estimation of a simultaneous equations model using 2SLS, 3SLS, and GMM methods in the following.

A.1 Single equation estimation

We can rewrite the j-th equation in our simultaneous equation model in terms of the full set of T observations:

$$\mathbf{y}_j = \mathbf{Y}_j\gamma_j + \mathbf{X}_j\beta_j + \mathbf{u}_j = \mathbf{Z}_j\delta_j + \mathbf{u}_j, \quad j = 1, 2, 3. \tag{38}$$

where $\mathbf{y}_j$ denotes $T \times 1$ vector of observations for the endogenous variables on left-hand side of j-th equation. $\mathbf{Y}_j$ denotes $T \times 2$ data matrix for the endogenous variables on right-hand side of this equation. $\mathbf{X}_j$ is a data matrix for all exogenous variables in this equation. For example, consider the investment equation in our three-equation model, $\mathbf{y}_j$ and $\mathbf{Y}_j$ are data matrices defined as $[\ \Delta\mathbf{Inv}\ ]$ and $[\ \Delta\mathbf{Div}\ \Delta\mathbf{Debt}\ ]$, respectively. $\mathbf{X}_j = [\ \mathbf{1}\ \mathbf{Inv}_{-1}\ \mathbf{Q}\ ]$ is a $T \times 3$ data matrix for the exploratory variables, where $\mathbf{1}$ is the constants term and $\mathbf{Inv}_{-1}$ denotes one-period-lagged data matrix of $\mathbf{Inv}$. $\mathbf{Z}_1 = [\ \mathbf{1}\ \Delta\mathbf{Div}\ \Delta\mathbf{Debt}\ \mathbf{Inv}_{-1}\ \mathbf{Q}\ ]$ is a $T \times 5$ data matrix for all variables on right-hand side of this equation. As discussed above, the 2SLS estimation uses all the exogenous variables in this system as instruments to obtain the predictions of $\mathbf{Y}_j$. Here, the instruments matrix $\mathbf{X} = [\ \mathbf{1}\ \mathbf{Inv}_{-1}\ \mathbf{Q}\ \mathbf{Div}_{-1}\ \mathbf{P}\ \mathbf{Debt}_{-1}\ \ln(\mathbf{A}_{-1})\ (\mathbf{E}/\mathbf{A})_{-1}\ ]$ is a $T \times 8$ matrix for all exogenous variables in this system. Then, the vector of 2SLS estimates is

$$\begin{aligned}\hat{\delta}_{1,2SLS} &= [(\mathbf{Z}_1'\mathbf{X})(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Z}_1]^{-1}(\mathbf{Z}_1'\mathbf{X})(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y}_1 \\ &= \begin{pmatrix} -2.4541 & 4.5640 & 42.0613 & -0.0900 & 0.0471 \end{pmatrix}'\end{aligned} \tag{39}$$

Here

$$(\mathbf{Z}_1'\mathbf{X})(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Z}_1 = \begin{pmatrix} 47.0000 & -2.6068 & 0.5292 & 1450.8413 & 3876.1612 \\ -2.6068 & 104.1431 & -0.4588 & -482.8651 & 402.7128 \\ 0.5292 & -0.4588 & 0.0242 & 21.7584 & 57.6402 \\ 1450.8413 & -482.8651 & 21.7584 & 57669.2721 & 127304.6882 \\ 3876.1612 & 402.7128 & 57.6402 & 127304.6882 & 354485.4669 \end{pmatrix}$$

and

$$(\mathbf{Z}_1'\mathbf{X})(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y}_1 = \begin{pmatrix} -52.8683 \\ 524.8281 \\ -1.6147 \\ 4038.9888 \\ -0.2784 \end{pmatrix}$$

The estimated covariance matrix of the 2SLS estimator is

$$\operatorname{cov}\left(\hat{\boldsymbol{\delta}}_{1,2\text{SLS}}\right) = [(\mathbf{Z}_1'\mathbf{X})(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Z}_1]^{-1}\sigma_{11} = \begin{pmatrix} 15.6513 & 2.0432 & 177.3873 & 0.0145 & -0.2 \\ 2.0432 & 0.9978 & 46.3458 & 0.0382 & -0.0 \\ 177.3873 & 46.3458 & 5509.9816 & 1.0725 & -3.2 \\ 0.0145 & 0.0382 & 1.0725 & 0.0053 & -0.0 \\ -0.2075 & -0.0447 & -3.2734 & -0.0023 & 0.0 \end{pmatrix}$$

while the estimate of σ_{11} is obtained by

$$\hat{\sigma}_{11} = \frac{\left(\mathbf{y}_1 - \mathbf{Z}_1\hat{\boldsymbol{\delta}}_{1,2\text{SLS}}\right)'\left(\mathbf{y}_1 - \mathbf{Z}_1\hat{\boldsymbol{\delta}}_{1,2\text{SLS}}\right)}{T-5} = 40.8431.$$

Then, the corresponding estimated standard errors of 2SLS estimates can be obtained by the square root of the diagonal elements of $\operatorname{cov}(\hat{\boldsymbol{\delta}}_{1,2SLS})$ as follows.

$$\text{s.e.}\left(\hat{\boldsymbol{\delta}}_{1,2\text{SLS}}\right) = \begin{pmatrix} 3.9562 & 0.9989 & 74.2293 & 0.0725 & 0.0615 \end{pmatrix}' \tag{40}$$

As for the GMM estimator with instruments $\mathbf{X}$ for the investment equation in our three-equation model, the moment conditions in the Equation (38) is,

$$\mathbb{E}_t(\mathbf{X}_t'u_{1t}) = \mathbb{E}_t[\mathbf{X}_t'(y_{1t} - \mathbf{Z}_{1t}\boldsymbol{\delta}_1)] = \mathbf{0}. \tag{41}$$

The GMM estimator based on the moment conditions (41) minimizes the following quadratic function:

$$Q(\boldsymbol{\delta}_1) = [\sum_{t=1}^{T}(y_{1t} - \mathbf{Z}_{1t}\boldsymbol{\delta}_1)\mathbf{X}_t']\widehat{\mathbf{W}}_1^{-1}[\sum_{t=1}^{T}\mathbf{X}_t'(y_{1t} - \mathbf{Z}_{1t}\boldsymbol{\delta}_1)] \tag{42}$$

Here, the optimal weighting matrix $\widehat{\mathbf{W}}_1$ is the asymptotic variance matrix of sample mean of moment conditions. We can apply the estimates of 2SLS estimation with instruments $\mathbf{X}$ in equation (39) to obtain the sample residuals $\hat{\mathbf{u}}_1 = \mathbf{y}_1 - \mathbf{Z}_1\hat{\boldsymbol{\delta}}_{1,2\text{SLS}}$. The estimated weighting matrix $\widehat{\mathbf{W}}_1$ for GMM estimator based on those residuals can be constructed by Newey-West (1987) estimation is

$$\widehat{\mathbf{W}}_j = \begin{pmatrix} 2.6802 & -0.0096 & 0.0003 & 0.0148 & 0.0012 & 0.0187 & -0.1984 & -2.0510 \\ -0.0096 & 0.0000 & 0.0000 & -0.0001 & 0.0000 & 0.0001 & 0.0007 & 0.0057 \\ 0.0003 & 0.0000 & 0.0000 & -0.0001 & 0.0000 & 0.0009 & -0.0002 & 0.0037 \\ 0.0148 & -0.0001 & -0.0001 & 0.0006 & 0.0001 & -0.0026 & -0.0005 & -0.0255 \\ 0.0012 & 0.0000 & 0.0000 & 0.0001 & 0.0001 & -0.0013 & 0.0001 & -0.0120 \\ 0.0187 & 0.0001 & 0.0009 & -0.0026 & -0.0013 & 0.2465 & -0.0253 & 0.4074 \\ -0.1984 & 0.0007 & -0.0002 & -0.0005 & 0.0001 & -0.0253 & 0.0174 & 0.0955 \\ -2.0510 & 0.0057 & 0.0037 & -0.0255 & -0.0120 & 0.4074 & 0.0955 & 3.6176 \end{pmatrix}$$

Then, the vector of GMM estimates that minimizes this quadratic function (42) through the Broyden-Fletcher-Goldfarb-Shanno (BFGS) algorithm is

$$\hat{\delta}_{1,\text{GMM}} = \begin{pmatrix} -1.1062 & 4.7143 & -1.8814 & 0.0132 & 0.0097 \end{pmatrix}' \tag{43}$$

The corresponding asymptotic variance of the GMM estimator can be obtained by $\mathbf{V}_T = \{\mathbf{D}_1'\widehat{\mathbf{W}}_1^{-1}\mathbf{D}_1\}^{-1}$. Here, $\mathbf{D}_1$ is the transpose of the Jacobian matrix of moment conditions in investment equation evaluated at GMM estimates.

$$\mathbf{D}_1 = \begin{pmatrix} -47.0000 & 2.6068 & -0.5292 & -1450.8414 & -3876.1612 \\ -1450.8413 & 482.8651 & -21.7584 & -57669.2782 & -127304.6842 \\ -3876.1612 & -402.7128 & -57.6402 & -127304.6946 & -354485.4658 \\ -166.5106 & 84.0313 & -2.8771 & -6768.0668 & -14813.9201 \\ -700.9190 & -174.1938 & -6.4491 & -24376.5476 & -62129.2397 \\ -24.8893 & 1.6723 & -0.2712 & -648.2833 & -2030.8573 \\ -498.4315 & 25.2313 & -5.9328 & -14821.2700 & -41185.2342 \\ -7.7955 & 0.3706 & -0.0669 & -262.8514 & -627.8541 \end{pmatrix}$$

and the resulting estimated asymptotic covariance matrix of GMM estimator $\mathbf{V}_{1T}$ is

$$\mathbf{V}_{1T} = \begin{pmatrix} 9.1371 & 1.7792 & 137.3474 & -0.1135 & -0.1053 \\ 1.7792 & 0.6805 & 32.8959 & -0.0027 & -0.0287 \\ 137.3474 & 32.8959 & 3358.5269 & -2.0750 & -1.5714 \\ -0.1135 & -0.0027 & -2.0750 & 0.0046 & 0.0003 \\ -0.1053 & -0.0287 & -1.5714 & 0.0003 & 0.0016 \end{pmatrix}$$

Then, the vector for estimated standard errors of single-equation GMM estimates can be obtained from the square root of diagonal elements of $\mathbf{V}_{1T}$ is

$$\text{s.e.}\left(\hat{\boldsymbol{\delta}}_{1,\text{GMM}}\right) = \begin{pmatrix} 3.0228 & 0.8249 & 57.9528 & 0.0682 & 0.0397 \end{pmatrix}' \tag{44}$$

A.2 System estimation

We can rewrite our full system of equations as

$$\mathbf{Y} = \mathbf{Z}\boldsymbol{\delta} + \mathbf{u} \tag{45}$$

where $\mathbf{Y}$ is a vector defined as $[\ \mathbf{\Delta Inv}\ \ \mathbf{\Delta Div}\ \ \mathbf{\Delta Debt}\ ]'$. $\mathbf{Z} = \text{diag}[\ \mathbf{Z}_1\ \ \mathbf{Z}_2\ \ \mathbf{Z}_3\ ]$ is a block diagonal data matrix for all variables on the right-hand side of this system with the form $\mathbf{Z}_1 = [\ \mathbf{1}\ \mathbf{\Delta Div}\ \mathbf{\Delta Debt}\ \mathbf{Inv}_{-1}\ \mathbf{Q}\ ]$, $\mathbf{Z}_2 = [\ \mathbf{1}\ \mathbf{\Delta Inv}\ \mathbf{\Delta Debt}\ \mathbf{Div}_{-1}\ \mathbf{P}\ ]$, and $\mathbf{Z}_3 = [\ \mathbf{1}\ \mathbf{\Delta Inv}\ \mathbf{\Delta Div}\ \mathbf{Debt}_{-1}\ln(\mathbf{A})_{-1}\ \ (\mathbf{E/A})_{-1}\ ]$. $\boldsymbol{\delta}$ is the vector of parameters of interest. Here, the instruments matrix defined as $\mathbf{X}_I = \text{diag}[\ \mathbf{X}\ \ \mathbf{X}\ \ \mathbf{X}\ ]$ with $\mathbf{X} = [\ \mathbf{1}\ \mathbf{Inv}_{-1}\ \mathbf{Q}\ \mathbf{Div}_{-1}\ \mathbf{P}\ \mathbf{Debt}_{-1}\ \ln(\mathbf{A}_{-1})\ (\mathbf{E/A})_{-1}\ ]$.

The 3SLS estimation involves an instrumental variable approach to produce consistent estimates and generalized least squares (GLS) technique to account for the possibility of contemporaneous correlation between the disturbances in different structural equation. The 3SLS estimation uses all exogenous variables as instruments in each equation of this system. Basically, the first two stages of 3SLS estimation is similar to 2SLS estimation, whereas in the third stage we apply GLS estimation to deal with the contemporaneous correlation across equations. The vector of estimates for each equation obtained by 2SLS estimation is

$$\hat{\boldsymbol{\delta}}_{2\text{SLS}} = \begin{pmatrix} \hat{\boldsymbol{\delta}}_{1,2\text{SLS}} \\ \hat{\boldsymbol{\delta}}_{2,2\text{SLS}} \\ \hat{\boldsymbol{\delta}}_{3,2\text{SLS}} \end{pmatrix} = \begin{pmatrix} [\ -2.4541\ \ 4.5640\ \ 42.0613\ \ -0.0900\ \ 0.0471\ ]' \\ [-0.6152\ \ 0.0991\ \ 12.0646\ \ -0.3697\ \ 0.1237\ ]' \\ [\ -0.1232\ \ 0.0008\ \ -0.0088\ \ -0.1397\ \ 0.0221\ \ -0.1548\ ]' \end{pmatrix} \tag{46}$$

Form the residuals of each equation by $\hat{\mathbf{u}}_j = \mathbf{y}_j - \mathbf{Z}_j\hat{\boldsymbol{\delta}}_{j,2SLS}$, and use these residuals to form the contemporaneous covariance matrix as follows:

$$\widehat{\boldsymbol{\Sigma}} = \begin{pmatrix} \hat{\sigma}_{11} & \hat{\sigma}_{12} & \hat{\sigma}_{13} \\ \hat{\sigma}_{21} & \hat{\sigma}_{22} & \hat{\sigma}_{23} \\ \hat{\sigma}_{31} & \hat{\sigma}_{32} & \hat{\sigma}_{33} \end{pmatrix} = \begin{pmatrix} 36.49811 & -3.30773 & -0.11242 \\ -3.30773 & 0.84160 & -0.00016 \\ -0.11242 & -0.00016 & 0.00116 \end{pmatrix} \tag{47}$$

while the estimate of σ_{ij} is calculated by

$$\hat{\sigma}_{ij} = \frac{\left(\mathbf{y}_i - \mathbf{Z}_i\hat{\boldsymbol{\delta}}_{i,2SLS}\right)'\left(\mathbf{y}_j - \mathbf{Z}_j\hat{\boldsymbol{\delta}}_{j,2SLS}\right)}{T}, \quad \text{for i, j} = 1, 2, 3.$$

Then, apply the GLS estimation to obtain the vector of 3SLS estimates as follows:

$$\hat{\boldsymbol{\delta}}_{3SLS} = \left\{\mathbf{Z}'\mathbf{X}_I[\mathbf{X}_I'(\widehat{\boldsymbol{\Sigma}} \otimes \mathbf{I}_T)\mathbf{X}_I]^{-1}\mathbf{X}_I'\mathbf{Z}\right\}^{-1}\mathbf{Z}'\mathbf{X}_I[\mathbf{X}_I'(\widehat{\boldsymbol{\Sigma}} \otimes \mathbf{I}_T)\mathbf{X}_I]^{-1}\mathbf{X}_I'\mathbf{Y}$$

$$\begin{pmatrix} \hat{\boldsymbol{\delta}}_{1,3SLS} \\ \hat{\boldsymbol{\delta}}_{2,3SLS} \\ \hat{\boldsymbol{\delta}}_{3,3SLS} \end{pmatrix} = \begin{pmatrix} [\,-2.1798 \;\; 5.1858 \;\; 79.0964 \;\; -0.0379 \;\; 0.0197\,]' \\ [\,-0.2861 \;\; 0.1357 \;\; 1.0691 \;\; -0.2040 \;\; 0.0734\,]' \\ [\,-0.0891 \;\; 0.0031 \;\; -0.0204 \;\; -0.1282 \;\; 0.0180 \;\; -0.1234\,]' \end{pmatrix} \tag{48}$$

The estimated standard errors of 3SLS estimates can be obtained by the square root of the diagonal elements from $\left\{\mathbf{Z}'\mathbf{X}_I[\mathbf{X}_I'(\widehat{\boldsymbol{\Sigma}} \otimes \mathbf{I}_T)\mathbf{X}_I]^{-1}\mathbf{X}_I'\mathbf{Z}\right\}^{-1}$ is

$$\begin{pmatrix} \text{s.e.}(\hat{\boldsymbol{\delta}}_{1,3SLS}) \\ \text{s.e.}(\hat{\boldsymbol{\delta}}_{2,3SLS}) \\ \text{s.e.}(\hat{\boldsymbol{\delta}}_{3,3SLS}) \end{pmatrix} = \begin{pmatrix} [\,2.8660 \;\; 0.7857 \;\; 62.5301 \;\; 0.0592 \;\; 0.0421\,]' \\ [\,0.3626 \;\; 0.0194 \;\; 9.1971 \;\; 0.0841 \;\; 0.0311\,]' \\ [\,0.0909 \;\; 0.0013 \;\; 0.0071 \;\; 0.0501 \;\; 0.0095 \;\; 0.0938 \;\; -0.1234\,]' \end{pmatrix} \tag{49}$$

As before, the system GMM estimator with instruments matrix $\mathbf{X}_I$, the moment conditions of this system (45) is

$$\mathbb{E}(\mathbf{X}_I\mathbf{u}) = \Big(\; \mathbb{E}[\mathbf{X}'(\mathbf{y}_1 - \mathbf{Z}_1\boldsymbol{\delta}_1)] \;\; \mathbb{E}[\mathbf{X}'(\mathbf{y}_2 - \mathbf{Z}_2\boldsymbol{\delta}_2)] \;\; \mathbb{E}[\mathbf{X}'(\mathbf{y}_3 - \mathbf{Z}_3\boldsymbol{\delta}_3)] \;\Big)' = \mathbf{0}.. \tag{50}$$

The system GMM estimator based on the moment conditions (54) minimizes the following quadratic function:

$$Q\left[\begin{pmatrix} \boldsymbol{\delta}_1 \\ \boldsymbol{\delta}_2 \\ \boldsymbol{\delta}_3 \end{pmatrix}\right] = \begin{pmatrix} (\mathbf{y}_1 - \mathbf{Z}_1\boldsymbol{\delta}_1)\mathbf{X}' \\ (\mathbf{y}_2 - \mathbf{Z}_2\boldsymbol{\delta}_2)\mathbf{X}' \\ (\mathbf{y}_3 - \mathbf{Z}_3\boldsymbol{\delta}_3)\mathbf{X}' \end{pmatrix}' \begin{pmatrix} \widehat{\mathbf{W}}_{11} & \widehat{\mathbf{W}}_{12} & \widehat{\mathbf{W}}_{13} \\ \widehat{\mathbf{W}}_{21} & \widehat{\mathbf{W}}_{22} & \widehat{\mathbf{W}}_{23} \\ \widehat{\mathbf{W}}_{31} & \widehat{\mathbf{W}}_{32} & \widehat{\mathbf{W}}_{33} \end{pmatrix} \begin{pmatrix} \mathbf{X}'(\mathbf{y}_1 - \mathbf{Z}_1\boldsymbol{\delta}_1) \\ \mathbf{X}'(\mathbf{y}_2 - \mathbf{Z}_2\boldsymbol{\delta}_2) \\ \mathbf{X}'(\mathbf{y}_3 - \mathbf{Z}_3\boldsymbol{\delta}_3) \end{pmatrix} \tag{51}$$

We can apply the estimates of 2SLS estimation with instruments $\mathbf{X}$ in each equation to obtain the sample residuals $\hat{\mathbf{u}}_j = \mathbf{y}_j - \mathbf{Z}_j\hat{\boldsymbol{\delta}}_{j,2SLS}$. The optimal weighting matrix of $\widehat{\mathbf{W}}_{ij}$ can be constructed by using the Newey-West estimation to estimate the variance matrix of sample mean of moment conditions. Then, the corresponding vector of system GMM estimates that minimizes this quadratic function (51) based on BFGS algorithm is

$$\begin{pmatrix} \hat{\boldsymbol{\delta}}_{1,\mathrm{GMM}} \\ \hat{\boldsymbol{\delta}}_{2,\mathrm{GMM}} \\ \hat{\boldsymbol{\delta}}_{3,\mathrm{GMM}} \end{pmatrix} = \begin{pmatrix} [\,-1.0786 \;\; 4.9479 \;\; 37.6671 \;\; -0.0333 \;\; 0.0129\,]' \\ [\,-0.5014 \;\; 0.1185 \;\; 10.9065 \;\; -0.3181 \;\; 0.1028\,]' \\ [\,-0.1235 \;\; 0.0008 \;\; -0.0060 \;\; -0.1364 \;\; 0.0209 \;\; -0.1078\,]' \end{pmatrix} \tag{52}$$

and the corresponding asymptotic variance of GMM estimator can be obtained by $\mathbf{V}_T = \{\mathbf{D}'\widehat{\mathbf{W}}^{-1}\mathbf{D}\}^{-1}$. Here, $\mathbf{D}$ is the transpose of the Jacobian matrix of moment conditions in Equation (50) evaluated at GMM estimates, and $\widehat{\mathbf{W}}$ is the optimal weighting matrix of this system. the vector for the estimated standard errors of system GMM estimates obtained from the square root of diagonal elements of $\mathbf{V}_T$ is

$$\begin{pmatrix} \mathrm{s.e.}(\hat{\boldsymbol{\delta}}_{1,\mathrm{GMM}}) \\ \mathrm{s.e.}(\hat{\boldsymbol{\delta}}_{2,\mathrm{GMM}}) \\ \mathrm{s.e.}(\hat{\boldsymbol{\delta}}_{3,\mathrm{GMM}}) \end{pmatrix} = \begin{pmatrix} [\,2.4437 \;\; 0.8378 \;\; 57.0179 \;\; 0.0648 \;\; 0.0346\,]' \\ [\,0.2703 \;\; 0.0179 \;\; 6.9756 \;\; 0.0772 \;\; 0.0309\,]' \\ [\,0.0837 \;\; 0.0007 \;\; 0.0041 \;\; 0.0429 \;\; 0.0082 \;\; 0.1032\,]' \end{pmatrix} \tag{53}$$

For example, the OLS estimator in the investment equation is $\hat{\alpha} = (\mathbf{Z}_1'\mathbf{Z}_1)^{-1}\mathbf{Z}_1\mathbf{y}_1$, namely $\mathbf{y}_j = \Delta\mathbf{Inv}$ and $\mathbf{Z}_1 = [\,\mathbf{1}\ \Delta\mathbf{Div}\ \Delta\mathbf{Debt}\ \mathbf{Inv}_{-1}\ \mathbf{Q}\,]$.

Hence, the resulting OLS estimates of investment equation are

$$\begin{pmatrix} \hat{\alpha}_1 \\ \hat{\alpha}_2 \\ \hat{\alpha}_3 \\ \hat{\alpha}_4 \\ \hat{\alpha}_5 \end{pmatrix} = \begin{pmatrix} 47.0000 & -2.6068 & 0.5292 & 1450.8413 & 3876.1612 \\ -2.6068 & 143.6629 & -0.2300 & -482.8651 & 402.7128 \\ 0.5292 & -0.2300 & 0.0674 & 21.7584 & 57.6402 \\ 1450.8413 & -482.8651 & 21.7584 & 57669.2721 & 127304.6882 \\ 3876.1612 & 402.7128 & 57.6402 & 127304.6882 & 354485.4669 \end{pmatrix}^{-1} \begin{pmatrix} -52.8683 \\ 574.2510 \\ -2.1041 \\ -4038.9888 \\ -0.2784 \end{pmatrix} = \begin{pmatrix} -5.5650 \\ 3.0264 \\ -27.8209 \\ -0.1492 \\ 0.1155 \end{pmatrix}$$

This table presents the summary statistics where we show the mean, median, first quartile, third quartile, and the standard deviation of each variable from 1965 to 2012. Only firms that survive 30 years or longer are included in the sample. These exclusions leave us with complete information for 564 firms. *N* is the number of firm-year observations. The sample consists of 22,492 firm-year observations from annual Compustat files, excluding financial and regulated firms. *Inv* denotes net property, plant, and equipment. *Div* denotes dividends. Both *Inv* and *Div* are measured on a per share basis. *Debt* refers to book leverage, defined as the ratio of total liabilities to total assets. All variables are winsorized at the 1st and 99th percentiles to avoid the influence of extreme observations.

Table 2 Results of 2SLS

Independent Variables \ Dependent Variables	ΔInv_{it}	ΔDiv_{it}	$\Delta Debt_{it}$
Constant	0.200 (1.77)	0.033 (5.95)	0.081 (10.27)
$Inv_{i,t-1}$	-0.296 (-28.43)		
$Div_{i,t-1}$		-0.224 (-28.35)	
$Debt_{i,t-1}$			-0.287 (-35.06)
ΔInv_{it}		0.046 (19.71)	0.012 (7.52)
ΔDiv_{it}	6.664 (6.51)		-0.096 (-6.80)
$\Delta Debt_{it}$	10.772 (8.35)	0.246 (2.87)	
Q_{it}	0.085 (14.31)		
P_{it}		0.039 (19.93)	
$\ln A_{i,t-1}$			0.011 (8.83)
$E_{i,t-1}/A_{i,t-1}$			-0.101 (-6.39)
Adjusted R-squares	0.53	0.49	0.15

This table presents the 2SLS regression results of a simultaneous equation system model for investment, dividend, and debt financing:

$\Delta Inv_{it} = \alpha_{1i} + \alpha_{2i}\Delta Div_{it} + \alpha_{3i}\Delta Debt_{it} + \alpha_{4i}Inv_{i,t-1} + \alpha_{5i}Q_{it} + \epsilon_{it}$,

$\Delta Div_{it} = \beta_{1i} + \beta_{2i}\Delta Inv_{it} + \beta_{3i}\Delta Debt_{it} + \beta_{4i}Div_{i,t-1} + \beta_{5i}P_{it} + \eta_{it}$,

$\Delta Debt_{it} = \gamma_{1i} + \gamma_{2i}\Delta Inv_{it} + \gamma_{3i}\Delta Div_{it} + \gamma_{4i}Debt_{i,t-1} + \gamma_{5i}\ln A_{i,t-1} + \gamma_{6i}(E_{i,t-1}/A_{i,t-1}) + \xi_{it}$.

The coefficients are shown in averages across the 564 firms. Regressions are based on non-missing observations and winsorization at the 1st and 99th percentiles. The three endogenous variables are ΔInv_{it} , ΔDiv_{it} , and $\Delta Debt_{it}$, which are the change in net plant and equipment, the change in dividends, and the change in book leverage ratio, respectively. The independent variables in the investment regression are lagged investment ($Inv_{i,t-1}$), and sales plus change in inventories (Q_{it}). The independent variables in the dividend regression are lagged dividends ($Div_{i,t-1}$), and net income before extraordinary items plus depreciation minus preferred dividends (P_{it}). All the variables in both of investment and dividend equations are measured on a per share basis. The independent variables in the debt financing regression are lagged book leverage ($Debt_{i,t-1}$), natural logarithm of lagged total assets ($\ln A_{i,t-1}$), and the lag of earnings before interest and taxes divided by total assets ($E_{i,t-1}/A_{i,t-1}$). Numbers in the parentheses are t-statistics.

Table 3 Results of 3SLS

P_{it}		0.033 (18.84)	
$\ln A_{i,t-1}$			0.009 (8.12)
$E_{i,t-1}/A_{i,t-1}$			-0.087 (-6.15)
Adjusted R-squares	0.38	0.36	-0.23

This table presents the GMM regression results of a simultaneous equation system model for investment, dividend, and debt financing:

$\Delta Inv_{it} = \alpha_{1i} + \alpha_{2i}\Delta Div_{it} + \alpha_{3i}\Delta Debt_{it} + \alpha_{4i}Inv_{i,t-1} + \alpha_{5i}Q_{it} + \epsilon_{it}$,

$\Delta Div_{it} = \beta_{1i} + \beta_{2i}\Delta Inv_{it} + \beta_{3i}\Delta Debt_{it} + \beta_{4i}Div_{i,t-1} + \beta_{5i}P_{it} + \eta_{it}$,

$\Delta Debt_{it} = \gamma_{1i} + \gamma_{2i}\Delta Inv_{it} + \gamma_{3i}\Delta Div_{it} + \gamma_{4i}Debt_{i,t-1} + \gamma_{5i}\ln A_{i,t-1} + \gamma_{6i}(E_{i,t-1}/A_{i,t-1}) + \xi_{it}$.

Panel A shows the coefficients in averages across the 564 firms. Regressions are based on non-missing observations and winsorization at the 1st and 99th percentiles. The three endogenous variables are ΔInv_{it} , ΔDiv_{it} , and $\Delta Debt_{it}$, which are the change in net plant and equipment, the change in dividends, and the change in book leverage ratio, respectively. The other variables are the same as in Table 1. Panel B shows the average standardized coefficients of speed-of-adjustment across the firms, that is, the coefficients of lagged investment, dividend, and debt financing. The standardized coefficient is calculated by multiplying the unstandardized coefficient by the ratio of the standard deviation of the independent variable (i.e. the lagged terms) to the standard deviation of dependent variable. Numbers in the parentheses are t-statistics.

Abstract

This paper examines the impact of board characteristics including size, composition, and CEO duality, on both accounting and market performance of Vietnamese publicly listed companies for a sample of 293 listed firms on the Ho Chi Minh Stock Exchange (HOSE) during 2012. The result shows that market – based performance is negatively affected by board size is consistent with Yermack (1996) and Eisenberg et al. (1998). It reveals that companies with larger board of directors report poorer market performance. Another interesting finding indicates that Vietnamese market seems not to be concerned about single leadership structure as the mean value of both market and financial performance are not statistically different for single and dual leadership groups. In addition, the relationship between ratio of independent director and the market valuation is positive but not statistically significant. The impact of financial leverage, firm size, and firm age on company efficiency is also confirmed.

1. Introduction

Over the last few decades, corporate governance has been becoming a worldwide mounting concern caused by a series of major events, e.g. Asian currency crisis during 1997 - 1998, collapse of some corporate giants due to fraud in corporate governance such as Enron, Tyco, WorldCom in 2001 - 2002. In addition, corporate governance is one of crucial factors affecting decision of investors according to a survey conducted by McKinsey in 2002. Its result of this survey also showed that good practice of corporate governance will help firms improve access to capital markets and reduce operating costs, thereby creating competitive advantage. This is the reason why corporate governance is now the centre of worldwide public attention, from government, media to investors and shareholders.

Within corporate governance framework, board of directors plays a central role as they are responsible for devising and overseeing company strategies, as well as controlling over management on behalf of the General Assembly of Shareholders (IFC, 2010). Its efficient operation is dependent upon various factors such as board size, structure, diversity of skills, experience and gender of board members. However, results of previous empirical studies on the impact of board characteristics upon firm performance were inconsistent, even contradictory.

To the best of our knowledge, there is no formal study by this time in Vietnam on the impact of board characteristics on the efficiency of company operation published on specialized journals. With the aim of filling this research gap and contributing more empirical evidence of emerging markets, this study tests hypotheses on the relationship between the size of the board, the presence of independent directors, leadership structure and the performance of Vietnamese publicly listed companies measured by both profitability ratio – ROE and market index – Tobin's Q.

2. LITERATURE BACKGROUND AND HYPOTHESES

2.1. *Relationship between board size and firm performance*

Jensen (1993) indicated that a small size will help the board operate more efficiently as increasing group size makes board members become inefficient because problems stemming from cooperation exceed benefits it could bring. In the case of larger board size, all board members will not be at their best to bring benefits to shareholders, then free - rider problem will occur and reduce efficiency of the whole board. In addition, coordination and communication problems arise and cause slower and less – efficient decision making (Lipton and Lorsch, 1992). In fact, the inverse relationship between board size and its efficiency has been empirically verified by Yermack (1996), Eisenberg, Sundgren, and Wells (1998). However, Pfeffer (1972), Zahra and Pearce (1989), and Dalton and Dalton (2005) presented a completely opposite standpoint about the impact of board size on firm performance. They argued that larger board size leads to a wide diversity in experience, skills and expertise which will facilitate the process of making rational strategic decisions, thereby bringing added value to shareholders (Dalton and Dalton, 2005). Moreover, the presence of independent or non –

executive directors in larger board is expected to reduce their dependency upon the CEO and provide better monitoring. Actually, few previous empirical studies demonstrated this positive correlation, e.g. Mak and Li (2001) and Adams and Mehran (2005)'s research. Besides empirical evidences supporting these two foregoing opposing views, some studies could not find any solid evidence to confirm the relationship between board size and the firm performance.

In brief, the majority of empirical studies into board size found that smaller board size would have better economic results. Large board is believed to function inefficiently and consume more operating cost. Planning, collaboration, making decision and arranging board meetings will become more difficult as the size of board increases. Based on the foregoing standpoint, the hypothesis H1 on the relationship between board size and firm performance is proposed:

H1: There is a negative impact of board size on firm performance.

2.2. *Relationship between board composition and firm performance*

Most theoretical studies have supported the viewpoint that an efficient board should have high rate of independent directors (Lorsch and MacIver, 1989; Mizruchi, 1983; Zahra and Pearce, 1989). This perspective stems from the theory of agency problem between shareholders and management. The separation between ownership and control in listed company causes asymmetric information between executives who directly manage all daily activities and gain complete access to all necessary information, and its shareholders who are indeed the owners but suffer a lack of company information. Being driven by self – interest, executives tend to prioritize their self – serving activities which could be harmful to shareholders' welfare (Mizruchi, 1983). Therefore, the monitoring role of independent board members is extremely important because it minimizes the self - interested actions by managers. In addition, skills, knowledge, business and managerial expertise, and objective standpoint that outside independent directors provide will improve quality and objectivity of board decision, thus bring benefits to the company. Some empirical evidences, which were found through studies of Baysinger and Butler (1985), Black, Jang and Kim (2006), and Dahya, Dimitrov and McConnell (2008), advocate the foregoing viewpoint. However, other studies including Daily and Dalton (1992; 1993), Kesner Victor and Lamont (1986), Mak and Kusnadi (2005) could not find any relationship between the number of outside independent directors and efficiency in company operation.

In summary, serving the role of active monitoring and providing objective judgments, independent board members are believed to improve board effectiveness, thus enhance firm value as well as promote welfare of shareholders. Based on the theoretical viewpoint about benefits from the presence of independent board members, this study proposes and tests the second hypothesis as follows:

H2: There is a positive impact of the proportion of independent board members on firm performance.

2.3. *Relationship between leadership structure and firm performance*

The state that CEO and chairman of the board are the same person is objected by scholars who advocate the theory of agency problem because this single leadership structure excessively empowers CEO, reduces board efficiency in oversight and monitoring role, and rises agency cost (Fama and Jensen, 1983; Rechner and Dalton, 1991; Finkelstein and D'Aveni, 1994). Moreover, it will make the information asymmetry existing between shareholders and managers worsen as CEO could abuse his power for self – serving activities and conceal similar actions of the executive board. In addition, it will be extremely difficult for other board members to deliver objective opinions to debate in board room. As a result, this leadership structure would negatively influence the board process of making decision. In contrast, if two roles are separated, there will be a difference in standpoint between chairman and CEO. Debate and constructive criticisms will help both board of directors and executives reach the most rational decision and reconcile interests of all related parties (Hung and Thang, 2012). In fact, the inverse relationship between CEO duality and board effectiveness was evidenced by studies of Rechner and Dalton (1991) and Pi and Timme (1993).

Contrary to agency theory, stewardship theory supports the occurrence of CEO duality. It proposes that managers are stewards of the company and they will work diligently for greatest benefits of the company and its shareholders (Donaldson and Davis, 1994). Having access to all information regarding company daily activities, CEO will help board of directors come to informed strategic decisions, facilitate and hasten the decision – making process (Thanh, 2012). In the case of dual leadership structure, it will take considerable time for the CEO to obtain board approval in order to adjust company strategy, thus leading to inflexibility and letting the company miss many golden opportunities (Hung and Thang, 2012). Furthermore, the fact that CEO duality prevents conflicts between Chairman and the head of management board and improves the understanding between executives and board members, is expected to enhance board efficiency. The positive impact of single leadership structure on company profitability was supported by experimental evidences of Donalson and Davis (1991) and Peng, Zhang and Li (2007). Nevertheless, there are still many research results could not confirm the relationship between CEO duality and financial measures (Berg and Smith, 1978; Daily and Dalton, 1992; Rechner and Dalton, 1989).

Although current Vietnamese law does not include code arguing explicitly against the concurrence of the CEO and Chairman position, relating bylaws tend to be in favor of the separation of these two crucial positions (Hung and Thang, 2012). Based on agency theory, the third hypothesis of this study is proposed as follows:

H3: *There is a negative impact of single leadership structure on firm performance.*

3. RESEARCH METHODS

3.1. *Data description*

This study gathers data of 330 publicly listed companies on Ho Chi Minh Stock Exchange (HOSE) on December 28th 2012. After eliminating firms with missing data and outliers, the final sample consists of 293 listed firms, accounting for 76.48% of the HOSE market capitalization at this point of time.

The main source is corporate governance documents that are publicly available on company website. They include annual report and annual financial statement, the two most important documents. Listing date and closed share price of each listed firm on December 28th 2012 were collected from reliable websites, namely http://www.cophieu68.vn, http://www.cafef.vn, and www.vietstock.vn. Also, disclosure on independent board members, ownership percentage and transaction announcements of major shareholders published on these websites and the official website of Ho Chi Minh Stock Exchange greatly assist in verifying the independence status of board members when annual report could not provide sufficient information.

3.2. *Research model*

Rashid et al (2010) developed a model to verify the relationship between board characteristics and firm performance in Bangladesh. Bangladesh is a country in South Asia and listed as an emerging market, similar to Vietnam (IFC, 2013). Our study will use this model to test the three hypotheses on the impact of board characteristics upon performance of publicly listed companies in Vietnam.

Model 1:

$$\mathrm{Q} = \alpha + \beta_1 \times \mathrm{LnBDSize} + \beta_2 \times \mathrm{BDComp} + \beta_3 \times \mathrm{CEOD} + \beta_4 \times CR$$
$$+\beta_5 \times \mathrm{Debt} + \beta_6 \times \mathrm{LnFirmSize} + \beta_7 \times \mathrm{LnFirmAge} + \varepsilon$$

and Model 2:

$$\mathrm{ROE} = \alpha + \beta_1 \times \mathrm{LnBDSize} + \beta_2 \times \mathrm{BDComp} + \beta_3 \times \mathrm{CEOD} + \beta_4 \times CR$$
$$+\beta_5 \times \mathrm{Debt} + \beta_6 \times \mathrm{LnFirmSize} + \beta_7 \times \mathrm{LnFirmAge} + \varepsilon$$

Where:

- Q is Tobin's Q ratio, proxy for market measure of firm performance. Tobin's Q is defined as ratio of sum of total market value of equity and book value of total debt to book value of total assets. In greater detail, market value of equity is the market capitalization of each company on December 28^{th} 2012.
- ROE is return on equity, represents accounting measure of firm performance, and is calculated as the ratio of profit after tax to book value of equity.
- BDSize represents board size, measured by the number of board members disclosed in annual report. Article 1, Section 2, Circular 121/2012 / TT-BTC has specified the minimum of 3 and the maximum of 11 people per board of directors in Vietnam.
- BDComp represents board structure, defined by the proportion of independent directors. Article 30, Section 2, Circular 121/2012 / TT-BTC has required that at least 1/3 of board members are independent directors. Definition of independent directors used in this study is based on Article 2, Section 3 of the Circular 121/2012 / TT-BTC.

- CEOD represents the status of CEO Duality. This dummy variable equals 1 if there is single leadership structure, and equals 0 if there is dual leadership structure.
- CR represents the percentage of shares owned by major shareholders. As defined in Article 6, Section 9 of the Law on Securities (2006), a major shareholder is who owns, directly or indirectly, 5% or more of the voting shares of the company.
- Debt is a critical control variable, measured by the ratio of book value of total debt to book value of total assets.
- LnFirmSize represents firm size, based on logarithm of company's market capitalization on December 28th 2012.
- LnFirmAge represents firm age, defined by the number of years listing on the Ho Chi Minh Stock Exchange.
- ε is residual term.

Table 1 – Descriptive statistics

	N	Minimum	Maximum	Mean	Std. Deviation	Skewness		Kurtosis	
	Statistic	Statistic	Statistic	Statistic	Statistic	Statistic	Std. Error	Statistic	Std. Error
ROE	293	-.60	.46	.0831	.13135	-.936	.142	3.584	.284
Q	293	.42	3.94	.9044	.30251	4.188	.142	35.118	.284
LnBDSize	293	1.39	2.40	1.7251	.19130	1.077	.142	.533	.284
BDComp	293	.0000	.6000	.078596	.1328229	1.661	.142	2.124	.284
CEOD	293	.0	1.0	.358	.4803	.594	.142	-1.659	.284
CR	293	.0000	.9775	.542144	.2124678	-.341	.142	-.419	.284
Debt	293	.0029	.9613	.515445	.2136460	-.199	.142	-.762	.284
LnFirmSize	293	1.8414	11.2031	5.747210	1.5159287	1.078	.142	1.871	.284
LnFirmAge	293	.0000	2.4849	1.107055	.6552441	-.149	.142	-.798	.284

4. REGRESSION ANALYSIS

Table 2 – One – way ANOVA for CEO Duality variable

ANOVA

Tobin's Q

	Sum of Squares	df	Mean Square	F	Sig.
Between Groups	.063	1	.063	.686	.408
Within Groups	26.658	291	.092		
Total	26.721	292			

ROE

	Sum of Squares	df	Mean Square	F	Sig.
Between Groups	.003	1	.003	.170	.681
Within Groups	5.035	291	.017		
Total	5.038	292			

Before running the regression model, we use the analysis of variance (ANOVA) to test whether there is any difference between dual and single leadership groups. The result shows that there is no significant difference in ROE and Tobin'Q between single leadership firm and other. This result reveals that the concern about CEO duality is not an issue at the emerging market in Vietnam. Therefore, hypothesis H3 is rejected as single leadership structure does not have significant impact on both accounting and market performance. As a result, variable CEOD is excluded from our models. After ANOVA test, our models are revised as the following:

Model 1:

$$\mathrm{Q} = \alpha + \beta_1 \times \mathrm{LnBDSize} + \beta_2 \times \mathrm{BDComp} + \beta_3 \times CR + \beta_4 \times \mathrm{Debt} \\ + \beta_5 \times \mathrm{LnFirmSize} + \beta_6 \times \mathrm{LnFirmAge} + \varepsilon$$

and Model 2:

$$\mathrm{ROE} = \alpha + \beta_1 \times \mathrm{LnBDSize} + \beta_2 \times \mathrm{BDComp} + \beta_3 \times CR + \beta_4 \times \mathrm{Debt} \\ + \beta_5 \times \mathrm{LnFirmSize} + \beta_6 \times \mathrm{LnFirmAge} + \varepsilon$$

Adjusted R2 of first model is 0.282, indicating that the model explains 28.2% of the variation in response variable, Q. Similarly, this goodness – of – fit measure of second model says that 21.8% of the variation in ROE is explained by independent variables. The p – value of F test in both models are approximately 0, which confirms their overall significance. Hence, our sample regression model could serve as a good proxy for the population regression models.

The regression results show that board size is negatively related to Tobin's Q ratio at significance level of 5%. This inverse relationship advocates the standpoint in favor of smaller board size. Larger board would lead to inefficient operation due to cooperation and communication problems arising among board members. In addition, firm has to pay more cost to maintain board operation if the number of board members augments. So, an increase in board size would result in a reduction in firm performance represented by market measure. With regards to the second model, the negative relationship between board size and profitability is not statistically significant because Sig value is greater than 10%. One of the most important duties of board is devising strategy and providing direction. As a result, the board usually focuses on long – term goals instead of short – term goals in order to ensure the company sustainable development and long – term interests of shareholders. Therefore, board efficiency could be reflected more accurately in market index of the company than in accounting performance of current fiscal year. This is the reason why board size and ROE do not have any correlation. Briefly, hypothesis H1 is accepted as the inverse relationship between board size and Tobin's Q has been found.

The effect of board independence on firm performance is ambiguous. In fact, the proportion of independent board members has a positive relationship with company efficiency measured by market index with regression coefficient 0.015. Meanwhile, the correlation between board independence and accounting performance is found to be negative. Nonetheless, these results are not statistically significant due to Sig. values are greater than 10%. Therefore, there is no empirical evidence that increasing level of board independence would lead to improvement of company performance. This finding partly reveals that, as the condition of significance level is not satisfied, the presence of independent directors in Vietnam has not contributed significantly to the company economic value yet. In fact, our sample data in 2012 reveals that in Vietnam, independent directors who strictly satisfy all requirements in Article 2, Section 3 of Circular

121/2012/TT-BTC were very scarce. As a matter of fact, independent members are often chosen from major shareholders, investment funds, strategic partners, family members of executives, or having managerial role at subsidiaries of the listed firm (Hai Li, 2010). As they are only nominally independent, independent directors cannot perform well their oversight and monitoring role and voice objective criticism. Besides, the majority of independent directors in developing countries like Malaysia and Vietnam did not undertake any official corporate governance training (Haniffa and Hudaib, 2006). Consequently, they have not been aware of their important role in corporate governance system, thus not fulfilling their duty. To sum up, findings show that there is no relationship between ratio of independent directors and firm performance, which makes hypothesis H2 rejected.

Our regression results suggest that CR, proxy for concentration ratio of listed firms, has a positive influence on both Tobin's Q and ROE although its coefficients are not statistically significant. Actually, major shareholders have more power and motivation to exercise controlling rights than minor shareholders do. Their active control of management prevents fraud as a result, thereby reducing agency cost in listed firms. Besides, positive relation between firm size and firm performance indicate that larger firms tend to achieve higher profitability and better market results thanks to their financial strength and ability of diversification. In contrast, the negative effect of firm age on market performance is found at significance level of 5%. It indicates that firms getting older encounter difficulties retaining creative people and their innovative ideas. In addition, according to O'Connor & Byrne (2006), mature firms tend to devote more resources to value preservation than to value creation. The lack of innovative strategies of mature firms makes them less attractive to investors who are usually motivated to gain rewards from innovative projects quickly. The relationship between debt ratio and firm performance is significantly negative in the first model. As our sample consists data of the year 2012, when Vietnamese market has not recovered yet from the global financial crisis 2007 – 2009, this result suggests that the more a firm is heavily in debt, the worse its performance is because this mounting debt reveals bad things of its financial health during the post – recession period.

5. CONCLUSION

In conclusion, the inverse relationship between board size and market performance of firm indicates that an increase in number of board members will reduce efficiency of board operation and lower company market value. CEO duality is also demonstrated to not to have any impact on both Tobin's Q and ROE ratio. It reveals the truth that single leadership structure seems not to be a serious concern of investors in Vietnamese market.

have positive impact on Tobin's Q at high significance level. This finding is against agency theory which advocates the separation between CEO and Chairman position, and contributes an empirical evidence supporting stewardship theory.

In addition, insignificant coefficients of ratio of independent directors in both models suggest that independent members of board in Vietnam currently do not have any remarkable contribution to company economic value as their independence status is not reliable and they are still not fully aware of their crucial role in corporate governance system. Besides, the comprehensive definition of an independent director was officially disclosed recently in Circular 121/2012 / TT-BTC which has taken effect since September 17th 2012. As a result, there was hardly any independent directors who could meet all requirements in the year of 2012. Hence, the impact of them on firm performance could not be measured accurately in this study.

To sum up, variables of board characteristics have clearer relationship with market ratio than with accounting measure. In fact, relations between board characteristics and ROE are almost not statistically significant. Thus, good corporate governance practices do not necessarily lead to higher profitability in short – term but numerous non – financial benefits, e.g. reputation, credibility, and investor confidence. These advantages brought by implementing good corporate governance will make listed firms become more attractive to both domestic and international investors and help them facilitate access to worldwide low – cost capital (IFC, 2010) to develop sustainably and bring long – term benefits to shareholders. Because of foregoing reasons, influence of board characteristics on market – based performance is observed clearly.

Notwithstanding several contributions that this study makes to the literature, especially impact of board size on market – based measures, it has a number of limitations which would represent further research opportunities.

Firstly, time – series data should be incorporated into sample of future studies to track the market perception over years. Actually our study only includes only cross – sectional observations for the year 2012, when Vietnam economy has not recovered yet from the global recession. This period of economic hardship has still adversely influenced operating performance and market value of firms. In fact, in our sample, 12.3% companies report negative ROE and 77.1% have Tobin's Q ratio less than 1.

Secondly, extensive investigations including publicly listed companies on the Hanoi Stock Exchange (HNX) would confirm the relationship between board characteristics and firm performance in the entire Vietnam stock market. Also, future research could incorporate data of longer period of time rather than focus on only cross – sectional observations for 2012 as current study does in order to examine the impact of corporate governance variables on mid – term and long – term corporate performance.

Thirdly, future research could include variables measuring quality of board operation, e.g. number of board meetings during a year, attendance ratio of directors, as well as active participation of independent directors in board meetings. The inclusion of these corporate governance variables is expected to ameliorate the goodness – of – fit statistic of the model and enhance our understanding of corporate governance mechanism and its actual effectiveness in publicly listed companies.

Last but not least, other control variables, for example industry and board and executives ownership, should be introduced to the model in order to improve fit measures. Last but no least, board of directors is an endogenous corporate governance factor according to Hermalin and Weisbach (2003) and Bhagat and Black (2000). So, future studies may test the link by using the method of Instrumental Variables (IV) or Simultaneous – Equation Method (SEM) to eliminate biases caused by endogenous variables.

Marginal Effects of Factors on the Unconditional Distribution of Financial Literacy in Taiwan

Zhi-fang Su
College of Economics and Finance Huaqiao University

Yu-Jen Hsiao
Department of Finance National Dong Hua University

Mei-Yuan Chen
Department of Finance National Chung Hsing University

In this paper, the marginal effects of factors on the unconditional distribution of financial literacy in Taiwan is investigated with the unconditional quantile estimation suggested by Firpo, et al (2009). Factors include higher education status, ratios of male/female, married/unmarried, urban/non-urban individuals are considered. Our empirical data is collected from three surveys on 2007, 2009, and 2011 conducted by Financial Supervisory Commission, R.O.C. Totally, there are 3155 individuals randomly selected and surveyed, 1005 on 2007, 919 on 2009, and 1231 on 2011. Applying the factor analysis suggested by van Rooij, et al (2011), the financial literacy is computed from 18 questionnaires about the knowledge of management on cash, savings, credit, and loans. Our empirical results conclude: 1. Incre- ment of the higher education not only increases the obtainment of financial literacy (since the mean becomes larger after the increase of higher education) but also decreases the dispersion of financial literacy distribution. This conclusion provides an evidence to support the policy of higher education expansion. Besides, the unconditional financial literacy distribution be- comes more skew to the left after the increase of higher education. 2. The marginal effects of ratio of male/female on the unconditional literacy distribution are negative and statistically significant at all quantiles except at extreme quantiles. This indicates the access of financial literacy is easier to female individuals relative to the males. The unconditional financial lit- eracy distribution changes from skew to the right to skew to the left after the increase of the ratio of males. 3. The marginal effects of ratio of married individuals on the unconditional literacy distribution are also negative and statistically significant at all quantiles. This indi- cates the access of financial literacy is easier to unmarried individuals relative to the married ones. The unconditional literacy distribution changes from skew to the right to skew to the left after the increase of the ratio of married individuals. 4. The marginal effects of ratio of individuals live at urban area on the unconditional literacy distribution are statistically insignificant negative at all quantiles.

Keywords Financial literacy, Recentered Influence Function, Unconditional Quantile Estimation

JEL Classification: C12, C46.

1 Introduction

Over the last few decades, financial development has introduced sophisticated financial instruments that require advanced skills for proper use. Marcolin and Abraham (2006) points out that financial literacy skills have been crucial for individuals being able to navigate the financial world. Financial literacy defined in Noctor, et al (1992) is as "the ability to make informed judgments and to take effective decisions regarding the use and management of money." More and more literature has emphasized the effects of financial literacy on household wealth accumulation (Behrman, et al (2012)), on retirement preparedness (Lusardi and Mitchell (2007)). van Rooij, et al (2011) finds that financial literacy is positively correlated with the access of financial markets and investment in stocks. At the macroeconomic level, Jappelli (2010) shows that the ability to reap the benefits of new investment opportunities and participate in financial markets depends crucially on economic literacy. Prete (2013) finds that income inequality grows less in countries where economic literacy is higher, and that financial development is negatively correlated to inequality growth. It is clear that both economic and financial literacy have significant positive effects on the financial market development in macro level and wealth accumulation in micro level. On the other hand, Carlin and Robinson (2012) emphasizes the role of financial education to improve the access of financial literacy. The financial education is provided mostly by the higher education system. Consequently, the acceptance of financial literacy should be positively correlated with the expansion of higher education system in mean level. The marginal effect of the change of proportion of higher educated people on the distribution of the access of financial literacy in Taiwan is investigated in Su, Hsiao, and Chen (2015).

In this paper, the marginal effects of factors on the "unconditional" distribution of financial literacy in Taiwan is studied with the unconditional quantile estimation suggested by Firpo, et al (2009). The factors we consider include higher education status, ratios of male/female, married/unmarried, urban/non-urban individuals. Section 2 introduces the unconditional quantile estimations comprehensively. Using a sample data from the survey conducted by the Financial Supervisory Commission, R.O.C. in 2007, 2009, and 2011, section 3 conducts the empirical study. Section 4 makes the conclusions and suggestions.

2 Unconditional Quantile Estimation

Let random variables $(Y,\boldsymbol{X})$ be defined on the sample space Ω as

$$(Y,\boldsymbol{X}):\Omega\to\mathcal{R}\times\mathcal{R}^k,$$

with joint CDF $F_{Y,\boldsymbol{X}}$. The conditional CDF of Y on $\boldsymbol{X}$ is denoted as $F_{Y|\boldsymbol{X}}$, and the marginal CDFs of Y and $\boldsymbol{X}$ are F_Y and $F_{\boldsymbol{X}}$, respectively. The problem under investigated is how the interested statistic changes by the changing of F_Y due to alerting $\boldsymbol{X}$ a little, i.e., from $F_{\boldsymbol{X}}$ to $G_{\boldsymbol{X}}$ where $G_{\boldsymbol{X}}$ is close to $F_{\boldsymbol{X}}$. Given the new distribution $G_{\boldsymbol{X}}$ after the change, the unconditional distribution of Y moves to $G_Y = G_{Y|\boldsymbol{X}}\cdot G_{\boldsymbol{X}}$ where $G_{Y|\boldsymbol{X}}$ is the conditional CDF of Y on $\boldsymbol{X}$. It is clear that the changes from F_Y to G_Y arise from (1) the change from F_X to G_X and (2) the change from $F_{Y|\boldsymbol{X}}$ to $G_{Y|\boldsymbol{X}}$. To be simplified, Firpo, et al (2009) assumes the conditional distribution of Y on $\boldsymbol{X}$ keeps constant. That is $G_{Y|\boldsymbol{X}} = F_{Y|\boldsymbol{X}}$ is assumed and then the counterfactural distribution $G_Y^* = F_{Y|\boldsymbol{X}}\cdot G_{\boldsymbol{X}}$ is the new distribution of Y given $F_{\boldsymbol{X}}$ changes to $G_{\boldsymbol{X}}$ keeping $F_{Y|\boldsymbol{X}}$ constant. Consequently, the effect of little altering $\boldsymbol{X}$ on the interested statistic becomes $T(G_Y^*)-T(F_Y)$ where $T(G_Y^*)$ and $T(F_Y)$ are the interested statistics measured at distributions G_Y^* and F_Y.

Firpo, et al (2009) defines the *Recentered Influence Function* (RIF) as

$$RIF(y;T,F_Y)=T(F_Y)+\int IF(y;T,F_Y)d\triangle_y(y)=T(F_Y)+IF(y;T,F_Y),$$

where $IF(y;T,F_Y)$ denotes the *Influence Function* of the functional $T(F_Y)$ evaluated at y. It is easy to have

$$E[RIF(y;T,F_Y)]=\int RIF(y;T,F_Y)\,dF_Y(y)=\int[T(F_Y)+IF(y;T,F_Y)]dF_Y(y)=T(F_Y).$$

This indicates that any magnitude of interest can be seen as an expectation. Besides, by the fact of $F_Y(y)=\int F_{y|\boldsymbol{X}=\boldsymbol{x}}dF_{\boldsymbol{X}}(\boldsymbol{x})$,

$$T(F_Y)=E\{E[RIF(y;T,F_Y)|\boldsymbol{X}=\boldsymbol{x}]\},$$

the random variables $\boldsymbol{X}$ have been introduced through the law of iterative expectation.

2.1 The Marginal Effects of Altering $\boldsymbol{X}$

Suppose $F_{\boldsymbol{X}}$ changes marginally in the direction of $G_{\boldsymbol{X}}$. Assume $F_{Y|\boldsymbol{X}}$ stays constant and let $\alpha(T)$ be the vector of partial effects on T of moving each coordinate of $\boldsymbol{X}$ separately as a location shift. Then (under some regularity)

$$\alpha(T) = \int \frac{dE[RIF(T, F_Y)|\boldsymbol{X} = \boldsymbol{x}]}{dx} dF_{\boldsymbol{X}}(\boldsymbol{x}).$$

2.2 RIF of Quantiles and Unconditional Partial Effect

Let q_τ be the τth quantile of Y (unconditional), i.e., $T(F_Y) = q_\tau$ and then the influence function is

$$\begin{aligned}
IF(y; T, F_Y) &= \frac{\tau - 1[y \le q_\tau]}{f_Y(q_\tau)}, \\
RIF(y; T, F_Y) &= T(F_Y) + IF(y; T, F_Y) = q_\tau + \frac{\tau - 1[y \le q_\tau]}{f_Y(q_\tau)}.
\end{aligned}$$

The derivations of $IF(y; T, F_Y)$ and $RIF(y; T, F_Y)$ of q_τ can be found in Huber and Ronchett (2009).

As $1[y \le q_\tau] = 1 - 1[y > q_\tau]$ and

$$\begin{aligned}
RIF(y; T, F_Y) &= q_\tau + \frac{\tau - 1[y \le q_\tau]}{f_Y(q_\tau)} \\
&= q_\tau + \frac{(\tau - 1) + 1[y > q_\tau]}{f_Y(q_\tau)} \\
&= \left[q_\tau + \frac{\tau - 1}{f_Y(q_\tau)}\right] + \left[\frac{1}{f_Y(q_\tau)}\right] 1[y > q_\tau] \\
&= c_{2,\tau} + c_{1,\tau} 1[y > q_\tau],
\end{aligned}$$

then

$$\begin{aligned}
E[RIF(T, F_Y)|\boldsymbol{X} = \boldsymbol{x}] &= \int RIF(y; T, F_Y) dF_{Y|\boldsymbol{X}=\boldsymbol{x}}(y) \\
&= \int \{c_{2,\tau} + c_{1,\tau} 1[y > q_\tau]\} dF_{Y|\boldsymbol{X}=\boldsymbol{x}}(y) \\
&= c_{2,\tau} + c_{1,\tau} \int 1[y > q_\tau]\} dF_{Y|\boldsymbol{X}=\boldsymbol{x}}(y) \\
&= c_{2,\tau} + c_{1,\tau} E[1[y > q_\tau]|\boldsymbol{X} = \boldsymbol{x}] \\
&= c_{2,\tau} + c_{1,\tau} P[y > q_\tau|\boldsymbol{X} = \boldsymbol{x}].
\end{aligned}$$

Thus, the unconditional partial effect is

$$\begin{aligned}
\alpha(\tau) &= \int \frac{dE[RIF|\boldsymbol{X} = \boldsymbol{x}]}{d\boldsymbol{x}} dF_{\boldsymbol{X}}(\boldsymbol{x}) \\
&= \int \frac{d\{c_{2,\tau} + c_{1,\tau} P[y > q_\tau|\boldsymbol{X} = \boldsymbol{x}]\}}{d\boldsymbol{x}} dF_{\boldsymbol{X}}(\boldsymbol{x}) \\
&= c_{1,\tau} \int \frac{d\{P[y > q_\tau|\boldsymbol{X} = \boldsymbol{x}]\}}{d\boldsymbol{x}} dF_{\boldsymbol{X}}(\boldsymbol{x}).
\end{aligned}$$

Based on assumptions on the functional form of $P[y > q_\tau | \boldsymbol{X} = \boldsymbol{x}]$, Firpo, et al (2009) suggests the following estimations of $\alpha(\tau)$.

2.3 Estimation: RIF-OLS

If the linear probability model (LPM) is considered as

$$P[y > q_\tau | \boldsymbol{X} = \boldsymbol{x}] = \boldsymbol{x}'\boldsymbol{\gamma}$$

so

$$\frac{d\{P[y > q_\tau | \boldsymbol{X} = \boldsymbol{x}]\}}{d\boldsymbol{x}} = \boldsymbol{\gamma}.$$

And then the unconditional partial effect vector is

$$\alpha(\tau) = c_{1,\tau}\boldsymbol{\gamma}.$$

Given LPM

$$1[y > q_\tau] = \boldsymbol{x}'\boldsymbol{\gamma} + u$$

with $E(u|\boldsymbol{x}) = 0$,

$$\begin{aligned} RIF(y; F_Y) &= c_{2,\tau} + c_{1,\tau}1[y > q_\tau] \\ &= c_{2,\tau} + c_{1,\tau}(\boldsymbol{x}'\boldsymbol{\gamma} + u) \\ &= c_{2,\tau} + \boldsymbol{x}'(c_{1,\tau}\boldsymbol{\gamma}) + c_{1,\tau}u \\ &= c_{2,\tau} + \boldsymbol{x}'\boldsymbol{\gamma}_\tau^* + u^*, \end{aligned}$$

this is the RIF regression for the τth quantile. For having the RIF regression estimatable, q_τ and $f_Y(q_\tau)$ have to be estimated first. q_τ can be estimated as the sample τth quantile, $\hat{q}_\tau$ and $f_Y(q_\tau)$ can be estimated using kernel density smoothing estimator at $\hat{q}_\tau$, $\hat{f}_Y(\hat{q}_\tau)$. Then for each observation $(y_i, \boldsymbol{x}_i)$, compute

$$\widehat{RIF}(y_i; F) = \hat{q}_\tau + \frac{\tau - 1[y_i \leq \hat{q}_\tau]}{\hat{f}_Y(\hat{q}_\tau)}$$

and then regress $\widehat{RIF}(y_i; F)$ on $\boldsymbol{x}_i$ and then obtain $\hat{\boldsymbol{\gamma}}_\tau^*$ which equals to $\hat{\alpha}(\tau)$.

2.4 Estimation: RIF-LOGIT

By specifying a Logit model, given the estimated $\hat{q}_\tau$,

$$P(y_i > \hat{q}_\tau | \boldsymbol{X} = \boldsymbol{x}_i) = \frac{\exp(\boldsymbol{x}_i'\gamma)}{1 + \exp(\boldsymbol{x}_i'\gamma)},$$

the marginal effect of the jth explanatory variable on $P(y_i > \hat{q}_\tau | \boldsymbol{X} = \boldsymbol{x}_i)$

$$\frac{dP(y_i > \hat{q}_\tau | \boldsymbol{X} = \boldsymbol{x}_i)}{dx_{ij}} = \gamma_j \left[\frac{\exp(\boldsymbol{x}_i'\gamma)}{1 + \exp(\boldsymbol{x}_i'\gamma)} \right] \left[1 - \frac{\exp(\boldsymbol{x}_i'\gamma)}{1 + \exp(\boldsymbol{x}_i'\gamma)} \right].$$

Denote $\tilde{\gamma}$ as the MLE of the Logit model. Thus, the expectation

$$\int \frac{d\{P[y > q_\tau | \boldsymbol{X} = \boldsymbol{x}]\}}{d\boldsymbol{x}} dF_{\boldsymbol{X}}(\boldsymbol{x})$$

could be approximated by by the sample mean of the estimated marginal effects

$$\frac{1}{n} \sum_{i=1}^{n} \tilde{\gamma}_j \left[\frac{\exp(\boldsymbol{x}_i'\tilde{\gamma})}{1 + \exp(\boldsymbol{x}_i'\tilde{\gamma})} \right] \left[1 - \frac{\exp(\boldsymbol{x}_i'\tilde{\gamma})}{1 + \exp(\boldsymbol{x}_i'\tilde{\gamma})} \right]$$

Then, the j-th element in $\boldsymbol{\alpha}(\tau)$ can be estimated by

$$\tilde{\alpha}_j(\tau) = \frac{1}{\hat{f}_Y(\hat{q}_\tau)} \left\{ \frac{1}{n} \sum_{i=1}^{n} \tilde{\gamma}_j \left[\frac{\exp(\boldsymbol{x}_i'\tilde{\gamma})}{1 + \exp(\boldsymbol{x}_i'\tilde{\gamma})} \right] \left[1 - \frac{\exp(\boldsymbol{x}_i'\tilde{\gamma})}{1 + \exp(\boldsymbol{x}_i'\tilde{\gamma})} \right] \right\}$$

This method is called the RIF-LOGIT estimation.

3 Empirical Data

Our empirical data is obtained from three surveys on 2007, 2009, and 2011 conducted by Financial Supervisory Commission, R.O.C. Totally, there are 6860 individuals were surveyed, 2133 on 2007, 2071 on 2009, and 2656 on 2011. Using the method of factor analysis suggested by van Rooij, et al (2011), the financial literacy is measured from 18 questionnaires about the knowledge of management on cash, savings, credit, and loans.

The explanatory variables considered in this paper are:

1. highedu: dummy variable, 1 for individual having degree from college, university, or graduate and 0 otherwise;

2. sex: dummy variable, 1 for male and 0 for female;

3. marriage: dummy variable, 1 for married and 0 otherwise;

4. pincome: 1 for annual personal income from NT$ 370 thousands to NT$ 680 thousands , 2 for NT$ 680 thousands to NT$ 1240 thousands, and 3 for above NT$ 1240 thousands;

5. fincome: 1 for annual family income from NT$ 660 thousands to NT$ 1230 thousands , 2 for NT$ 1230 thousands to NT$ 2150 thousands, and 3 for above NT$ 2150 thousands;

6. Dfulltime: dummy variable, 1 for having full-time job and 0 otherwise;

7. Darea: dummy variable, 1 for living in urban area and 0 otherwise;

The summary statistics of empirical data are shown in Table 1. As shown in Table 1, the ratio of male individuals is 0.448 and the ratio of individuals having higher education (defined as receiving degree from college, university, or graduate) is 0.461. The proportion of married individuals under survey is 0.644. The sample average of "pincome" is 0.686 which indicates that the average personal income is below NT$ 370 thousands. Meanwhile, the sample average of "fincome" is 0.853 which indicates that the average family income is below NT$ 660 thousands. The ratio of individuals who have full-time jobs is 0.640 and the ratio of individuals living in urban area is 0.723.

3.1 Empirical UQE Estimation

The regression model considered in this paper is

$$\begin{aligned}\text{literacy} &= \beta_1 + \beta_2\text{highedu} + \beta_3\text{age} + \beta_4\text{sex} + \beta_5\text{pincome} \\ &\quad + \beta_7\text{marriage} + \beta_7\text{fincome} + \beta_8\text{Dfulltime} + \beta_9\text{Darea} + error.\end{aligned}$$

For comparisons, the mean regression estimated by OLS, the conditional quantile regressions and unconditional quantile regressions at quantiles 0.1, 0.5 , and 0.9 are considered. The estimated results are presented in Table 2. Robust standard errors for OLS and bootstrapped standard errors (2000 replications) for CQR (conditional quantile), RIFOLS (RIF-OLS estimation), and RIFLOG (RIF-LOGIT estimation) are provided in parentheses. These estimations are conducted with R3.0.2. The package "ks" is used to estimate the density function and package "boot" is to do the bootstrapping for estimating the variance-covariance matrix of coefficients. The R codes and empirical data are available from authors upon request.

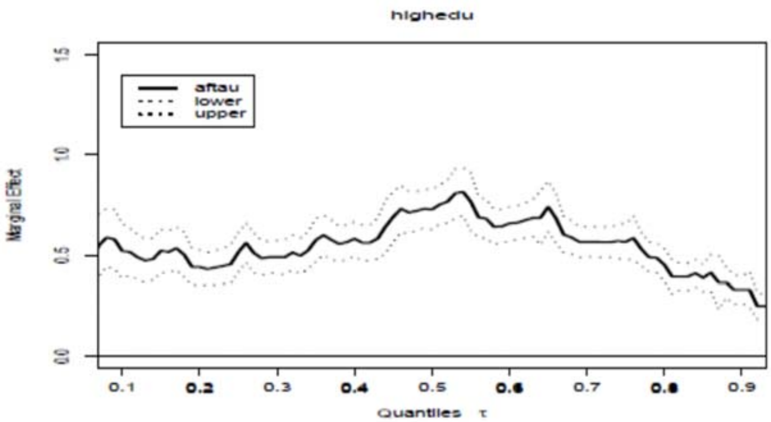
3.2 Marginal Effect of Higher Education

From Table 2, the OLS estimated coefficient of "highedu" is 0.546 and significant from zero which indicates the increment of the proportion of high-educated individuals has significant positive impact on the conditional mean of financial literacy obtainment. At quantiles 0.1, 0.5, and 0.9, the CQR estimated coefficients of "highedu" are 0.469, 0.736, and 0.372 and are statistically significant. The impact of "highedu" on the conditional quantile is getting large at high quantiles which demonstrates that increase the proportion of high-educated population increase the dispersion of conditional distribution of obtainment of financial literacy. For the

Figure 1: Marginal Effects of Higher Education

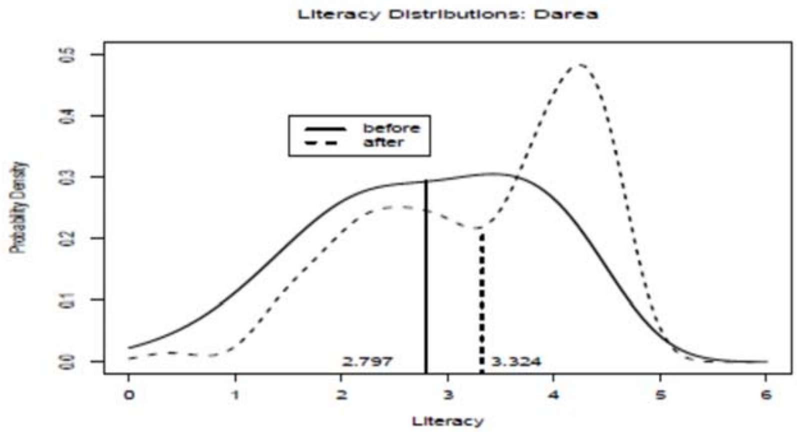


RIF-OLS (RIF-LOG), the estimated coefficients of "highedu" at quantiles 0.1, 0.5, and 0.9 are 0.467 (0.521), 0.768 (0.728), and 0.306 (0.331). These results indicate that the proportion of high-education population always has positive effect on the quantiles of financial literacy distribution.

To study the marginal effects of higher education on the unconditional distribution of financial literacy comprehensively, we estimate the sample quantiles of the financial literacy, $\hat{q}_\tau$, and the marginal effects using RIFLOG, $\tilde{\alpha}_\tau$, for $\tau = 0.01, 0.02, \ldots, 0.98, 0.99$. The estimated $\tilde{\alpha}_\tau$ for 99 τs (represented as line "aftau") and their 95 % confidence intervals (represented as lines "upper" and "lower") are plotted in Figure 1. It is clear that all 99 $\tilde{\alpha}_\tau$s are significant from zero at 5 % of Type I error. It is also found that $\tilde{\alpha}_\tau$s are decreasing from $\tau = 0.01$ to 0.2 and turn to be increasing at increasing rate from $\tau = 0.2$ to 0.53. But from $\tau = 0.53$ to 0.99, $\tilde{\alpha}_\tau$s are decreasing at increasing rate which is larger the increasing rate from $\tau = 0.2$ to 0.53. And then, we find that the marginal effects, $\tilde{\alpha}_\tau$s, at high τs are smaller relative to the ones with small τs.

Denote $\tilde{\alpha}_\tau(\textit{higher education})$ as the estimated marginal effect of higher education. Using the kernel smoothing density estimator, the density function of "before" (before change) is estimated using $\hat{q}_\tau$ and the one of "after" (after change) is estimated using $\hat{q}_\tau + \tilde{\alpha}_\tau(\textit{higher education})$. The "after" density function describes the new unconditional distribution of financial literacy

Figure 2: "before" and "after" Change of Higher Education



after an unit change of higher education. The estimated density functions are represented as in Figure 2.

As shown in Figure 2, the mean of the estimated "after" density function is 3.324 which significantly larger than 2.797, the mean of estimated "before"density function. This indicates that an increment of higher education moves the unconditional distribution of financial literacy to the right. In other words, an increment of higher education moves all quantiles of financial literacy to the right. However, the lower quantiles are moved to the right more than the higher quantiles are. Besides, the dispersion of estimated "after" distribution becomes smaller than the "before" one. In addition, it is interesting to find the "after" uncondition distribution of financial literacy becomes bimodal and the density at right mode is much higher than the one at left mode. This result implies that increment of higher education not only increases the level of financial literacy but also decreases the dispersion of literacy. Finally, the skewness of the unconditional literacy distribution becomes larger from "before" change to "after" change. The distribution becomes more skew to the left "after" the change.

To a summary, the estimated impacts of higher education on the unconditional distribution of financial literacy are concluded as following:

1. Increment of the status of higher education will have statistically significant positive marginal effects on conditional and unconditional distributions of financial literacy, i.e., move conditional and unconditional distributions to the right.

2. The increase of higher education reduces the dispersion more for the unconditional distribution than for the conditional distribution.

3. Increment of higher education will make the unconditional literacy distribution more skew to the left.

These conclusions imply that increase the higher education not only increases the obtainment of financial literacy (more significant at quantiles smaller that 0.53) but also decrease the dispersion of financial literacy distribution. Therefore, the extension of higher education in Taiwan is supported by our findings.

3.3 Marginal Effect of Sex

From Table 2, the OLS estimated coefficient of "sex" is -0.14 and significant from zero which indicates the increment of the proportion of male individuals has significant negative impact on the conditional mean of financial literacy obtainment. At quantiles 0.1, 0.5, the CQR estimated coefficients of "sex" are -0.125, -0.179 and are statistically significant. However, the CQR estimated coefficients of "sex" at quantile 0.9 is -0.030 which is statistically insignificant. Similar results are found for the estimations from RIF-OLS and RIF-LOG. For the RIF-OLS (RIF-LOG), the estimated coefficients of "sex" at quantiles 0.1, 0.5, and 0.9 are -0.097 (-0.119), -0.241 (-0.241), and -0.007 (-0.005). These estimations are statistically significant at quantiles 0.1 and 0.5, but insignificant at 0.9. Since all estimated coefficients are negative, the obtainment of financial literacy is easier to female relative to male individuals.

From Figure 3, it is clear to know the negative marginal effect of "sex" is getting large for quantiles from 0.01 to 0.5 and then getting smaller for quantiles larger than median. The marginal effects are statistically significant at most of quantiles except at the extreme small (less than 0.1) and large (larger than 0.85) quantiles. Besides, the marginal effects display almost symmetric pattern at median. This symmetric marginal effects make the skewness of unconditional literacy distribution changed. As shown in Figure 4, the original unconditional literacy distribution denoted as solid line and symbolled with "before" is skew to the left. However, the unconditional literacy distribution after change which is denoted as dotted line

Figure 3: Marginal Effects of Sex

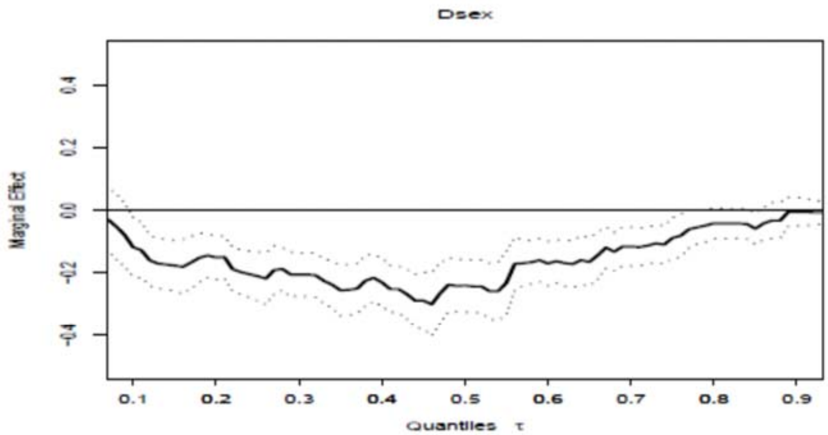


Figure 4: "before" and "after" Change of Sex

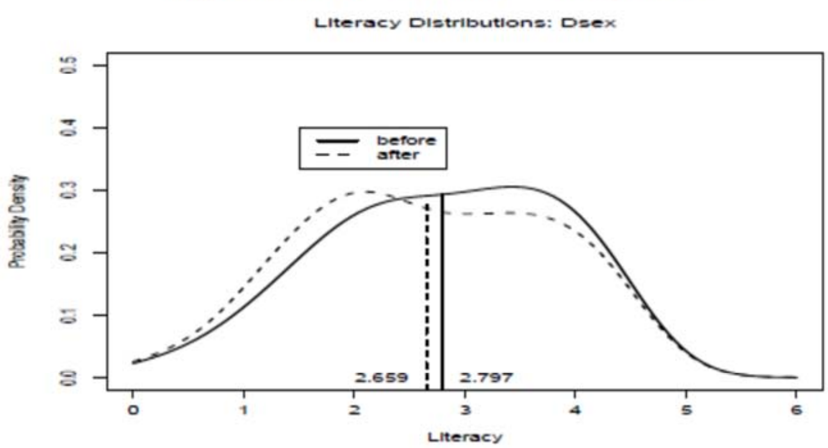

and symbolled with "after" becomes skew to the right. Finally, the mean of unconditional literacy distribution changes from 2.797 to 2.659 after the change. As to the dispersion of literacy distribution, there is no significant difference between "before" and "after" change.

To a summary, for the factor "sex", we find that

1. The marginal effects of "sex" are negative and statistically significant for all quantiles except at extreme small and large quantiles.
2. The access of financial literacy is easier to female individuals relative to males.
3. The mean of unconditional literacy distribution "after" change is smaller than the one "before" change.
4. The unconditional literacy distribution is skew to the right "before" change and then is skew to the left "after" change.

3.4 Marginal Effect of Marriage

The OLS estimated coefficient of "marriage" is -0.196 and significant from zero which indicates the increment of the proportion of married individuals has significant negative impact on the conditional mean of financial literacy obtainment. At quantiles 0.1, 0.5, and 0.9, the CQR estimated coefficients of "marriage" are -0.106, -0.249, and -0.141 and are all statistically significant. For the RIF-OLS (RIF-LOG), the estimated coefficients of "marriage" at quantiles 0.1, 0.5, and 0.9 are -0.247 (-0.183), -0.291 (-0.290), and -0.097 (-0.097) and are also all statistically significant from zero. These results indicate that married individual are easier to access financial literacy than the ones without marriage.

As shown in Figure 5, the negative impact of "marriage" on the conditional quantile is getting smaller for quantiles from 0.01 to 0.25 and is getting larger for quantiles from 0.25 to 0.5. For quantiles larger than 0.5, the negative marginal effects becomes smaller and smaller. For all quantiles from 0.01 to 0.99, the marginal effects are statistically significant. Since the marginal effects are all negative, the mean of the unconditional literacy distribution becomes smaller. As shown in Figure 6, the mean of the unconditional literacy distribution

Figure 5: Marginal Effects of Marriage

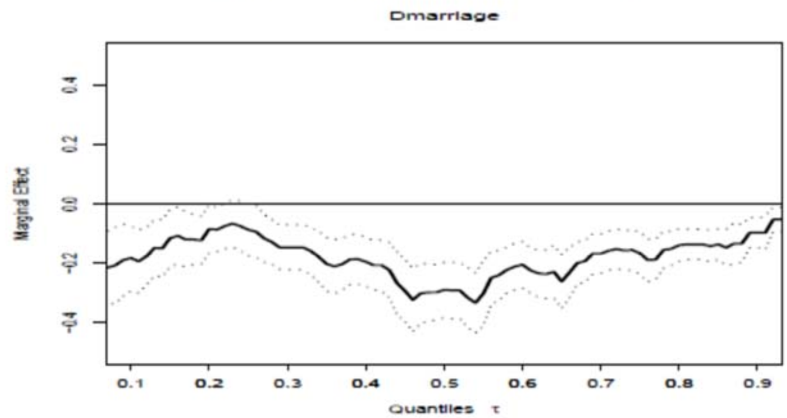

Figure 6: "before" and "after" Change of Marriage

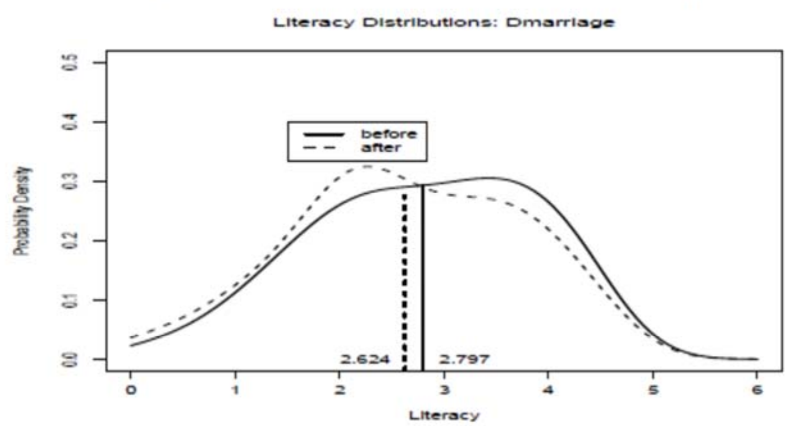

"before" change is 2.797 and is 2.624 "after" the change. Besides, the unconditional literacy distribution "before" the change is skew to the left and then becomes skew to the right "after" the change.

To a summary, for the factor "marriage", the estimated results are similar to the ones of "sex". We find that

1. The marginal effects of "marriage" are negative and statistically significant for all quantiles.

2. The access of financial literacy is easier for unmarried individuals relative to the married ones.

3. The mean of unconditional literacy distribution "after" change is smaller than the one "before" change.

4. The unconditional literacy distribution is skew to the right "before" change and then is skew to the left "after" change.

3.5 Marginal Effect of Area

From Table 2, the OLS estimated coefficient of "Darea" is -0.017 and not significant from zero which indicates the increment of the proportion of individuals living at urban area has significant positive impact on the conditional mean of financial literacy obtainment. At quantiles 0.1, 0.5, and 0.9, the CQR estimated coefficients of "Darea" are -0.029, -0.052, and 0.032 and are statistically insignificant. For the RIF-OLS (RIF-LOG), the estimated coefficients of "Darea" at quantiles 0.1, 0.5, and 0.9 are -0.009 (-0.019), -0.079 (-0.079), and 0.045 (0.053) and all of them are statistically insignificant. These results indicate that the proportion of urban population always has insignificant effect on the quantiles of unconditional financial literacy distribution. That is, the unconditional distribution of financial literacy is not different for individuals live at urban area or countryside. This result might be attributed to the well established internet and communication infrastructure in Taiwan.

As shown in Figure 7, it is obvious that the marginal effects of "Darea" on the unconditional literacy distribution are statistically insignificant for all quantiles considered. Since

Figure 7: Marginal Effects of Area

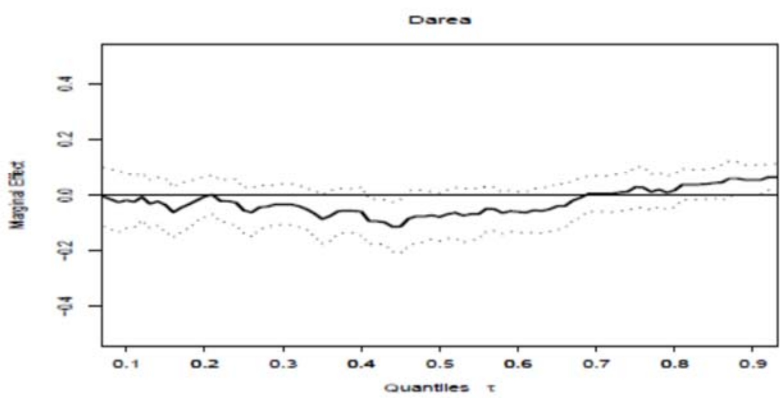

Figure 8: "before" and "after" Change of Area

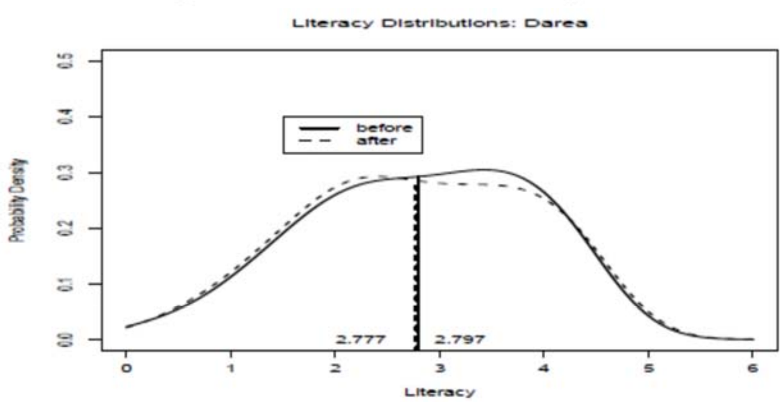

the marginal effects are insignificant, the mean and skewness of the unconditional literacy distribution change a little from "before" to "after", as shown in Figure 8. The mean changes from 2.797 to 2.777.

4 Conclusions and Suggestions

This paper investigates the marginal effects of higher education status, ratios of male/female, married/unmarried, urban/non-urban individuals on the conditional and unconditional distributions of financial literacy. Using the surveyed samples from Financial Supervisory Commission, R.O.C. on 2007, 2009, and 2011, the quantile regression of Koenker and Bassett (1978) and the unconditional quantile estimation of Firpo, et al. (2009) are used to study the conditional and unconditional distribution of financial literacy, respectively.

Our empirical results conclude: 1. Increment of the higher education not only increases the obtainment of financial literacy (since the mean becomes larger after the increase of higher education) but also decreases the dispersion of financial literacy distribution. This conclusion provides an evidence to support the policy of higher education expansion. Besides, the unconditional financial literacy distribution becomes more skew to the left after the increase of higher education. 2. The marginal effects of ratio of male/female on the unconditional literacy distribution are negative and statistically significant at all quantiles except at extreme quantiles. This indicates the access of financial literacy is easier to female individuals relative to the males. The unconditional financial literacy distribution changes from skew to the right to skew to the left after the increase of the ratio of males. 3. The marginal effects of ratio of married individuals on the unconditional literacy distribution are also negative and statistically significant at all quantiles. This indicates the access of financial literacy is easier to unmarried individuals relative to the married ones. The unconditional literacy distribution changes from skew to the right to skew to the left after the increase of the ratio of married individuals. 4. The marginal effects of ratio of individuals live at urban area on the unconditional literacy distribution are statistically insignificant negative at all quantiles.

The Impacts of Asymmetric Information and Short Sales on the Illiquidity Risk Premium in the Stock Option Market

Chuang-Chang Chang
Department of Finance, National Central University, Taiwan

Department of Finance, National Central University, Taiwan
Yaw-Huei Wang
Department of Finance, National Central University, Taiwan
wangyh@ntu.edu.tw

The illiquidity risk premium hypothesis implies the existence of a positive relationship between illiquidity in the option markets and option returns. Based upon numerous studies within the extant literature examining the roles of informed traders in the option markets, we explore the ways in which asymmetric information and short sales can affect the illiquidity risk premium hypothesis. Our findings reveal that the illiquidity risk premium is higher for the options of those firms with higher information asymmetry, as well as those firms with higher short sales demand or supply. These results are found to be particularly robust for short-term and/or OTM contracts.

Keywords: Information asymmetry; Short sales; Short-sales constraints; Informed traders; Option illiquidity premium.

JEL Classification: G14.

1. Introduction

Numerous studies have explored the relationship between illiquidity and expected returns within the stock, bond, and foreign exchange markets and generally identified the existence of a positive relationship between illiquidity and expected returns. There is also a growing body of evidence on the existence of illiquidity premiums in derivatives markets. However, unlike stocks, bonds, or currencies, derivatives are traded with a zero net supply; thus the relationship between illiquidity and expected returns may depend on whether liquidity providers are net long or net short stock options.

In a derivatives market, a negative net demand by the end users in the stock should be economically equivalent to the positive net supply. However, traditional option pricing models didn't consider the role of financial intermediaries and thus the impact of supply and demand on option prices.[1] Garleanu, Pedersen, and Poteshman (2009) provided a demand-based option theory and indicated that market makers who suffer from higher unhedgeable risks will move the price up (down) when the net demand is positive (negative), whilst Lakonishok, Lee, Pearson, and Poteshman (2007) documented a negative net demand for stock options. Bongaerts et al. (2011) demonstrated that when investors with short positions in zero net supply assets are taken into consideration, the illiquidity premium could actually be zero, positive or negative; indeed, Deuskar et al. (2011) and Bongaerts et al. (2011) respectively found negative illiquidity premiums in the credit default swap market and the interest rate derivative market, whilst Christoffersen, Goyenko, Jaconbs and Karoui (2014) found a positive relationship in the stock option market. Such inconsistencies within the derivatives markets motivate us to further investigate the factors potentially affecting the illiquidity risk premium in the stock option market.

As compared to trading in the underlying assets, option trading involves lower transaction costs and provides higher leverage; thus, informed traders may choose to trade in options in order to take advantage of their private information. As suggested by Easley, O'Hara and

[1] Classical references include Black and Scholes (1973), Hull and White (1987), and Heston (1993).

Srinivas (1998), in order to earn profits, informed traders with private information are more likely to trade in the option markets when the option liquidity level is satisfactory and information asymmetry in the stock market is high. Of particular significance is the fact that options can be used as a device for circumventing the short-sale constraints in the stock market.

Many of the prior related studies, such as Manaster and Rendleman (1982) and Sheikh and Ronn (1994), indicate that information is reflected in the option markets prior to being reflected in the underlying stock markets, whilst Diamond and Verrecchia (1987) suggested that informed traders with unfavorable information on the underlying stocks will prefer to trade in the option markets. Furthermore, following the demonstration by Vayanos and Wang (2012) of the ways in which information asymmetry and imperfect competition affect liquidity and asset prices, we posit that the involvement of informed traders may well play an important role in the determination of the illiquidity risk premium in the option markets.

Whilst a number of studies have undertaken theoretical explorations of the ways in which the existence of informed trading may affect the general risk premium, such studies have reported quite mixed findings. For example, although both Leland (1992) and Wang (1993) suggested that the existence of informed traders causes information asymmetry and thus lowers the cost of capital for a firm, a number of other studies have subsequently concluded that information asymmetry actually increases such capital costs.

From their examination of the differences in the composition of public and private information, Easley and O'Hara (2004) noted that uninformed traders would tend to demand a greater risk premium when trading with informed traders, since they recognize the existence of an informational disadvantage, and hence, will tend to hold fewer assets. This will ultimately drive down the prices of those securities with high levels of private information (or information asymmetry), thereby leading to an increase in the cost of capital for these firms.

These empirical findings suggest that private information induces a new form of systematic risk, and that in equilibrium investors require compensation for taking such risk. Thus, it seems natural to question whether the involvement of informed traders changes the positive association between option illiquidity and expected option returns; indeed, several related studies have documented the influence of information asymmetry on the future dynamics of asset prices, with particular focus on the links between information asymmetry and subsequent stock returns.

For example, Pan and Poteshman (2006) found that stocks with low put-call ratios outperformed stocks with high put-call ratios, with the predictability of stock returns being higher for those stocks with high concentrations of informed traders. Furthermore, using volatility spreads to predict stock returns based upon various types of informational circumstances, Atilgan (2014) found that the predictability of stock returns was stronger during major information events. Thus, our initial objective in the present study is to examine whether the level of information asymmetry plays an important role in the determination of the illiquidity risk premium across firms in the option markets.

In addition to the level of information asymmetry, both short sales demand and supply are also found to have impacts on trading by informed traders. On the demand side, it was noted by Figlewski and Webb (1993) that the level of short interest ratio in the underlying stock can significantly affect the option prices of the stock; thus, they argued that short selling was undertaken primarily by market professionals who are also be likely to be informed traders. On the supply side, several studies have demonstrated that short-sales constraints in the stock market affect trading activities in the option market, with Hu (2014), for example, recently noting that option trading is often considered to be an effective method of mitigating short-sales constraints, and thus, conveying more information for those firms with greater short-sales constraints. Our second objective is therefore to examine whether the demand and supply levels of short sales have impacts on the illiquidity risk premium across firms in the option markets.

Our empirical analysis involves the use of the 'information asymmetry index' (ASY-INDEX) and the 'probability of informed trading' (PIN) to measure information asymmetry and the levels of short interest ratio and institutional ownership in a stock to respectively measure the demand and supply for short sales. Our findings based upon US listed stocks and options are summarized as follows.

Firstly, we present evidence to show that the level of information asymmetry has significant impacts on the option illiquidity risk premium across different firms, particularly in the case of call options. The positive relationship that exists between option illiquidity and expected option returns is found to be increased in those cases where there is a higher concentration of informed traders, a finding which is consistent with that of Easley and O'Hara (2004).

Secondly, we find that an increase in short sales strengthens the positive relationship between option illiquidity and expected option returns for call options, whilst higher short interest ratio weakens the negative relationship for put options. Whilst uninformed traders will demand greater compensation when holding more call options (Easley and O'Hara, 2004), when there is higher short interest ratio, the dissemination of information on prices will reduce the uncertainty in the put prices thereby reducing the illiquidity premium (Wang, 1993).

Finally, we find that higher short-sales costs (low institutional ownership) tend to strengthen the positive relationship between option illiquidity and expected option returns for put options; the reason for this is that put options contain more information when there are greater short-sales constraints on the stocks.

In summary, we provide evidence to show that information asymmetry and the demand and supply of short sales are important factors in the determination of the option illiquidity risk premium across firms; this is consistent with the argument put forward by Easley and O'Hara

(2004) that uninformed traders will demand a greater risk premium when trading with informed traders. Our empirical results are also found to be particularly robust for short-term OTM options, which is consistent with the general belief that informed traders tend to prefer to use those contracts with higher leverage, better liquidity or lower transaction costs in order to take advantage of their private information.

In addition to confirming the findings of Christoffersen et al. (2014), we contribute to the extant literature by introducing the influences of informed traders on the determination of option prices. We also demonstrate that information asymmetry and the demand and supply of short sales are important factors influencing the illiquidity risk premium across different firms.

The remainder of this paper is organized as follows. Section 2 provides details of our hypothesis development, followed in Section 3 by a description of the data and empirical measures used in our study. The empirical methodology adopted for our analysis is described in Section 4, with Section 5 subsequently presenting and discussing the empirical results. Finally, the conclusions drawn from this study are presented in Section 6.

2. HYPOTHESIS DEVELOPMENT

Using the component firms of the S&P 500 index, Christoffersen et al. (2014) examined the ways in which option illiquidity affected expected option returns and identified a positive relationship between these two factors, which is consistent with the risk premium hypothesis proposed by Amihud (2002). However, in contrast to spot assets with a positive net supply, given that derivatives are zero net supply assets, certain factors may play important roles in determining the risk premium.

It has been noted in many of the prior studies, such as Manaster and Rendleman (1982) and Sheikh and Ronn (1994), that information is reflected in the option market more rapidly than in the corresponding stock market, thereby leading to the suggestion that the option market is the preferred venue for informed traders to realize their private information. Easley, O'Hara and Srinivas (1998) set up a market microstructure model to demonstrate that informed traders preferred to trade in the option markets when option liquidity was high; Easley and O'Hara (2004) subsequently noted that uninformed investors will tend to demand a higher risk premium when they are faced with informed traders in the market.

From their analysis of the ways in which information asymmetry and imperfect competition affect liquidity and asset prices, Vayanos and Wang (2012) found a positive relationship with expected returns under information asymmetry when the illiquidity was measured using Kyle's lambda. In other words, the involvement of informed traders may well vary across different firms, with uninformed traders requiring a higher risk premium when there are more informed traders in the market in order to compensate for their informational disadvantage, thereby leading to a higher level of information asymmetry.

Based upon the findings and theorems of the related studies referred to above, we argue that the level of information asymmetry may influence the relationship between option illiquidity and expected option returns. We expect to find an increasingly positive relationship between option illiquidity and expected option returns with the level of information asymmetry. Accordingly, we propose the first of our hypotheses, as follows:

Hypothesis 1: The relationship between option illiquidity and expected option returns will be more positive for firms with higher information asymmetry.

Figlewski and Webb (1993) demonstrated that the significantly higher average level of short interest ratio with 'optionable' stocks (those stocks selected as the underlying asset of an option) provides support for the argument that option trading facilitates short selling. They also found that short interest ratio in the underlying stock could significantly affect option prices and went on to suggest that short sales were primarily undertaken by market professionals.

Diamond and Verrecchia (1987) had earlier indicated that speculative short sellers were more likely to trade in the option markets (with a particular focus on trading in put options) essentially because, on the one hand, such trading could reduce their short sales costs, whilst on the other hand, it could increase their leverage. These studies therefore seem to jointly suggest that the level of short interest is positively related to the amount of informed trading, since short selling is widely regarded as being carried out primarily by market professionals.

Given that informed traders prefer to trade in the option market when they have access to private (especially negative) information, the level of short interest ratio should be positively related to the level of information asymmetry. As suggested by Easley and O'Hara (2004), uninformed traders demand a greater risk premium when trading with informed traders because compensation is required for their losses. Thus, if uninformed traders hold more call options of those stocks with higher short interest ratio, they naturally assume greater risk as a direct result of their informational disadvantage. Accordingly, investors holding more call options of those stocks with higher short interest ratio may require a greater risk premium. This leads to the development of our second hypothesis, as follows:

Hypothesis 2: The relationship between option illiquidity and expected option returns will be more positive for firms with higher short interest ratio, particularly in the case of call options.

In addition to the demand side of short sales explored by the studies referred to above, the stock market supply side (short-sale constraints or short-sales costs) can also affect trading activities in the option markets. Informed traders with negative information could trade in the option market as an alternative to short selling, particularly in those cases where the difficulty of engaging in short selling in the stock market is high; that is to say, if there are higher levels of short-sales constraints in the stock market, informed traders with negative information are more likely to trade in the option market.

Some of the prior studies using institutional ownership as a proxy for the market supply of short interest have identified the existence of a negative relationship between the level of institutional ownership and the difficulties involved in engaging in short selling (see D'Avolio, 2002; Asquith, Pathak and Ritter, 2005). Hu (2014) also found that the informational benefit of option trading was higher for stocks with greater short-sales constraints.

Given that informed traders have incentive to buy put options to realize their private negative information for firms with higher short-sales costs, uninformed traders buying put options may assume greater levels of risk. We therefore consider shorting supply to construct our third hypothesis, as follows:

Hypothesis 3: The relationship between option illiquidity and expected option returns will be more positive for firms with lower institutional ownership (higher short-sales costs), particularly in the case of put options.

3. DATA

The primary dataset adopted for this study includes stock option quotes and the illiquidity measures of both stocks and options, with the measures of both information asymmetry and the demand and supply of short sales also being utilized in our empirical analysis. The sample period adopted for this study runs from January 1996 to December 2007.

3.1. *Stock Option Quotes and Computation of Option Returns*

The stock options data were collected from Option Metrics, with the dataset including daily closing bid and ask quotes, implied volatility levels and the deltas of all stock options listed in the US exchanges. As regards time to maturity, short-term options are defined as those with maturity periods ranging from 20 and 70 days, whilst long-term options are those with maturity periods ranging from 71 and 180 days.

Following Bollen and Whaley (2004) and Driessen, Maenhout and Vilkov (2009), we also adopt the option delta for our classification of moneyness in the present study. The call (put) deltas for OTM options range from 0.125 to 0.375 (–0.375 to –0.125), whilst those for ATM options range from 0.375 to 0.625(–0.625 to –0.375) and those for ITM options range from 0.625 to 0.875 (–0.875 to –0.625).

Those option contracts which meet the following criteria are excluded from our sample in order to deal with concerns regarding liquidity or reliability: (i) prices violate the no-arbitrage conditions; (ii) ask price $\leq$ bid price; (iii) open interest is equal to 0; (iv) price details are incomplete; (v) price < \$3 and bid-ask spread < \$0.05 or price $\geq$ \$3 and bid-ask spread < \$0.10.

Following Frazzini and Pedersen (2012) and Christoffersen et al. (2014), we compute the daily delta-hedged returns of options as:

$$\tilde{R}^{O}_{t+1,n} = R^{O}_{t+1,n} - R^{S}_{t+1} S_t \frac{\Delta_{t,n}}{O_{t,n}} \qquad (1)$$

where $R^{O}_{t+1,n}$ is the daily raw return of option n and $\Delta_{t,n} = \frac{\partial O_{t,n}}{\partial S_t}$ is computed based upon the Cox, Ross and Rubinstein (1979) binomial tree model allowing for early exercise, given that all stock options are American style options. S_t is the price of the underlying stock at time t and R^{S}_{t+1} is the stock return computed from S_t and S_{t+1}. All of the details on stock prices are obtained from CRSP.

Following Coval and Shumway (2001), we use the bid-ask midpoints to compute the raw option return ($R^{O}_{t+1,n}$) as the equally-weighted average of the daily returns of all available options in each moneyness and maturity category. In other words, the return of a particular category of a firm from t to $t+1$ is defined as:

$$R^{O}_{t+1} = \frac{1}{N} \sum_{n=1}^{N} \frac{O_{t+1}(K_n, T_n - 1) - O_t(K_n, T_n)}{O_t(K_n, T_n)} \qquad (2)$$

The corresponding delta-hedged return is then computed as:

$$\tilde{R}^{O}_{t+1} = \frac{1}{N} \sum_{n=1}^{N} \frac{O_{t+1}(K_n, T_n - 1) - O_t(K_n, T_n)}{O_t(K_n, T_n)} - R^{S}_{t+1} S_t \frac{1}{N} \sum_{n=1}^{N} \frac{\Delta_t(K_n, T_n)}{O_t(K_n, T_n)} \quad (3)$$

where N is the number of available contracts in each category at time t with quotes at time $t+1$; and $O_t(K_n, T_n)$ is the mid-point quote of an option with strike price K_n and maturity T_n.[2]

The summary statistics of the option returns across various maturity-moneyness categories for call and put options are reported in Table 1. We first of all compute the descriptive statistics for each firm and then take the cross-sectional averages of these statistics, as a result of which we find that the returns of put options are generally higher than those of call options. Returns on short-term options are more volatile than returns on long-term options, especially for OTM

[2] We use the adjustment factor provided by Option Metrics for splits and other distribution events.

contracts.

3.2. *Stock and Option Illiquidity Measures*

Using the data obtained from the high-frequency intraday 'trade and quote' (TAQ) database, stock illiquidity is calculated in this study as the effective spread.[3] The effective spread is defined as:

$$IL_k^S = 2\,|ln(P_k) - ln(M_k)| \qquad (4)$$

where P_k is the price of the k^{th} trade; and M_k is the midpoint of the best bid and offer prices at the time of the k^{th} trade.

The dollar-volume weighted average of all IL_k^S computed over all trades during the day defines the daily effective spread of the stock, IL^S, as follows:

[3] The same illiquidity measure has also been adopted in many of the prior related studies, including Hasbrouck and Seppi (2001), Huberman and Halka (2001), Chordia, Roll and Subrahmanyam (2000; 2001) and Chordia, Sarkar and Subrahmanyam (2005).

$$IL^S = \frac{\sum_k DolVol_k IL_k^S}{\sum_k DolVol_k} \tag{5}$$

where DolVolk refers to the dollar-volume computed as the product of the stock price and the trading volume.
Similar to Cao and Wei (2010), we adopt the relative quoted bid-ask spread as the measure of option illiquidity, which is computed from the end-of-day quoted bid and ask prices provided by Ivy DB Option Metrics. For each contract, we compute the daily relative quoted spread as:

$$IL_{t,n}^O = \frac{OA_t(K_n,T_n) - OB_t(K_n,T_n)}{O_t(K_n,T_n)} \tag{6}$$

where $O_t(K_n, T_n)$, $OA_t(K_n, T_n)$ and $OB_t(K_n, T_n)$ are the respective end of day closing mid-point, ask and bid quotes for an option with strike price K_n and maturity T_n. It should be noted that $O_t(K_n, T_n) = (OA_t(K_n, T_n) + OB_t(K_n, T_n))/2$.

$$IL_t^O = \frac{1}{N}\sum_{n=1}^{N} IL_{t,n}^O \tag{7}$$

where N is the number of available contracts within the category at time t.

The summary statistics of the relative bid-ask spread illiquidity measures for all firms are presented in Table 2. According to the option illiquidity (IL^O), we find that short-term contracts are more illiquid than long-term contracts for both call and put options, with OTM contacts exhibiting the highest overall illiquidity.

Variables	Mean	Min.	Max.	Std. Dev.
Panel A: Calls				
a. IL^O for Short-term Options

3.3 Information Asymmetry Measures

Two measures of information asymmetry are adopted in this study. Firstly, following Drobetz et al. (2010), we create an information asymmetry index with the exclusion of those firms with a fiscal year not ending with the corresponding calendar year. Secondly, we follow several of the prior related studies on informed trading to use the 'probability of informed trading' (PIN) to measure information asymmetry.[4]

Various measures of information asymmetry have been introduced within the prior empirical studies; for example, Vermaelen (1981) identified the tendency for a reduction in information asymmetry with firm size, whilst Smith and Watts (1992) discovered an increase in information asymmetry with growth opportunities. Krishnaswami and Subramaniam (1999) indicated that information asymmetry was reduced in line with the number of analysts tracing the firm, and went on to suggest the use of analyst forecast errors as an effective measure for information asymmetry. Finally, Aboody and Lev (2000) also found an increase in information asymmetry with R&D expenditure.

For our first measure of information asymmetry in the present study, we follow the method of Drobetz et al. (2010) to construct an information asymmetry index (ASY-INDEX) based upon the various dimensions of the concepts described above. These dimensions include analyst forecast errors,[5] firm size, R&D expenditure, Tobin's Q and the number of analysts

[4] See Easley et al. (1998) and Easley, Kiefer and O'Hara (1997; 2002).

[5] We use the following measure of analyst forecast errors: $ERRORF = ln(1 + |EPS_{Forcast} - EPS_{Actual}|/|Median\ EPS|)$, where $EPS_{Forecast}$ is the earnings per share forecast, which is the average of all forecasts for a firm provided by all analysts in November and December of the previous year. The difference between actual and forecasted earnings per share is scaled by the median earnings per share forecast.

tracing the firm.[6] The accounting data, which is obtained from Compustat, includes R&D expenditure and total assets. Details on the analyst forecasts and the number of tracking analysts are collected from I/B/E/S.

For our compilation of the index, we first of all calculate the annual quintile ranking of a firm over all firms for each dimension of information asymmetry, with a higher score indicating a higher level of information asymmetry; for instance, a firm will be assigned a score of 5 (1) if it belongs in the smallest (largest) 20 per cent of all firms in a given year. We then sum the ranks for all five dimensions of information asymmetry, with the largest (smallest) value of the ASY-INDEX for firms with the highest (lowest) level of information asymmetry being 25 (5). The PIN is used as the second measure of information asymmetry in our analysis, with the quarterly PIN estimates for the period from January 1996 to December 2006 having been obtained from Stephen Brown.

3.4 Short Sales Measures

One stream of the extant literature on short sales suggests that high short interest ratios (shares sold short over shares outstanding) predicts low future returns,[7] whilst an alternative stream indicates that short sales are dependent upon the institutional ownership of the stock.[8]

[6] Elton, Gruber and Gultekin (1984) noted that most of the forecast error in the last month of the fiscal year could be explained by erroneous estimation of firm-specific factors. Diamond and Verrecchia (1991) and Ozkan and Ozkan (2004) further indicated that large firms may be faced with less information asymmetry essentially because they are more mature and have more transparent disclosure policies; thus, they tend to receive more attention from the market. From their analysis of insider trading gains in firms with high and low R&D expenditure, Aboody and Lev (2000) found that the insider gains in R&D firms were larger than those in firms with no R&D, and provided evidence to show that R&D was related to information asymmetry. Following the indication by Smith and Watts (1992) that information asymmetry was more serious for firms with significant growth opportunities, McLaughlin, Safieddine and Vasudevan (1998) used investment opportunities as a proxy for information asymmetry. In the present study, we use Tobin's Q, defined as the book value of assets minus the book value of equity plus the market value of equity divided by the book value of assets, to measure growth opportunities. Chang, Dasgupta and Hillary (2006) suggested that the greater the analyst cover of a firm, the higher the information released to the public, and hence, the more limited the level of information asymmetry; the number of analysts can therefore also be used to proxy for information asymmetry. Brennan and Subrahmanyam (1995) argued that higher analyst coverage could reduce the adverse selection costs, as measured by the inverse of market depth.

[7] Examples include Figlewski (1981), Figlewski and Webb (1993), Senchack and Starks (1993), Asquith and Meulbroek (1995) and Desai et al. (2002).

[8] See D'Avolio (2002), Asquith et al. (2005) and Hu (2014).

We also follow Asquith et al. (2005) to consider both short sales demand and supply so as to define the level of stocks to short sales. We follow Figlewski and Webb (1993) to use the short interest ratio as a proxy for short sales demand and as suggested by D'Avolio (2002) and Asquith et al. (2005), we take institutional ownership as the proxy for the market supply of short interest, since it has a negative correlation with the difficulties involved in short selling.

The data on short interest are obtained from Compustat on the fifteenth day of the month (or the nearest trading day if the fifteenth day is not a trading day), whilst the institutional ownership data are obtained from 13-F filings. The descriptive statistics on the information asymmetry measures, comprising of the means, medians, standard deviations and 10%, 50% and 90% percentiles, are reported in Table 3.

Variables	P_{10}	P_{50}	P_{90}	Mean	Std. Dev.
ASY-Index	11.0000	15.0000	18.0000	14.7072	2.9757
PIN	0.0785	0.1391	0.2265	0.1483	0.0732
SI	0.0005	0.0117	0.0821	0.0347	0.1761
OP	0.0828	0.2636	0.6944	0.3419	0.3219

4. METHODOLOGY

Christoffersen et al. (2014) identified a positive relationship between option illiquidity and expected option returns, attributing this result to the option illiquidity premium. However, given that derivatives are zero net supply assets, they are more complicated than assets with positive net supplies; therefore, for our examination of the ways in which information asymmetry and short sales affect the positive relationship identified by Christoffersen et al. (2014), we modify the regressionmodel adopted in their study to consider the effect of information asymmetry in order to test Hypothesis 1, as follows:

$$\tilde{R}_{i,t}^{O} = a_{0,t} + \beta_{1,t}\tilde{R}_{i,t-1}^{O} + \beta_{2,t}IL_{i,t-1}^{\mathrm{O}} + \beta_{3t}IL_{i,t-1}^{\mathrm{S}} + \beta_{4,t}IL_{i,t-1}^{\mathrm{O}}$$

$$\times Dummy_{Asy.Info.} + \beta_{5,t}IL_{i,t-1}^{\mathrm{S}} \times Dummy_{Asy.Info.} + \beta_{6,t}Dummy_{Asy.Info.} \quad (8)$$
$$+ \beta_{7,t}\sigma_{i,t-1} + \beta_{8,t}ln(size_{i,t-1}) + \beta_{9,t}b_{i,t-1} + \beta_{10,t}lev_{i,t-1} + \varepsilon_{i,t}$$

where $\tilde{R}_{i,t}^{O}$ are the delta-hedge option returns; $IL_{i,t}^{O}$ refers to the option illiquidity and $IL_{i,t}^{S}$ denotes the stock illiquidity; $Dummy_{Asy.Info.}$ is a dummy variable which takes the value of 1 if the ASY-INDEX for stock i is ranked in the top 20 per cent; otherwise 0; and $\sigma_{i,t}$ denotes the historical volatility estimated using the daily stock returns from the GARCH(1,1) model.

As suggested by Duan and Wei (2009), $b_{i,t}$ is the square root of the R^2 from running the daily OLS regressions of the excess stock returns on the four factors proposed by Fama and French (1993) and Carhart (1997), with a one-year rolling window. Furthermore, we follow both Dennis and Mayhew (2002) and Duan and Wei (2009) to control for size and leverage; $size_{i,t}$ is the natural logarithm of the market capitalization of the firm; and $lev_{i,t}$ is defined as the sum of long-term debt and the par value of the preferred stock, divided by the sum of long-term debt, the par value of the preferred stock and the market value of equity.

We expect to find that if the illiquidity premium hypothesis holds, then β_2 will be positive, and if investors require a higher risk premium for the options of stocks with higher levels of information asymmetry, then β_4 will be significantly positive. Based upon the replication argument proposed by Leland (1985) and Boyle and Vorst (1992), we also expect to find that β_3 will be positive.[9]

When using the PIN as an alternative proxy for information asymmetry, the terms with $Dummy_{Asy.Info.}$ are not included in the regression model; instead, we first of all group the firms based on their quarterly PIN levels into the three categories of low (<30%), mid (30-70%) and high (>70%), and then run the cross-sectional regression model without the dummy term for the returns of options across various moneyness-maturity categories in order to examine the significance of the mean of the β_2 coefficients for each category.

As regards the short sales demand side, we follow Figlewski and Webb (1993) to use the relative short interest (that is, the number of shares sold short divided by the total outstanding shares of the firm) as the measure of the annual average short interest ratio. For the supply side,

[9] An option can be replicated by trading the underlying asset and a risk free bond in a frictionless and complete-market model; however, this is not the case, given the existence of liquidity risk. Market makers have net long positions in the equity option markets, and hence, need to create a synthetic short option using the underlying stock. This will lead to a reduction in the price that market makers receive from shorting the synthetic option with the illiquidity of the stock market, thereby reducing the option price.

we follow Asquith et al. (2005) and Hu (2014) to consider institutional ownership as the proxy for short-sales constraints (short-sales costs) and then rewrite the regression models, as shown below, to respectively test Hypotheses 2 and 3:

$$\tilde{R}^{O}_{i,t} = a_{0,t} + \beta_{1,t}\tilde{R}^{O}_{i,t-1} + \beta_{2,t}IL^{O}_{i,t-1} + \beta_{3t}IL^{S}_{i,t-1} + \beta_{4,t}IL^{O}_{i,t-1} \times Dummy_{RSI} + \beta_{5,t}IL^{S}_{i,t-1} \times Dummy_{RSI} + \beta_{6,t}Dummy_{RSI} + \beta_{7,t}\sigma_{i,t-1} + \beta_{8,t}ln(size_{i,t-1}) + \beta_{9,t}b_{i,t-1} + \beta_{10,t}lev_{i,t-1} + \varepsilon_{i,t} \qquad (9)$$

and

$$\tilde{R}^{O}_{i,t} = a_{0,t} + \beta_{1,t}\tilde{R}^{O}_{i,t-1} + \beta_{2,t}IL^{O}_{i,t-1} + \beta_{3t}IL^{S}_{i,t-1} + \beta_{4,t}IL^{O}_{i,t-1} \times Dummy_{op} + \beta_{5,t}IL^{S}_{i,t-1} \times Dummy_{op} + \beta_{6,t}Dummy_{op} + \beta_{7,t}\sigma_{i,t-1} + \beta_{8,t}ln(size_{i,t-1}) + \beta_{9,t}b_{i,t-1} + \beta_{10,t}lev_{i,t-1} + \varepsilon_{i,t} \qquad (10)$$

where the $Dummy_{RSI.}$ variable takes the value of 1 if the relative short interest for stock *i* is ranked in the top 20 per cent; otherwise 0; and the $Dummy_{op.}$ variable takes the value of 1 if the institutional ownership for stock *i* is ranked in the bottom 20 per cent; otherwise 0. Similarly, if Hypothesis 2 (3) holds, then we would expect to find that β_4 will be significantly positive, particularly for call (put) options

5. EMPIRICAL RESULTS

5.1 Preliminary Results

Prior to using our regression models to formally test for the impacts of information asymmetry and short sales on the illiquidity risk premium, we provide some preliminary evidence on the existence of the illiquidity risk premium in the option markets. We short the stocks according to their previous-day illiquidity measures and form three groups of firms in the categories of low (<30%), mid (30-70%) and high (>70%) illiquidity for each day. We then calculate the delta hedge returns of options for each group of firms across various moneyness-maturity categories. The average option returns for all categories are reported in Table 4.

Regardless of which moneyness or maturity is considered, the average return for the high-illiquidity group is always found to be higher than that for the low- illiquidity group, with almost all of the differences being significant at the 1% level. In other words, the average option returns are positively associated with the option illiquidity levels; this is in line with the findings of Christoffersen et al. (2014) and confirms the existence of the illiquidity risk premium in the option markets

5.2 Results on Information Asymmetry

In order to test Hypothesis 1, we first of all run the cross-sectional regression model specified in Equation (8) for each day and then take the time-series averages of the regression coefficients. We report the results based upon the information asymmetry index (ASY-INDEX) in Table 5, with Newey and West (1987) adjusted t-statistics. As shown in Panel A, the overall results on call options are found to be consistent across all moneyness and maturity groups.

The positive significance of β2 is in line with the illiquidity risk premium hypothesis, which is again consistent with the findings of Christoffersen et al. (2014). The positive β3 provides support for the option replication argument proposed by Leland (1985) and Boyle and Vorst (1992), although it is found to be insignificant for long-term OTM call options. The β4 coefficient is found to positively significant at the 5% level for all groups, with the one exception of short-term ITM call options, thereby confirming Hypothesis 1. In other words, our regression results on call options strongly indicate that the higher the level of information asymmetry, the higher the illiquidity risk premium.

Furthermore, the information asymmetry effect is found to be particularly strong for short-term call options, essentially because β2 + β4 is higher for short-term contracts than long-term contracts. This finding could be attributable to the fact that informed traders are more likely to trade in short-term contracts, as opposed to long-term contracts, so that they can take advantage of certain aspects of the former, such as higher leverage and liquidity.

By contrast, as shown in Panel B, the results from put options are less convincing since the β4 coefficient is found to be positively significant only for OTM options, which could be attributable to uninformed investors tending to view put options as insurance against existing long positions on the underlying asset, whilst also choosing not to speculate on negative news. Although the effect of information asymmetry is less robust for put options, full support is still provided for the illiquidity risk premium hypothesis since all of the β2 coefficients are found to be positively significant at the 1% level.

Our finding that the effect of the impact is particularly pronounced for OTM contracts, which are not dependent on call/put or short-/long-term contracts, is of some importance, since this finding suggests that informed traders prefer to trade in OTM options in order to take advantage of their private information, and thus, uninformed traders require a higher risk premium when trading in this group of contracts to compensate for the risk that they face due to their informational disadvantage.

The empirical results obtained from PIN, the alternative proxy for information asymmetry, are shown in Table 6. Since the PIN dataset is obtained with quarterly frequency, we run the cross-sectional regression model specified in Equation (8) without the information asymmetry dummy variable for each day on the returns of options across various moneyness-maturity categories for the three groups of firms grouped by their PIN levels. The means of the β2 coefficients and their t-statistics are reported in Table 6.

The results based upon the PIN levels are generally consistent with those based upon the ASY-INDEX, with strong support being provided for the illiquidity risk premium hypothesis since virtually all of the β2 coefficients are found to be positively significant at the 1% level. Furthermore, the β2 coefficients of the higher PIN groups are found to be larger than those of the lower PIN groups for the majority of the moneyness-maturity categories, a finding which is particularly robust for OTM (call and put) contracts.

In summary, both the ASY-INDEX and PIN results indicate that uninformed traders require a higher illiquidity risk premium for the options of firms with higher levels of information asymmetry, thereby confirming Hypothesis 1.

5.3 Results on Demand and Supply of Short Sales

Following Asquith et al. (2005), we consider the demand-side and supply-side measures of short sales in order to investigate their overall impact on the illiquidity risk premium hypothesis when informed traders are in possession of negative private information. The results from the demand-side measure for short interest ratio are shown in Table 7.

For call options, with the exception of ITM contracts, we find that the illiquidity risk premium is higher when there is higher short selling of stocks, essentially because all of the $\beta 4$ coefficients are found to be positively significant at the 5% level; however, there is no clear pattern for put options. In summary, the effect of the demand of short sales on the illiquidity risk premium is particularly high for OTM call options, with these findings being largely consistent with Hypothesis 2, as well as the ASY-INDEX and PIN results.

A higher level of short interest ratio indicates a bearish prospect for the firm. Given unfavorable information on the underlying stocks, informed traders will not only short sell the stocks, but also buy put options, since trading in the latter attracts lower transaction costs, whilst providing higher leverage. Under such circumstances, uninformed traders buying more call options will require a higher risk premium as they are more likely to lose out to informed traders who may trade more put options, an argument which is consistent with that of Easley and O'Hara (2004).

Conversely, the short interest ratio level signals the release of negative information, which lowers the uncertainty of trading in put options. Consequently, investors trading in put options will not demand a higher illiquidity risk premium when the level of short interest ratio in the underlying stock is higher. For most of the moneyness- maturity categories, we even find a negative β4 coefficient, which is consistent with the argument of Wang (1993), that the illiquidity risk premium for put options will be lower when there is greater short interest ratio in the underlying stock.

The results on the impact of the supply-side measure (short-sales constraints or short-sales costs) on the illiquidity risk premium are shown in Table 8. Although there are no significant findings for call options, for put options, almost all of the β4 coefficients are found to be positive, with significance at the 1% level, for OTM contracts. In contrast to our earlier findings using other measures, the findings on short-sales constraints suggest that uninformed investors trading in put options will tend to demand a higher illiquidity risk premium for those stocks with higher short-sales constraints.

The option market can be used as a device for circumventing short-sales constraints in the stock market. For those stocks with greater short-sales constraints, informed traders will inevitably choose to trade in put options when they are in possession of private negative information. Therefore, uninformed traders buying put options on those stocks with high short-sales constraints will require a higher illiquidity risk premium since the risk arising from their informational disadvantage is higher. Although uninformed traders may realize that the put option market is a channel for informed traders to take advantage of their private negative information, they do not know when they will choose to do so; however, this is not the case for call options. These findings are generally consistent with Hypothesis 3.

In summary, we provide evidence to show that for both call and put options, information asymmetry and short sales have significant impacts on the illiquidity premium. Our findings reveal that information asymmetry and short interest (short-sale costs) are positively associated with the option illiquidity risk premium, particularly for call (put) options. Furthermore, these results are found to be especially robust for short-term or OTM option contracts, a finding which is consistent with the common belief that informed traders are more likely to trade in these contracts in order to realize their private information.

6. CONCLUSIONS

Based on the extant literature on the roles of informed traders in the option markets, we extend the work of Christoffersen et al. (2014) to examine the ways in which information asymmetry and short sales affect the option illiquidity risk premium. In addition to using the two measures of information asymmetry (ASY-INDEX and PIN), we also use the demand-side and supply-side measures of short sales (short interest and short-sales constraints) in order to examine their impacts on the relationship between option returns and option illiquidity.

Our findings reveal that both information asymmetry and short sales have significantly positive impacts on the option illiquidity risk premium, with our empirical results being found to be particularly robust for short-term contracts. These findings are also consistent with the argument put forward by Easley and O'Hara (2004) that uninformed traders will demand a greater risk premium when trading with informed traders.

In addition to confirming the findings of Christoffersen et al. (2014), we also contribute to the extant literature by introducing the influences of informed traders on the determination of option prices and documenting that information asymmetry and the demand and supply of short sales are important factors influencing the illiquidity risk premium across different firms.

This research aims to explore the role of service encounters and customers' participation in the interaction process to co-create value, leading to customer satisfaction. A model was developed which was tested in the health care context. Based on the data of 320 paired patient-physician cases, the analysis revealed that physician's interactions are critical customer-oriented behaviors which directly affect customer value. More importantly, it plays a key role in activating the customer participation to a service creation. From the customer view, although actively participating in a service requires more resources, it is worthy because it creates much more value-in-use.

Keywords: Value co-creation, customer participation, provider interaction behavior, health care service, Vietnam.

1. Introduction

In the recent years, the participation of customers in a service has received increasing attention from marketing academia as well as practitioners. Several studies have attempted to provide insights into the nature of customer participation, its mechanism, antecedents as well as consequences (Alam, 2011; Jo Bitner, Faranda, Hubbert, & Zeithaml, 1997; Lovelock & Young, 1979; Ordanini & Parasuraman, 2010; Ramaswamy & Gouillart, 2010; Tanev et al., 2011). Terms such as co-producer (Wikström, 1996), “partial” employee (Larsson & Bowen, 1989), value co-creator (Vargo & Lusch, 2004) have been suggested in the marketing literature to highlight the participative role of customer in a service.

The service dominant logic (Vargo & Lusch, 2004) and service logic (Grönroos, 2008) advocate that in the process of need-fulfillment, customers are the co-creator of value for themselves and the service provider is not a supplier of value but a facilitator of the customer’s value creation process. Service scholars indicate further that customers and service firm co-create value through resource integration and interaction (Gummesson & Mele, 2010; Vargo, Maglio, & Akaka, 2008). Despite this important notion, few studies have clearly analyzed the specific roles of service provider and the customer in the value co-creation process (Grönroos & Voima, 2013). Particularly, research to provide insights into the interaction behaviors of customers and a service firm (i.e., the service encounters) to create customer value is scant. Moreover, as individual customer has different level of resources and willingness to participate actively in the service process, it is important to understand how a service encounter can help to mobilize customers to participate in the service process.

In this context, the primary purpose of this research is to investigate how interaction behaviors of service encounters activate customer participation behaviors, and how both of which together create value for customers, leading to their satisfaction.

This research problem is specifically imperative in the health care context, where customers (or patients) are no longer considered as passive recipients of medical treatment, but actually play a more active role in improving the effectiveness of therapeutic activities (McColl-Kennedy, Vargo, Dagger, Sweeney, & van Kasteren, 2012). In this regards, Bodenheimer, Wagner, and Grumbach (2002) suggest to consider patient - professional partnership as the new paradigm of chronic disease management. In this partnership, physicians (doctors) are experts about diseases and patients are experts in their own lives and conditions. Thus, the collaboration process between a patient (customer) and a physician (service encounter) would be critical for the successful outcomes for customers (Yi & Gong, 2013).

The rest of this paper is organized as follows. The next section will present the theoretical background of key concepts, which is followed by the development for proposed hypotheses. Research design will then be reported which is featured by a dyadic approach to data collection. Data analysis, result discussions and implications are made up the final sections of the paper.

2. Theoretical background

2.1. *Customer participation behaviors to co-create value*

In a broad sense, value co-creation is described as a process in which efforts are combined among of firms, employees, customers, stockholders, government agencies, and other entities related to any given exchange, but is always determined by the beneficiary (e.g., customer) (Vargo et al., 2008). In this process, customers and the service firm hold crucial roles; and interaction between them is the key to value co-creation (Grönroos & Voima, 2012). In the interaction, the firm engages in the customer's value creation process as a value facilitator, and customer becomes a collaborator with service provider as a co-producer (Grönroos, 2008).

From the behavioral view, Yi and Gong (2013) describe customer co-creation behaviors as a construct made up of two components: participation behaviors and citizenship behaviors. Participation behaviors are an integral component of the production of a service. On the other hand, citizenship behaviors are customer activities related to the service, but out of the service process. These citizenship behaviors are not compulsory for the service creation, thus are beyond the scope of this current study.

Customer participation behaviors occur during the direct interaction with service encounter and are necessary to attain a proper performance in the service co-creation process. This concept has evolved from the interference of customer in service production (Levitt, 1972) to the engagement of customer in value creation (Grönroos & Ravald, 2011; Lusch & Vargo, 2006). Several studies have stressed that customer participation behavior can only occur in an interaction in the joint sphere of the service (Chan, Yim, & Lam, 2010; Grönroos, 2008; Yi, Nataraajan, & Gong, 2011). Specifically, Yi and Gong (2013) identify four dimensions of customer participation behaviors which represent the value co-creation process: (1) Information seeking – customers actively look for information about how to perform their tasks, what they are expected to do, and how they are expected to perform those tasks, in order to understand the nature of service and their roles in the value co-creation process; (2) Information sharing – customers share relevant information and expectation to help firms understand their particular needs and expectations; (3) Responsible behavior – customers recognize their duty and take responsibility to coordinate and ensure successful cooperation; and (4) Personal interaction – interpersonal relations between customers and employees, which are manifested by social aspects such as courtesy, friendliness, and respect.

2.2. *Service providers' interaction behaviors*

In an effort to bring the service dominant logic perspective into practice, Karpen, Bove, Lukas, and Zyphur (2014) introduce a framework of a firm's interaction capabilities to co-create value with customers. These interaction capabilities are then reflected by six corresponding manifestations as behaviors to facilitate the value co-creation process with customers. They include (1) Individuated interaction – behavior aiming to understand individual customers' unique contexts, their preferences and expected outcomes; (2) Relational interaction – behavior to improve social and emotional connections with customers in the service process; (3) Ethical interaction – behavior to reflect a fair manner towards customers in the service context; (4) Empowered interaction – behavior to empower customers to utilize their skills to shape the nature and content of exchange in the service process; (5) Developmental interaction – behavior to assist customers in developing their knowledge, competence, and skills; and (6) Concerted interaction – behavior to facilitate, coordinate and integrate customers in the service process. These six behaviors also reflect the resource integration mechanism of the service firm in the value co-creation process. Karpen et al. (2014) suggest that implementing these behaviors is an important strategy to drive customer-related participative performances, leading to perceived value, satisfaction, trust, repurchase intention, and positive word-of-mouth.

2.3. *Customer perceived value*

Perceived value, which is often understood as the overall assessment of the trade-off associated with customers’ experiences based on the perceptions of what is received and what is given (Zeithaml, 1988), can be considered as one of the main reasons for customers’ engagement with an organization. It is very important for firm to understand how to deal with and manage customer interactions in the value co-creation process, otherwise it may make customers perceive less value and lead to unexpected outcome (Sinnya, 2014).

Sweeney and Soutar (2001) introduce four dimensions to explain customers’ perceived value, including emotional, social, functional value (quality/ performance), and price dimensions. In the health care service context, the functional value and emotional value are most important to patients’ perception of service value since health care is regarded as 'high credence' services due to the need for high level of trust in health care professionals and its impacts on the quality of life (Venkatesh & Balaji, 2012). Therefore, the functional and emotional value (the utility generated from expected service’s performance and from feeling or affective mood through the service) will play the key roles in measuring perceived value in this study.

3. Proposed hypotheses

3.1. *Provider interaction behavior, customer participation and perceived value*

Interaction behaviors of service provider are important to activate customer participation and ensure the success of value co-creation. When using a service, each customer has a certain degree of resources such as knowledge and skills that can contribute to the service process (Grönroos, 2008). However, to activate these customer resources, the service firm needs to have certain behaviors to encourage customers to contribute their knowledge and skills and interact as a co-creator of value (Prahalad & Ramaswamy, 2000). As value is created in usage, interaction can make the value creation process of customers accessible by service providers and can provide them with an opportunity to influence customer’s experiences in the joint sphere and take part in the customer’s value creation process as a co-creator (Grönroos & Voima, 2013). Therefore, the service provider behavior to interact with customer and enhance collaboration are expected to have positive impact on the extent of customer participation.

In the health care service, behaviors to foster two-way communication or to open dialogue between physician and patient is also important to provide patients with the needed social or emotional support, making them feel at ease and psychologically comfortable during treatment and keep them engaging in value co-creation. As patients often possess little knowledge of their illness and therefore feel stressed and emotional (Berry & Bendapudi, 2007), the more pleasant and positive the social environment is, the more likely patients would be to collaborate in the treatment process (Lengnick-Hall, Claycomb, & Inks, 2000). Moreover, as physician attempts to share all relevant and non-misleading information during discussion or is willing to clarify any potential risks associated with certain types of treatment, confidence can also be built, potentially leading to active participation.

Physician's interaction behavior with patient in an individual basis is also critical to foster participation. Different patients, even with the same medical condition, may have completely different circumstances or context. If physicians are capable of approaching each patient individually and having a more thorough understanding of their idiosyncratic conditions (such as medical condition, their unique circumstance, preference for particular treatment options, and expected outcome of treatment), they can offer solutions that better fit each individual patient's expectation, which in turn will enhance the collaboration and facilitate value co-creation.

Furthermore, patient would be more willing to comply with the treatment options that they have jointly developed with the physician (Prahalad & Ramaswamy, 2004). If physicians are open to patients' suggestions and constantly provide feedback for preferred treatment option, patients would be more willing to get involved in the treatment process, and value co-creation would be facilitated and enhanced.

In combination, as physicians can interact with patients in an individual, relational, and ethical manner, patients would be more willing to take an active participation role in value co-creation and the value perceived by patients would also be increased. It is therefore, hypothesized that:

H1: Physician interaction behaviors have a positive impact on patient participation.

H2: Physician interaction behaviors have a positive impact on patients' perceived value.

3.2. *Customer participation and perceived customer value*

Kellogg, Youngdahl, and Bowen (1997) suggest that treating customer participation as a variable of their own value equation can create more implications for both researchers and managers. Within the health care context, patient participation in the treatment process can be demonstrated through various types of behavior.

First, patients may seek information to clarify service requirements and to understand the nature of service and their roles in the value co-creation process, helping them become more integrated into this process (Kelley, Donnelly, & Skinner, 1990; Kellogg et al., 1997; Yi & Gong, 2013). With adequate information, patients would feel more confident, uncertainty would be reduced, and they would be ready to cooperate with physicians, enhancing value co-creation.

Second, they may also express opinions, state preferences, and explore options (Cegala, Street Jr, & Clinch, 2007). By providing physicians with proper information and honestly answer all treatment-related questions, patients could help physicians make accurate diagnosis, understand their particular needs and successfully perform the duties, enhancing the value perceived by patients.

In addition, patients should cooperate with physicians in the value co-creation process through accepting the guidance and following advice and consultancy (Yi & Gong, 2013). As patients recognize their duties and responsibilities and what are expected of them, they would be more cooperative and the value co-creation would likely be successful, increasing the perceived value.

In short, as patients attempt to participate in the treatment process, their perceived value can be increased. Thus:
H3: Patient participation has a positive impact on patient's perceived value of the health care service.

3.3. *Perceived value and customer satisfaction*

Customer satisfaction is a widely researched construct in the literature which can be understood as the customer's emotional response to the fulfillment of needs, expectations, wishes or desires (Keiningham et al., 2015). It is defined as an affective state as the result of comparing the expected performance and the perceived performance of a service (Oliver, 1980). Customer satisfaction has been showed to have strong impact on positive word-of-mouth and loyalty (Ravald & Grönroos, 1996).
In health care service, patient satisfactions are regarded as common evaluation in achieving quality service and the goal of chronic treatment (Aliman & Mohamad, 2013; Anderson & Zimmerman, 1993; Porter, 2010) because it is related to patients' acceptance to treatment continuation, relationship with physician, patient adherence and subsequent desired outcomes. Empirical evidence suggests that perceived value is a contributing factor to satisfaction (Yang & Peterson, 2004); and that service providers can spend their effort on improving value perceived by customers to increase customer satisfaction. Vega-Vazquez, Ángeles Revilla-Camacho, and J. Cossío-Silva (2013) also prove a positive relationship between value co-creation and customer satisfaction. The patients' participation in making decision together with health care professionals could improve their disease status, reduce stress, and therefore increase their perceived value and satisfaction. Therefore, it is hypothesized that:

H4: Patients' perceived value has a positive impact on their satisfaction.

3.4. *Research model*

Figure 1 depicts the proposed research model. In this model, the interaction behaviors of a service provider, the participation behaviors of customer and customer's perceived value are all operationalized as second-order reflective constructs. Within the health care context, physician interaction behaviors are reflected by individuated interaction, relational interaction and concerted interaction. Patient's participation behaviors are reflected by information seeking, information sharing and responsible behavior, while perceived value includes functional and emotional value.

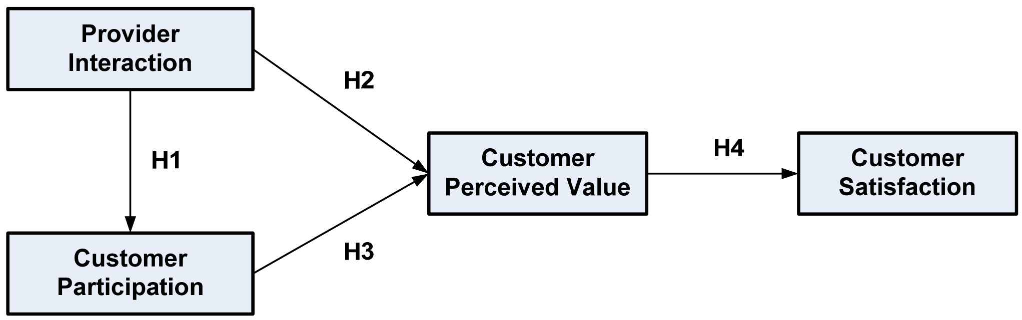

Figure 1: The proposed research model

4. Method

Quantitative data were collected via face-to-face interviews with a structured questionnaire at outpatient departments of 59 public and private hospitals in HCM City based on convenient sampling method. At each interview site, the dyadic technique was applied which matched one patient and the corresponding physician into a paired case. For each paired case, the physician was first interviewed about his/her interaction behaviors, and then he/she was asked to recommend one chronic patient for a following interview about participation behavior, perceived value and satisfaction level.

The scale measuring physician interaction behaviors was based on Karpen, Bove, and Lukas (2011) and consisted of 11 items reflecting three dimensions (individuated interaction, relational interaction, and concerted interaction). Patient participation behaviors were measured by 10 items reflecting three dimensions (information seeking, information sharing, and responsible behavior) and were adapted from Yi and Gong (2013). Patient perceived value and satisfaction were measured by 4 and 5 items, respectively, which were adopted from Sweeney and Soutar (2001) and Aliman and Mohamad (2013). All items were measured in 5-point Likert scale.

5. Results

5.1. Sample characteristics

A total of 320 pairs of response (i.e., 320 cases) were collected and qualified for use in the data analysis. The sample characteristics are presented in Table 1.

Table 1 – Sample characteristics

Hospital type:	
Public	65%
Private	35%
Chronic disease:	
Cardiology	12%
Hypertension	13%
Diabetic	10%
Asthma + COPD	20%
Rheumatology, Hepatitis	9%

	Combined disease			20%
	Others			15%
Frequency of visit:				
	First time			11%
	Two times per month			44%
	Once per month			33%
	Once per 2 months			12%
Gender:				
		Physician		
		Male		Female
Patient	Male	24%		19%
	Female	29%		28%
Age group:				
		Physician		
		25-35	36-45	46 & above
Patient	35 and below	4%	5%	6%
	36-45	7%	8 %	5%
	46-55	5%	11%	6%
	56 and above	11%	21%	11%

5.2. Validity and reliability of measures

Exploratory factor analysis (EFA) and Cronbach alpha were first employed for preliminary assessment of dimensionality, reliability and construct validity. Then, the qualified items were submitted to confirmatory factor analysis (CFA) to examine the full measurement model. The test for normality showed that 24 remaining items have kurtosis values range from -1.036 to 1.630 and skewness values range from -0.883 to 0.183 which indicate a slight deviation from normal distribution (Kline, 2011). Therefore, maximum likelihood (ML) was an appropriate estimation method (Fabrigar, Wegener, MacCallum, & Strahan, 1999).

The CFA of the full measurement model resulted in satisfactory fit indices: Chi-square = 265.01; dF = 173; GFI = 0.931; CFI = 0.970; TLI = 0.960; RMSEA = 0.041. The HOETLER index of 247 was above the threshold value of 200, indicating that the sample size was large enough for this analysis (Byrne, 2001). These results showed an acceptable fit between the measurement model and the data collected. Factor loadings of items ranged from 0.50 to 0.86 and composite reliabilities were from 0.57 to 0.87. Correlation coefficients between pairs of constructs ranged from 0.26 to 0.84, which were below 1.00 (at p = 0.05). Thus, the measurement scales for each first-order concepts were satisfactory in terms of reliability, convergent validity and discriminant validity.

5.3. Structural model estimation and hypothesis testing

Given the satisfactory fit of the measurement model, the proposed hypotheses were then tested using structural equation modeling. In order to reduce the complexity of the model which comprises many second-order reflective constructs, item parceling technique (Bagozzi & Heatherton, 1994) was applied. Accordingly, 11 composite indicators were created from 22 original indicators, with kurtosis values ranging from -0.917 to 1.570 and skewness values ranging from -1.003 to 0.044. Maximum likelihood method is still appropriate for estimation.

The estimation of the proposed structural model using Maximum Likelihood method resulted in a good fit: Chi square = 66.977; dF = 40; CFI = 0.980; GFI = 0.964; TLI = 0.972; RMSEA = 0.046. Loadings of items on their respective latent constructs ranged from 0.50 to 0.86

Based on the standardized path coefficients (Table 2), we found that all four hypotheses were supported. As predicted, physician interaction behaviors have a strong and positive impact on patient participation behaviors ($\beta = 0.62$; $p < 0.01$) as well as value perceived by patient ($\beta = 0.32$; $p < 0.01$); patient interaction behaviors are strongly and positively associated with their perceived value ($\beta = 0.57$; $p < 0.01$); and patient perceived value has a strong and positive impact on their satisfaction ($\beta = 0.89$; $p < 0.01$).

The results also showed that the proportion of the variance in patient's perceived value explained by patient participation and physician interaction behaviors was considerably high at 65% and patient perceived value explained 78% variance of patient satisfaction.

The hypotheses testing results are summarized in Table 2, along with the standardized parameter estimates.

Table 2. Standardized estimates

	Hypothesis	Standardized Coefficients	Sig.	Result
H1 (+)	Physician Interaction → Patient Participation	0.62	***	Supported
H2 (+)	Physician Interaction → Perceived Value	0.30	***	Supported
H3 (+)	Patient Participation → Perceived Value	0.57	***	Supported
H4 (+)	Perceived Value → Patient Satisfaction	0.89	***	Supported

6. Discussions

Literature advocates that customer and service provider co-create value (Grönroos, 2008); and that the value is co-created through resource integration and interaction (Gummesson & Mele, 2010). In this specific study in the context of health care service, the results provide more concrete empirical evidence on the roles and mechanism in which the two sides, i.e., service encounters and customers interact directly within the joint sphere to co-create value for customers.

Firstly, co-creation of value requires that services are not solely produced by the firm and customers are not passive recipients of value. It reflects the reality that customers must participate in the service creation process (Vargo & Lusch, 2004). In the health care context, the participation or involvement of customers is compulsory. Previous studies have shown that patient participation behaviors taken in the forms of information sharing and information seeking are key to patient-physician relationship and patient satisfaction (Epstein & Street, 2011; Holman & Lorig, 2004; Yi & Gong, 2013). However, participating in a service process also means that customers must spend more of their own resources in addition to the amount of money they pay. In the customer view, whether there is an additional value in the trade-off between the spending additional resources and receiving a more customized and/or better quality service. With the empirical result indicating the positive effect of customer participation on customer perceived value in health care context, the current study provides an empirical evidence to consolidate the notion that the more actively a patient participate the better service value he or she would receive. In other words, this study is in strong support of the view on customer as co-creator or co-producer of value in the foundational premises of service dominant logic suggested by Vargo and Lusch (2004) and Grönroos (2008).

Secondly, the participation of service customers in a service must be inquired in the context of its interaction with service provider (Gummesson & Mele, 2010). The current study extends our understanding on this interaction by specifying the role of the two sides. Particularly, it is founded that there is a significant positive effect of interaction behaviors of the service provider (i.e., service encounters) on customer participation. That is, the extent of customers' participation is depended on how the service provider interacts with them in the role of an initiator. Given the notion that both sides are co-creators of value, this result indicates that service encounters actually keep the initiative role in activating the service customers to participate. This role of service provider is very important in service contexts where customer participation is a required part of the value co-creation procedure but customers are reluctant or not confident to participate, such as health care, education, consulting or other professional services (Lengnick-Hall et al., 2000).

The third issue relates to capability of service encounters in directly creating value for customer through their interaction behaviors. In this case of health care service, physician interaction behaviors are positively associated with patient perceived value. Interaction activities undertaken by physicians may include detailed discussion with patient about treatment plan, explanation about how the patient can best assist the healing process, or any additional information sources the patient may find useful, which in turn will translate into more informed decisions. In addition, as physician attempts to address each patient individually, spend time listening to their concerns and demonstrate sympathy and care, patient can feel emotionally supported. Thus, confidence can be built and patient can make better and more informed choices regarding their treatment procedure. All of these potential outcomes will definitely enhance customer perception of service value in both process and outcome forms.

From the practical view, some managerial implications can be drawn from the results of this study. In Vietnam, one of the most challenging barriers for patient participation in the treatment process stem from inadequate information and knowledge on the patient side. Additionally, the lack of commitment, interpersonal and communication skills on the physician side may potentially lead to therapeutic failure. It would be more difficult to enhance patient participation in public hospitals since physicians may not have sufficient time to spend on consulting individual patient due to the heavy workload (Krueger et al., 2001). Therefore, measures to improve the physician's interpersonal and communication skills can increase collaboration and interaction between physicians and patients, which will then enhance patient satisfaction and lead to positive effect on treatment adherence and outcomes.

7. Conclusion

In aggregation, the current study contributes to extend our knowledge about the twofold roles of interaction behaviors of service encounters in the context of heath care. Interaction behaviors are primarily a reflection of the customer-oriented behavior (COB), a critical success factor in any high-contact service (Mechinda & Patterson, 2011). Moreover, it also plays crucial role in activating the participation of customers to contribute their resources for a better service production, leading to higher value perception and customer satisfaction. From the customer view, although actively participating in a health care service requires more resources, it is worthy to do so because it creates much greater value-in-use for them.

From the methodological view, a feature of this study is the dyadic approach to data collection. While many prevailing quantitative studies employed survey data collected from single informants, the current study relied on paired-case approach to data collection for a better reflection the nature of two-side interaction. More importantly, it is considered one among the most effective ways to minimize the common method bias in the survey data which leads to systematic errors (Podsakoff, MacKenzie, Lee, & Podsakoff, 2003).

There are a number of limitations of this study, which suggest areas for further research. From the general theoretical view on the provider – customer interaction to co-create value, this research confined within one service industry context (i.e. health care). Given the diverse nature of services, further research is suggested to examine the roles of interaction in services with different features in terms of level of contact (high vs. low), knowledge distance between customer and provider (high vs. low), target of service acts (object vs. human), relation base (membership vs. contract-based). Another issue that is worthy to explore relates to the changing roles in the interaction between service encounters and customers in different stages of the service value co-creation, which are out of the direct interactive joint sphere of the process.

nguyenhoang.pham1@live.vu.edu.au

Abstract

Purpose **–** Given the knowledge gap in the mediated effects of ownership structure on

firm performance, the purpose of this paper is to test whether agency costs and corporate risk-taking mediate the relationship between equity ownership structure and firm performance.

Methodology **–** The causal-steps approach is adopted to model the relationship from past ownership structure via current agency costs and current risk-taking to current firm performance. The generalized method of moments (GMM) and panels corrected standard errors (PCSEs) estimations are used with a sample of 475 observations on listed firms on the Vietnamese stock markets over a five-year period (2008-2012).

Findings **–** The results suggest that agency costs mediate the positive effect of past government ownership and past insider ownership on current firm performance, while risk- taking mediates the negative effect of past foreign ownership on current firm performance.

Implications/Originality **–** This new evidence enhance our understanding of how ownership structure affects firm performance. Government ownership and insider ownership, but not foreign ownership, can mitigate agency problems in listed firms in transitional and emerging countries.

Keywords Ownership structure, firm performance, agency costs, risk-taking, mediation, Vietnam

1. Introduction

Performance of a firm can be influenced by its ownership structure due to several reasons: i) owners have different power, incentives and ability to monitor managers due to the difference in their identities, concentration and resource endowments; and ii) owners have varying goals for their involvement in firms, resulting in different effects on firm performance (Douma, George & Kabir 2006). However, ownership-performance issue is not only involved with such a question of why ownership structure affects firm performance but also how, or via which channels, the former affects the latter. Since most prior literature on this issue has ignored mediation approach, the mechanisms by which the effects of ownership structure are transmitted to firm performance are not adequately understood.

In practice, ownership structure-firm performance relationship has a long tradition of research, at least since Berle et al. (1932) with emphasis on manager ownership-firm performance; but the issue remains controversial until recently, in particular for other dimensions and/or forms of equity ownership such as ownership concentration, government ownership or foreign ownership. For instance, while many authors such as Megginson, Nash and Randenborgh (2012) or Djankov and Murrell (2002) argue that government ownership is inefficient and negative for firm performance, some other authors such as Tian and Estrin (2008) or Vaaler and Schrage (2009) claim that government ownership at a certain levels helps improve firm performance.

Moreover, most prior studies on the association between ownership structure and firm performance have adopted the direct approach (i.e. ownership structure directly affect firm performance). It can be argued that this approach may lead to spurious results because the indirect links may exist in reality and they can divert the effect of ownership structure. Consequently, the estimated coefficients obtained from this approach merely indicate the total effect of the former on the latter, while the other types of effects such as indirect and direct effect are not identified.

Consistent with Le and Buck (2011), this research firstly argues that ownership structure does not itself 'cause' firm performance, and agency cost is a 'missing link' in this relationship. Agency theory suggests that the relation between firm performance and ownership structure is closely associated with agency costs because different forms of ownership may have different levels of agency costs. In turn, agency costs can adversely affect firm performance (Brown, Beekes & Verhoeven 2011). The out-of-equilibrium model of relation between corporate governance and firm performance also suggests that corporate governance has a causal effect on firm performance indirectly through its impacts on the agency conflict of the firm, which is embodied with the incentives and monitoring of the management (Tan 2009).

In addition, agency theory also suggests the link between equity owners and risk- taking. Accordingly, shareholders have different risk preferences; for example, managers are commonly regarded as risk-averse shareholders since their human capital invested in the firm is not diversified (Himmelberg, Hubbard & Palia 1999). It can be argued that these differences can influence risk-taking behaviours of the firm. In addition, it is well documented in corporate risk management theory that risks are closely associated with firm performance. 'High risk-high return' is a well-known hypothesis in this connection. As a result, another issue of concern is whether there is a continual connection of ownership structure-corporate risk taking-firm performance; that is, whether corporate risk-taking transmits the impact of ownership structure to firm performance. However, the understanding of a mediation mechanism among these three variables is quite limited in the literature. It is thus argued in this paper that corporate risk-taking is another 'missing link' between ownership structure and firm performance.

Taken together, this paper is aimed at answering the following research questions:

1) Is the relationship between ownership structure and firm performance mediated by agency costs and risk-taking?

2) Do agency costs contribute as much as risk-taking to explaining the effect of ownership structure on firm performance?

The focus of this study is on the relationship between three ownership identities (government ownership, insider ownership and foreign ownership), two mediator variables (agency costs and corporate risk-taking), and financial firm performance (return on assets or Tobin's Q). A two-mediator model is established to examine the related paths among these variables. All ownership variables are lagged by one year to formulate potential causal effects between ownership structure and firm performance.

In terms of research context, this study examines the issue from the context of the stock markets in the developing and transitional economy of Vietnam for several reasons: 1) no prior research has been undertaken on the mediated relationship between ownership structure and performance of the Vietnamese listed firms; 2) this country has unique characteristics in terms of newly developed stock markets, risk-seeking attitudes of shareholders and transitional economy.

Using causal-steps approach (Baron & Kenny 1986), I find evidence of the mediation effect of agency costs and risk-taking. Specifically, agency costs fully mediate the positive effect of past government ownership and past insider ownership on firm performance, while

risk-taking mediates the negative effect of foreign ownership on market performance only. The finding for government ownership is consistent with Le and Buck (2011) and it challenges prior studies on developed markets which postulate a negative impact of government shareholding. The finding for insider ownership supports the 'alignment of interest effect' hypothesis. The result for foreign ownership suggests that foreign shareholders are risk-adverse investors in the Vietnamese stock markets. Additionally, the risk-seeking behaviours of government and insider shareholders do not lead to higher firm performance.

This study contributes to the literature in several aspects. First, this is the first study that adopts mediation approach to examine the relationship between multiple forms of ownership structure and firm performance. Second, this study contributes to the application of agency theory in a mediation context. Third, this research extends Le and Buck (2011) in terms of developing two-mediator model to explain the relationship. Forth, this research provides useful implications for the privatization process in developing countries because it explores the effect of both public and private forms of equity ownership on listed companies' performance. Last, this first study is the first that examines the inter-relationship between equity ownership structure, agency costs, risk-taking and firm performance of the Vietnamese listed companies.

This paper has some limitations. First, the findings may be generalized to listed firms only because the sample does not contain the firms outside stock markets. Second, causal- steps approach suffers from a few limitations, including the lack of the specific indirect effects and standard errors of mediated effects. Third, the reverse causal effect of firm performance on ownership structure is not yet considered in this research. A more proper understanding of the mediated relationship could be obtained if the feedback effect of firm performance is accounted for.

Section 2 of this paper presents a review of related literature on the issue. Section 3 discuses theoretical foundation of research. Section 4 describes data sample. Section 5 introduces empirical models, estimation methods and variable measurement. Section 6 reports the main results of the study. Section 6 discusses empirical results and concludes the paper.

2. Review of related literature

As aforementioned, almost all prior studies only examine the total effect of ownership structure on firm performance due to direct approach to the issue. This section reviews related literature on the total effects between three types of equity ownership (government ownership, insider ownership and foreign ownership) and firm performance, and agency costs and risk-taking where they are relevant.

Government ownership-firm performance

An overwhelming viewpoint is that government ownership is normally associated with inefficiency and bureaucracy, i.e. negative relationship between government ownership and firm performance (Djankov & Murrell 2002; Netter & Megginson 2001; Thomsen & Pedersen 2000). However, there is a considerable amount of empirical evidence that runs counter to such position. Many authors claim that government ownership can contribute to improving firm performance, conditionally among a certain group of listed companies or subject to country-specific contexts. For example, in China's stock market, Tian and Estrin (2008) report that government ownership is positively related to firm performance when the government ownership reaches a certain high level or more than 25%; LI, Sun and Zou (2009) find that the negative effect of government ownership on firm performance is 'only among the more profitable firms'. Vaaler and Schrage (2009) state that government ownership is also able to positively contribute to firm performance if government holds no more than 50% ownership in a low policy stability country, and no more than 25% of ownership in a low-to-mid policy stability country.

Insider ownership-firm performance

There are basically three main streams of literature regarding the relationship between managerial/insider ownership and firm performance. The first is termed 'alignment of interest effect' (Jensen & Meckling 1976). Berle et al. (1932) argue that the separation of ownership from control will reduce manager's incentives to pursuit the goal of corporate profit maximization. As a result of the conflict of interest between managers and shareholders, or between majority and minority shareholders (Clacher, Hillier & McColgan 2010), if the interests are aligned between managers and shareholder, the higher proportion of managerial ownership can support an improved firm performance level. This proposition is supported by empirical evidence such as Bhagat, Bolton and Romano (2010) and Mehran (1995) who also claim that managerial equity ownership and firm performance is positively associated.

In contrast, the second stream postulates 'entrenchment effect' so that as the proportion of equity owned by managers increases, they will have less incentives to pursuit the target of corporate profit maximization. In other words, managerial ownership and firm performance is negatively related. According to Shleifer and Vishny (2008), managers will get involved in non-maximizing behaviours when they hold up to a certain level of a firm's ownership.

The third stream of literature in this regard argues a non-linear relationship between managerial ownership and firm performance. The overall effect of managerial ownership on firm performance may depend on the relative strengths of two above-mentioned forces: alignment of interest effect and entrenchment effect; accordingly, managerial ownership at a certain range of managerial ownership is positive for firm performance if the alignment effect is dominant and vice versa over some other ranges if the entrenchment effect dominates (Morck, Shleifer & Vishny 1988; Thomsen & Pedersen 2000).

Foreign ownership-firm performance

Studies on the effect of foreign ownership also provide mixed results. On the one hand, a large body of literature find a significant positive effect of foreign ownership on firm performance, whereby it can bring about an increase in firm value (Dwivedi & Jain 2005; Sabur, Omar Al & Wares 2012; Sarkar & Sarkar 2000). On the other hand, foreign ownership is found to be significantly negatively associated with firm performance (Sulong & Nor 2008).

Ownership structure-agency costs-firm performance

In terms of a potential mediation role of agency costs in ownership-performance relation, some authors such as Thomsen and Pedersen (2000) show that ownership structure may affect agency costs and consequently a firm's financial performance and investment opportunities. Denis (2010) and Jensen and Meckling (1976) also indicate that concentrated ownership may reduce agency costs because large shareholders have more incentive and ability to influence managers, thus increasing firm value when there is the concentration of cash flow rights.

Many studies have been undertaken to examine the impact of agency costs in a range of finance-related choices such as ‘capital structure, maturity structure, dividend policy, and executive compensation’(Ang, Cole & Lin 2000, p. 81). However, few studies have sought the intervening role of agency costs in equity ownership-performance relationship; while most others merely investigate separately the association either between ownership structure and agency costs, or between agency costs and firm performance. For example, Ang, Cole and Lin (2000) argue that agency costs are closely associated with the agency conflict between shareholders and managers within a firm. They eventually find that agency costs are inversely related to managerial ownership in the U.S. market. In the context of a developing country, Sabur, Omar Al and Wares (2012) argue that there exists a high agency problem and

that agency conflict lies with shareholdings by sponsors, government, institutions, and foreigners as indicated by the negative effects of such identities on firm performance.

The most relevant literature on the mediated effect of ownership structure on firm performance is Le and Buck (2011). Using causal-steps approach, Le and Buck (2011) find that agency costs mediate the positive impact of government ownership on firm performance measured by return on assets and return on equity, and there is no direct effect of government ownership on firm performance in the Chinese stock market. However, the investigation of the authors is merely confined to government ownership; and all variables are measured contemporaneously, leading to weak inference for potential causal effects of government ownership on firm performance.

In general, it can be argued that the literature on the mediated relationship is between ownership structure and firm performance is rather limited. Apart from Le and Buck (2011), mediation analysis approach has not been applied to identify the mediating effect of agency costs associated with other forms of ownership such as insider ownership and foreign ownership.

Ownership structure-risk-taking-firm performance

Like the case of agency costs, most previous studies do not treat risk-taking as a mediating variable in the association between equity ownership and firm performance. It is quite common in the literature that only individual directions of effects are tested, either between ownership and risk-taking or between risk-taking and firm performance.

John, Litov and Yeung (2008) investigate the association between investor protection and risk-taking, and then between risk-taking and country-wide performance (productivity and GDP growth). The authors argue that insider or manager ownership is among a number of factors that influence risk-taking. In particular, in countries with low investor protection, managers are often dominant insiders and they may prefer to avoid risk-taking to protect their expected private benefits. This is a useful implication for follow-up studies that use data from developing countries where investor protection is poor. However, due to the objectives of research, John, Litov and Yeung (2008) do not attempt to examine the intervening role of risk-taking in the association between insider ownership and performance.

In the context of Korean market, Kim (2011) to examines the association between foreign ownership and risk-taking in investment of firm, and the relation between risk-taking and firm growth. Controlling for endogeneity by 2SLS regressions, Kim (2012) reports that foreign ownership is found to be positively related to risk-taking in firms with greater opportunities for investment, and risk-taking in turn improves firm growth. However, since this study uses cross-sectional data, a limitation of Kim (2012) is the lack of discussion about the changes of foreign ownership and risk-taking over time, which is important when the time effect is available. Besides, risk-taking as a connecting point between foreign ownership and firm growth is not considered in this study.

Using a panel data sample of the Turkish market, Guner and Kursat (2002) investigate the effect of ownership structure on firm performance and risk-taking, respectively. Applying ordinary least squares (OLS) regression for panel data, the authors report significant links between ownership structure and firm performance, and between ownership structure and risk-taking. Firms with highly concentrated ownership and government-owned firms are found more easily to take risk. Like previous studies, a potential connected link from ownership structure-risk taking-firm performance is not examined in this study

3. Potential mediating role of agency costs and risk-taking in ownership-performance relationship

Agency theory defines agency relationship as a contract between the principles and the agent, under which the latter is delegated with authority to perform some service on the former's behalf (Jensen & Meckling 1976). Two agency problems are concerned in the agency relationship: 1) the conflict in the goals of the principle and the agent, and 2) the risk sharing between the principle and the agent when there is difference in their risk preferences (Dias & Mroczkowski 2012). Therefore, it can be argued that the conflict of interests and risk preference are the two core factors that can explain the relationship between equity ownership and firm performance.

In terms of the conflict of interests, it is widely known from the agency theory that 'the agent will not always act in the best interest of the principal', and 'it is impossible for the principal or the agent at zero cost to ensure that the agent will make optimal decisions from the principal's viewpoint'(Jensen & Meckling 1976, p. 5). Hence, it is documented in agency models that the misalignment of interests between managers and shareholders causes costly actions undertaken by managers (Bhagat & Jefferis 2002). Intuitively, agency costs are incurred by firm due to the divergence in the interests of managers and shareholders. Regardless of the existence of agency costs, shareholders are still willing to provide a considerable amount of their capital to corporations run by managers; it is thus popular that equity ownership structure is widely held (Jensen & Meckling 1976). As a result, each type of ownership structure may be related to a certain level of agency costs.

Additionally, ownership structure can influence agency problems in the sense that it can be used as a mechanism to control such problems (Agrawal & Knoeber 1996). For instance, an increase in the level of insider ownership is regarded as one of effective corporate governance mechanisms to mitigate the agency conflicts in such a way that they are consistent with shareholders' interest and if a contract between the firm and managers cannot make it possible (Bhagat, Bolton & Romano 2010). The formation of a board of directors is also a solution to the agency problems (Hermalin & Weisbach 2003).

Ownership structure may have effect on agency costs and consequently firm performance and investment opportunities (Thomsen & Pedersen 2000). In this connection, the out-of-equilibrium model, which is based on "inefficient hypothesis", holds that since corporate governance structure is not optimal, any adjustment on corporate governance will result in direct effect on agency conflict, which in turn affects firm performance (Hermalin & Weisbach 2003; Tan 2009). Thus, it is assumed in this model that there is an indirect link between corporate governance mechanisms and firm performance through agency costs.

With regards to risk preference aspect, agency theory also suggests that the degree of corporate risk-taking is influenced by the risk preference of equity owners. Individual shareholders may have different risk attitudes, which indicate the link between ownership structure and risk-taking. Specifically, the risk preference of a shareholder may be categorized into one of the following three types: risk aversion, risk neutrality and risk seeking (McGuigan, Moyer & Harris 2005; Merna & Al-Thani 2008).

Most prior literature on corporate risk-taking in agency context focuses on the behaviour of inside managers (Kim 2011) and often regards managers as risk-averse shareholders. Unlike outside shareholders who tend to take higher risks to the extent that they can diversify, insiders may ignore risky projects because the human capital of managers invested in the firm is not diversifiable. The greater corporate resources the insiders expect to divert, the more the insiders will avoid taking risky investments to protect their private benefits (Himmelberg, Hubbard & Palia 1999).

Overall, it can be argued that agency theory can explain the indirect link between ownership structure- agency costs - firm performance, as well as the direct link between ownership structure and risk-taking, but it does not suggest the direct link between risk-taking
and firm performance. Corporate risk management theory can complement this limitation of agency theory. The focus of corporate risk management is on the risk-return trade-off (Gordon, Loeb & Tseng 2009); and a conventional assumption in finance theories is that 'higher risk' implies 'higher potential return' (Drever, Stanton & McGowan 2007). Corporate

risk management has become another area of corporate governance. Taking care of risk- taking in entrepreneurism is crucial to ensure that directors are accountable for the firm. Hence, an issue of common concern is how to make a balance between regulation and control on the one hand and the opened room for risk-taking and innovation necessary for economic growth on the other hand (Farrar 2008). Therefore, risk-taking can be viewed as another intervening factor that transmits the effect of ownership structure on firm performance.

4. Data Sample

4.1. Data sources

Financial data of listed firms are obtained from audited annual financial statements,
which are sourced from DataStream. Stock price data are retrieved from the database of stock exchanges which are available on the websites of Hanoi Stock Exchange and Hochiminh Stock Exchange1. Ownership data are hand-collected from company annual reports, which are also downloadable from the websites mentioned above. Since all such data are publicly disclosed as required by the Securities Law, an advantage of this collection is that every single item in the data sample can be cross-checked for accuracy from different sources on the markets, including database of securities companies and listed companies themselves.

4.2. Sample collection and data cleansing procedures

Data in this thesis started with a population of 288 firms, which is the number of all
listed companies on Vietnam's stock markets in 2008, including both Hanoi Stock Exchange and Ho Chi Minh Stock Exchange. The period from 2008 to 2012 is selected due to three following reasons: (i) the year of 2008 was one year after the Securities Law of 2007 in Vietnam came into effect, which is believed to enhance the quality of mandatory information disclosure due to strict legal enforcement; (ii) Data from 2008 of Vietnam's listed companies and stock market were provided in international data terminals such a DataStream; and (iii) Almost all financial reporting standards applicable on Vietnam's stock markets, which are based on the International Financial Reporting Standards (IFRS), were completed and adopted since 2008.

The listed companies must have full 5 years of continuous listing in the period from 2008 to 2012 to enable the efficient use of lagged values of variables. Following previous studies, financial companies were excluded due to the incompatibility or differences in financial statements as compared to non-financial companies. To maintain the quality of data, companies with incomplete data, i.e. lacking annual reports or financial statements of one or more fiscal years, were removed. Finally, a balanced panel data sample is obtained with 475 observations in total (95 firms and 5 years).

In order to mitigate the effect of potential outliers, the most common procedure is to winsorize variables (Leone, Minutti-Meza & Wasley 2014). In comparison with other procedures of data accommodation such as trimming or piecewise linear regression, winsorizing is unaffected by sample size and it helps a regression model fit the data well while having a low level of prediction error (Kennedy, Lakonishok & Shaw 1992). Although there is no generally-accepted guideline for an appropriate fraction of observations to be winsored, a low percent winsorization may miss out many outliers. The percentage of gross errors can be a few in average-quality data and quite realistic at 10% in fairly low-quality data (Hampel 1986). In this thesis, following Miller, Xu and Mehrotra (2014), a 5% winsorization level is selected. While these authors apply the 5% winsorization to dependent variables only, this thesis winsorizes both dependent (outcome) and independent (predictor) variables; i.e. except control variables. This is because winsorizing predictor variables but not dependent variables can lead to biased coefficients (Leone, Minutti-Meza & Wasley 2014). In addition, similar to Chen, W, Liu and Ryan (2008), the lower tails of government ownership and foreign ownership are not winsorized because they are bounded by zero and contain some zero observations (i.e. firms without shareholding of government ownership and foreign ownership).

5. Mediation model and variables

5.1. Recursive model and causal-steps approach

The literature on mediation mechanism suggests that it is unlikely for the effect of a variable to be mediated by only a single mediator variable in most situations (Preacher & Hayes 2008). In the meantime, it is suggested in agency theory and risk management theory that agency costs and risk-taking can be considered as two main mediators of the effect of ownership structure on firm performance as already mentioned. Hence, this research develops a two-mediator model where the direction of effects flow from past equity ownership via current agency costs and current risk-taking to current firm performance. It is plausible to specify ownership structure at past period and firm performance at current period to formulate potential causal effects in ownership-performance relationship. If variables are measured at the same time, there may be not enough time for independent variable to affect mediator variable or mediator variable to affect outcome variable (Gollob and Reichardt 1991, cited in MacKinnon 2012); and more accurate conclusions about mediation can be obtained by considering the temporal order of change over time (MacKinnon 2012).

Following MacKinnon (2012), a two-mediator recursive model is specified with four equations below:

Firm Performance = $i1 + cL$.Ownership Structure $+Z1 + \varepsilon 1$ (1)

Agency Cost = $i2 + a1L$.Ownership Structure $+ Z2 + \varepsilon 2$ (2)

Risk-Taking = $i3 + a2L$.Ownership Structure $+ Z3 + \varepsilon 3$ (3)

Firm Performance = $i4 + b1$Agency Costs $+ b2$Risk-Taking$+ c'L$.Ownership Structure $+Z4 + \varepsilon 4$ (4)

where a1 and a2 are the parameter relating one-year lagged ownership structure (L.Ownership Structure) to the first mediator (agency costs) and to the second mediator (risk-taking), respectively. b1 represents the effect of the agency costs on firm performance adjusted for ownership structure and risk-taking. b2 represents the effect of risk-taking on firm performance adjusted for ownership structure and agency costs. c and c' are the total effect and direct effect of one-year lagged ownership structure on firm performance, respectively. L.Ownership Structure consists of lagged government ownership, lagged insider ownership and lagged foreign ownership. Firm Performance is either ROA or Tobin's Q. Z1, Z2 Z3 and Z4 are vectors of control variables that influence dependent variables. ε1, ε2, ε3 and ε4 are error terms that contain random disturbance and unobserved heterogeneity. i1, i2, i3 and i4 are intercepts.

In this model, agency costs, risk-taking and firm performance are not endogenous covariates since only Equation 4 depends on Equation 2 and Equation 3. Thus, each equation in this system can be individually estimated by a different regression method under the causal-steps approach proposed by Baron and Kenny (1986). According to Preacher and Hayes (2008) and MacKinnon (2012), the causal-steps approach can be used in multiple- mediator context, and the main concern under such approach will be the significance of the paths defining specific indirect effects (a and b parameters in the above model). As summarized by Preacher and Hayes (2008) and MacKinnon

(2012), the Baron and Kenny (1986) causal-step approach can be applied to confirm mediating effect if the following conditions are met:

1) The relationship between predictor variables (ownership structure) and outcome variables (firm performance) is significant (Equation 1 above).
2) The relationship between predictor variables (ownership structure) and mediator variables (agency costs and risk-taking) is significant (Equation 2 and Equation 3 above).
3) The effect of mediator variables (agency costs and risk-taking) on outcome variables (firm performance) controlling for predictor variables (ownership structure) is significant (Equation 4 above).
4) The effect of predictor variables (ownership structure) on outcome variables (firm performance) decreases substantially when both predictor variables and mediator variables are simultaneously regressed.

Following the conditions above, each equation in the recursive model will be regressed in order, starting from Equation 1; hence there will be four steps of regression. Under the 4th condition, partial mediating effect is established if the effect of predictor variables is decreased but still significant; and full mediating effect occur when this effect is no longer significant.

5.2. Predictor variables

Lagged government ownership (L.GOV)

This proxy is measured as the one-year lagged of the proportion of shares owned by government agencies or SOEs over the total common shares of a firm. In fact, the ratios of government ownership can be obtained straightforwardly without any calculation because they are clearly stated in the annual reports of the Vietnamese listed firms.

In Chinese context, Le and Buck (2011) find that the effect of government ownership on firm performance is positively mediated by agency costs. Since Vietnam shares similar characteristics with China in terms of the dominant role of government ownership in the economy, it is plausible to expect that the relationship between L.GOV and firm performance is positively mediated by agency costs; that is, the higher percentage of L.GOV is followed by the lower level of agency costs, and lower agency costs are associated with an improved firm performance level. Besides, for political reasons and power, government shareholders may have strong incentives for preserving and increasing the value of the state capital in listed firms. Hence, they would tend to seek for potential returns by supporting risky investment projects. Because the ‘high risk-high return’ assumption is expected to hold in this research, the risk-seeking preference of government shareholders would be related to an increase in firm performance. Therefore, it is also expected that the relationship between L.GOV and firm performance is positively mediated by risk-taking; that is, L.GOV is positively associated with risk-taking, and higher risk-taking is associated with higher firm performance.

Lagged insider ownership (L.INSIDER)

In the seminal work of Jensen and Meckling (1976), inside equity is defined as the equity ownership by the manager. Following Davidson and Singh (2003) and Tan (2009), L.INSIDER in this thesis is defined as the one-year lagged proportion of common equity owned by the members of the board of directors, including managers, to the total common equity.

Since this proxy consists of shares held by both managers and directors, it is assumed that the interests of both directors and managers are homogeneous, which is suitable to reflect the problem of little separation of ownership and control in the context of a developing country like Vietnam. This is also suitable to the traditional focus of economics and finance literature on the agency problems solved or created by the board of directors (Adams, Hermalin & Weisbach 2010). In order to obtain the accurate private amount of shares owned by insiders, government shares nominally owned by directors are excluded from this ratio.

Based on the ‘alignment of interest’ hypothesis, it is expected that the relationship between L.INSIDER and firm performance is positively mediated by agency costs. That is, the higher percentage of L.INSIDER is followed by the lower level of agency costs, and lower agency costs are associated with higher firm performance. Contrary to conventional assumption of a risk-adverse attitude of insider/managers, in addition, insider ownership is expected to positively related to risk-taking in the context of Vietnam’s stock market. There was a common trend in the period of study that listed firms did engage actively in trading stocks for short-term profits such as dividend and capital gains. In addition, they established an array of subsidiaries for the main purpose of expanding business areas and hence hold a part or majority of common shares of the newly-established ones. It can be argued that such financial investments indeed reflect risk-taking behaviours of insider shareholders of the firms. Together with ‘higher risk, higher return’ assumption, therefore, the effect of L.INSIDER on firm performance is expected to be positively mediated by risk-taking; that is, L.INSIDER is positively associated with risk-taking, and higher risk-taking is associated with higher firm performance.

Lagged foreign ownership (L.FOREIGN)

L.FOREIGN is measured by the one-year lagged fraction of common equity held by foreign investors to the total common equity of a listed firm. It should be noted that the maximum value of foreign ownership is 49% in this research because this is the highest level of foreign ownership in the Vietnamese listed firms according to applicable laws in Vietnam.

Since foreign ownership is not controlling and restricted at 49% in Vietnam’s stock market, there is good reason to suspect that foreign investors in this market have short-term views of investment and want to avoid risky projects. Thus, it is expected that the relationship between L.FOREIGN and firm performance is negatively mediated by risk-taking; that is, L.FOREIGN is negatively associated with risk-taking, and lower risk-taking is associated with a decrease in firm performance. Simultaneously, foreign ownership can be a mechanism to mitigate agency problems due to the monitoring role of foreign investors. It is thus expected that the relationship between L.FOREIGN and firm performance is positively mediated by agency costs; that is, the higher percentage of L.FOREIGN is followed by the lower level of agency costs, and lower agency costs are associated with higher firm performance.

5.3. Mediator variables

Agency costs (AC)

Following Davidson and Singh (2003), this research employs asset utilization ratio as the primary measure of agency costs. The higher value of utilization ratio, the lower level of agency costs is implied since it measures the ability of managers to deploy asset efficiently, and hence an improvement in firm performance is expected.

Risk-taking (RT)

This reseach adopts the common measure of risk that is based on historical stock prices (market-based measure of risk). Following Minton, Taillard and Williamson (2014) and

Huang and Wang (2014), RT is defined as the standard deviation of the marked-adjusted daily stock returns. Specifically, the natural logarithm of variance of daily stock returns is applied to calculate returns; these values are then adjusted to eliminate market-driven risk factor by taking the difference between daily stock returns and the daily returns on stock market index. By subtracting the market-related risk component, this measure can better reflect firm-specific risk-taking behaviours. The higher value of standard deviation indicates higher risk-taking level and vice versa. As aforementioned, RT is expected to be positively associated with firm performance.

5.4. Outcome variables

In the literature, return on assets (ROA) and Tobin's Q (Q) are among the most commonly-used measures of firm performance where the former is accounting-based performance and the latter is stock market-based performance. ROA is a measure of backward-looking perspective because it reflects firm performance accomplished in the past, while Q can provide a forward-looking perspective of what the firm will perform in the future (Demsetz & Villalonga 2001; Hu & Izumida 2008). This paper also employs these two measures to proxy firm performance.

ROA

ROA is defined as the ratio of earnings before tax (EBT) over total assets of the firm. It should be noted that net profit is not used because it was the preferential policy during the initial stage of stock market development in Vietnam that newly-listed companies would be offered 100% exemption from corporate income tax for the first year of listing, plus 50% exemption over the next two years. As the year of listing is different among the listed companies in data sample, therefore, net profit will vary across firms. Hence, the use of EBT is employed to facilitate cross-sectional comparisons.

Q

Q is defined as the simplified Tobin's Q (Hu & Izumida 2008; Tian & Estrin 2008), which is calculated as which is calculated as ratio of the market value of common equity and preferred stock plus the book value of liabilities to the book value of total assets. The numerator of Q can be regarded as the value of the firm, and the dominator represents the replacement value of assets (Himmelberg, Hubbard & Palia 1999). As preferred stocks are rarely issued in Vietnam during the period of study, the value of preferred stocks in numerator are not present in the calculation of Q.

5.5. Control variables

The literature on the issue suggests that the following control variables can be employed in this paper.

1. Financial leverage (LEV): This ratio is calculated as total liabilities divided by total assets of a firm. As an important firm-specific characteristic, LEV is used to grasp the influence of financial leverage on agency costs, risk-taking and firm performance.
2. Firm size (SIZE): This variable is defined as the natural logarithm of total assets. There may be significant differences between large firms and small ones. SIZE is used to capture the influence of firm size on agency costs and firm performance.
3. Firm age (AGE): This variable is defined as the difference between the observed year and the initial year of listing on national stock exchanges. Hence, it shows for how many years a firm has been traded on stock exchanges. AGE is employed to account for the influence it may have on agency costs.

4. Firm growth (GROWTH): This proxy is calculated as the percentage of change in annual sales divided by one-year lagged sales (Hu & Izumida 2008). GROWTH is employed to account for the effect of firm growth on risk-taking.
5. Financial investment (FIN): This variable is defined as the sum of short-term and long-term financial investment scaled by total assets. Short-term financial investment include marketable securities, and other financial assets which are available for sale within one fiscal year; while long-term financial investment consists of capital investments in long-term projects such as equity holdings in unconsolidated companies. FIN is an important control variable in the context of Vietnam's stock market where it is believed that financial investment reflects risk-taking preference of listed firms.
6. Lagged firm performance (L.FP): This variable is defined as the one-year lagged value firm performance. L.FP is used as control variable in firm performance equations under the assumption that the current-year firm performance is influenced by the last-year firm performance.
7. Big-4 audit company (BIG4AUDIT): This is a dummy variable to control for the influence of audit quality offered by Big-4 international audit companies on risk-taking and firm performance. BIG4AUDIT takes a value of 1 if the firm's financial statements are audited by one of Big-4 international audit affiliates, and zero otherwise.

Table 1: Summary of variables

Denotation	Definition
Predictor variables	
L.GOV	The one-year lagged government ownership. It is the one-year lagged value of the ratio of shares owned by government over total common shares.
L.INSIDER	The one-year lagged insider ownership. It is the one-year lagged value of the ratio of shares owned by the board of directors over total common shares.
L.FOREIGN	The one-year lagged foreign ownership. It is the one-year lagged value of the ratio of shares owned by foreign investors over total common shares.
Mediator variables	
AC	Asset utilization ratio. It is calculated as annual sales divided by total assets.
RT	Corporate risk-taking. It is calculated as the standard deviation of market-adjusted stock returns, where stock returns are the natural logarithms of variance of daily closing prices of stocks.
Outcome variables	
ROA	Return on Assets. It is a proxy of accounting-based firm performance and calculated as earnings before tax (EBT) over total assets.
Q	A proxy of market-based firm performance. It is calculated as market value of equity and book value of liabilities over book value of assets.
Control variables	
LEV	Financial leverage. It is calculated as ratio of total liabilities over total assets. [1,2,3,4]
SIZE	Firm size. It is calculated as the natural logarithm of the book value of total assets. [1,2,4]
AGE	Years of listing on stock markets. It is calculated as the difference in the observed year and listed year of a firm. [2]
GROWTH	Firm growth. It is calculated as the percentage change in annual sales to one-year lagged sales. [3]
FIN	Financial investment. It is calculated as the ratio of total financial investment over total assets.[3]
L.FP	One-year lagged firm performance. It is the one-year lagged value of the ROA or Q. [1,4]
BIG4AUDIT	A dummy variable. It is equal to 1 if a firm's financial statements are audited by one of the Big-4 audit affiliates, and 0 otherwise. [1,4]

Note: [1,2,3,4] indicates control variables are used in Equation 1, 2, 3 and 4 respectively

5.6. Description of variables

Table 2 shows the summary of statistics of all main variables except dummy ones. Both current-year and one-year lagged ownership variables are presented. Government ownership (GOV) ranges from zero to 55.54% with the standard deviation of about 21.93% around the mean 28.92%. It can be seen that the standard deviation and average value of GOV are the largest in comparison with those of other ownership variables. The high values of government ownership suggest that the distribution of government variable is quite dispersed and that government is major shareholder in many firms.

Similarly, there is a large difference between the minimum and maximum level of insider ownership (INSIDER) at 0.1% and and 47.73%, respectively. The very small proportion of INSIDER at the lower end is applicable to some listed SOEs where the proportion of government ownership is large. Since only the private shareholding of these members are calculated as INSIDER, as defined earlier, the above-mentioned low ratio is justifiable.

The range of foreign ownership (FOREIGN) is from zero to 36.6%. This is because foreign investors do not invest in a number of Vietnam's listed companies; while they are not owning more than the restricted threshold of 49% of equity in the others. The mean and standard deviation of foreign ownership are smaller in comparison with government ownership and insider ownership, which are 8.999% and 11.07%, respectively.

The summary statistics of lagged ownership variables are almost similar to the original ones. The only exception is that the number of observations is less by 95 due to the lagging process of these variables.

Table 2: Summary statistics

Variable	Obs	Mean	Std.Dev.	Min	Max
GOV (%)	475	28.92	21.93	0	55.54

There is a large difference in extreme values of agency cost variable (AC), which varies between 0.208 and 3.055. The standar deviation of AC is 0.771 around the mean of 1.175.

The variable of risk-taking (RISK) ranges from 1.874 to 4.523. The mean value of risk- taking at 2.983 is higher than that of agency costs, but the standard deviation of risk-taking is slightly smaller than that of AC, at 0.767.

In terms of firm performance variables, the standard deviation, the minimum and maxium value of ROA are 7.46%, minus 1.734% and 25.86%, respectively. The nagative value of ROA shows that some listed companies suffered from loss during the period of study. However, ROA is averaged at 8.621 %, suggesting that most of the listed companies in this sample are profitable. The lowest and highest value of Q is 0.613 and 2.131, indicating that the market value of some firms is smaller than their assets. On average, however, the mean value of Q is more than 1 times, at 1.040, and the standard deviation of Q of 0.369. Statistics for lagged ROA and lagged Q are almost similar to those of Q.

6. Results

6.1 Total effect of ownership structure on firm performance

The first step of causal-steps approach for the recursive model in this study is to estimate the total effects of ownership structure on firm performance in Equation 1. Since the GMM estimation is applied to this equation as mentioned earlier, a primary task is to classify endogenous, predetermined and exogenous variables.

Treatment of variables

All explanatory variables of interests, consisting of lagged government ownership, lagged insider ownership and lagged foreign ownership, are treated as endogenous assuming that they are correlated with the unobserved fixed effects of the firm. The Durbin-Wu-

Hausman test of endogeneity of these variables confirms this treatment (DWH statistic=32.69, p<0.01).

Besides, it is plausible to argue that financial leverage, firm size and lagged firm performance are not strictly exogenous since they can be affected by prior shocks or changes in firm-specific characteristics; for instance, firm performance is potentially pre-determined because firm value has persistence (Hu & Izumida 2008). Hence, financial leverage, firm size and lagged firm performance are treated as predetermined variables in dynamic GMM regression of Equation 1.

According to Roodman (2009), one assumption for the use of system GMM regression is that there is no correlation across individuals (firms) in the idiosyncratic disturbances; and the inclusion of time dummies can make this assumption more likely to hold. Therefore, year dummy variables are added to Equation 1. In addition, industry dummies are added to account for the industry-specific effects in GMM estimation (Tan 2009). As dummy variables, Big-4 audit, time dummies and industries dummies are treated as exogenous in Equation 1.

Empirical results

The GMM regression of Equation 1 for the determinants of accounting firm performance (ROA) and market firm performance (Q) are presented in the table below.

Notes: *This table reports the results of dynamic system GMM regressions of both measures of firm performance in Equation 1. It examines how ROA and Q are affected by ownership structure and other control variables. Endogenous variables are lagged government ownership, lagged insider ownership, and lagged foreign ownership. Predetermined variables are financial leverage, firm age and lagged firm performance. Exogenous variables are Big4audit, time dummies and industry dummies. When ROA is regressed, in the transformed equation, the lags 2 of endogenous variables, and lags 1 of predetermined variables, are used as instruments. In the level equation, the first lags of differenced endogenous variables and the contemporaneous differenced predetermined variables are used as instruments. When Q is regressed, in the transformed equation, the lags 1 to lags 2 of endogenous variables, and the contemporaneous lags to lags 1 of predetermined variables are used as instruments. In the level equation, the lags 2 of the differenced endogenous variables and the first lags of differenced predetermined variables are used as instruments. The parameters are estimated using two-step procedures for dynamic system GMM. The robust standard errors using the Windmeijer correction for small-sample are included in parentheses. Estimators of year and industry dummies are excluded from the table for brevity.*

In ROA regression, the total effects of both lagged government ownership and lagged insider ownership are found to be significantly positive at the 5% level, where the degree of influence of latter on current-year ROA is stronger than that of the former. The coefficient of lagged foreign ownership is also positive, but it is not significant.

Among control variables of ROA, higher financial leverage is significantly associated with lower accounting firm performance at the 1% level. Firm size does not have any influence on current-year ROA. There is no significant difference between firms audited by Big-4 audit affiliates and the other firms. Lastly, the effect of lagged ROA is positive and significant at the 1% level.

In Q regression, it is found that lagged insider ownership has significant total effect on market firm performance at the 10% level. Lagged Q has significantly positive effect on current Q at the 1% level. The impacts of all other variables on Q are weak and insignificant.

Therefore, the ownership variables of interests in the next steps of regression will be lagged government ownership and lagged insider ownership because it is found that both of them have significant total effect on ROA and the latter has significant total effect on Q. The *first condition* for a mediating effect is met for lagged government ownership and lagged insider ownership in relationship with ROA, and for lagged insider ownership in relationship with Q.

6.2 Direct effect of ownership structure on agency costs

The second step for testing mediating effects in this paper is to regress agency costs on ownership structure and other controlling variables in Equation 2 to investigate whether the relationship between ownership structure on agency costs are significant.

Diagnostic tests

The multicollinearity test shows that the problem of collinearity among explanatory variables in this equation is not present since all the variance inflation factors (VIF) are less than 10 and the mean VIF value is 5.47. The Wooldridge test for serial correlation indicates that the first-order autocorrelation is existent in this equation because null hypothesis is rejected ($F = 29.334$, $p < 0.01$). In addition, the likelihood-ratio test for panel data shows that there is heteroscedasticity in error terms (the LR chi square value is 451.03, $p<0.01$).

The test for firm fixed-effect show that there is unobserved firm fixed effect in Equation 2 (F = 42.31, p < 0.01). The Hausman test also indicates that a fixed-effects model can be used (chi-square statistic=17.75, p<0.01). Thus, the Pesaran's (2004) CD test for cross-sectional dependence problem in fixed-effects model is conducted. The CD test indicates that there is the problem of cross-sectional dependence in Equation 2. The average absolute value of correlation among residuals is quite high at 0.563, corresponding to a strong rejection of the null hypothesis of no cross-sectional dependence. This result is further confirmed by the Frees's test.

To account for first-order autocorrelation, heteroskedasticity and cross-sectional dependence problems in Equation 2, Prais-Winsten regression with panel corrected standard errors (PCSE) is employed. Under this method, the standard errors based on large-T asymptotics assumption performs well in small panels, which are robust to heteroscedasticity, contemporaneously cross-sectional correlation and autocorrelation of type AR(1) (Hoechle 2007). Furthermore, it is assumed that the AR(1) parameters are specific to panels, i.e. autocorrelation structure is different across individual firms. Year dummies are included to account for common shocks influencing agency costs; and industry dummies are added to control for industry-specific effects.

Empirical results

The empirical results for the effects of ownership structure on utilization measure of agency costs are presented in the table below. To compare for robustness, the results of PCSE estimation with common AR(1) structure are also reported.

Notes: *This table reports the results of Equation 2 for agency costs (asset utilization ratio). It examines how agency costs are affected by ownership structure and other control variables.*

Prais-Winsten estimators with common AR1 and firm-specific AR1 are presented in column 1 and column 2, respectively. Corrected robust standard errors are reported in parentheses. Estimators of year and industry dummies are excluded from the table for brevity.

The above table shows that two regression methods produce fairly similar results. As already noted, the ultimate results of Equation 2 are based on the standard errors under the assumption of firm-specific autocorrelation structure (in column 2), which is supported by higher R-squared.

Lagged government ownership and lagged insider ownership are consistently found to be significantly positively related to utilization measure of agency costs at the 1 percent level. The effect of lagged foreign ownership is not significant at all. Financial leverage and firm age are estimated to have significantly positive effect on agency costs at the 10 percent and 1 percent level respectively, whereas firm size has significantly negative association with agency costs at the 1 percent level.

At this step of regression, it is found that the direct path between lagged government ownership and agency costs are significant and robust. Lagged insider ownership has similar effect. An increase in the proportion of government and insider shareholdings in this year is followed by a higher asset utilization ratio or lower agency costs in the next year. Hence, the second condition of mediation is satisfied for the link between the above two ownership structure and the first mediator variable (agency costs).

6.3. Direct effect of ownership structure on risk-taking

The third step of testing mediation mechanism in the recursive model in this study is

the regression of risk-taking on ownership structure and other control variables in Equation 3.

Diagnostic tests

The test for multicollinearity is first conducted. The result shows that the problem of collinearity among explanatory variables in Equation 3 is not present since all the variance inflation factors (VIF) are less than 10 and the mean VIF value is 5.26. Like Equation 2, serial correlation test is conducted. The result indicates that the first-order autocorrelation is not present in Equation 3 (F statistic = 0.394, $p > 0.5$). The likelihood-ratio test for hetoroskedasticity rejects the null hypothesis that the error terms are homoskedastic (LR chi square value is 148.41, $p < 0.1$).

The test for fixed-effect shows that there is unobserved firm fixed effect (F-statistic = 3.55, $p < 0.01$). The Hausman test also indicates that a fixed-effects model is preferred (chi-square statistic = 21.72, $p<0.01$). Hence, the Pesaran's (2004) CD test for cross-sectional dependence in fixed-effect model is performed for Equation 3. Like Equation 2, the result shows that there is the problem of cross-sectional dependence in Equation 3. The null hypothesis of no cross sectional dependence is strongly rejected at 1% significance level; and the average absolute value of correlation among residuals is high at 0.500. However, the Frees' test does not confirms this result since the Frees' statistic is smaller than the critical value at $\alpha = 0.10$. Even though, since the average absolute value of the off-diagonal elements in CD test is very high (0.5), there is evidence suggesting that the cross-sectional dependence is potential in Equation 3.

As a result, it can be said that Equation 3 is involved with unobserved firm fixed effect, heteroskedasticity and probably cross-sectional dependence; and hence PCSE approach is used with OLS regression instead of Prais-Winsten regression due to the absence of autocorrelation. Year and industry dummies are included to account for common shocks and industry-specific effects respectively. Since the cross-sectional dependence problem is not quite certain in Equation 3, two types of standard errors under PCSE method will be reported to make a comparison: 1) standard errors robust to heteroscedasticiy only, and (2) standard errors robust to both heteroscedasticiy and cross-sectional dependence. The ultimate results are based on the latter.

Empirical results

Empirical results for Equation 3 for the direct effect of lagged ownership structure on risk-taking are presented in the table below.

Notes: This table reports the results of Equation 3 for corporate risk-taking (market-adjusted risk). It examines how risk-taking is affected by ownership structure and other control variables. Linear regression with heteroskedastic panels corrected standard errors and linear regression with correlated panels corrected standard errors are reported in column 1 and column 2 respectively. Corrected robust standard errors are reported in parentheses. Estimators of year and industry dummies are excluded from the table for brevity.

The estimators in column 1 and column 2 are almost identical. It demonstrates that the cross-sectional dependence problem is not serious in Equation 3. As argued earlier, the ultimate results are based on column 3 where both hetorescedasticiy and cross-sectional dependence problems are controlled.

Lagged government ownership is statistically not significant related to risk-taking. By contrast, both lagged insider ownership and lagged foreign ownership are found to have significant relation with risk-taking at the 10 percent level; where the effect of the former is positive and that of the latter is negative.

The higher level of financial leverage is estimated to be related to the higher level of risk-taking, which is significant at the 1 percent level. The coefficient on Big-4 auditing is negative, suggesting that firms audited by Big-4 auditing affiliates have lower risk than the others. Lastly, it is found that corporate risk-taking is not affected by a change in firm growth and financial investment.

At the third step of regression, the path between lagged government ownership and risk-taking is not significant. However, the path between the other variable of interest, lagged insider ownership, and risk-taking is established. Although it appears that the total effect of lagged foreign ownership does not exist to be mediated as found in Equation 1, there is evidence that lagged foreign ownership is significantly related to risk-taking. Hence, the second condition for risk-taking to be a mediator in the links between lagged insider ownership, and perhaps lagged foreign ownership, and firm performance is met.

6.4. *Direct effect of ownership structure on firm performance controlling for agency costs and risk-taking*

The final step of causal-steps regression for recursive model is the estimation of

Equation 4, which is revised from Equation 1 to include the effects of agency costs and risk- taking. This equation is needed to estimate the direct effects of ownership structure on firm performance when mediator variables are controlled, as well as the direct effect of mediator variables on firm performance.

In Equation 4, the explanatory variables of interests are ownership structure variables, agency costs and risk-taking. Consistent with Equation 1, ownership structure variables are treated as endogenous ones; and predetermined variables include financial leverage, firm size and lagged firm performance. Big4-audit dummy, year and industry dummies are treated as exogenous variables. Two newly-added variables, agency costs and risk-taking, are also treated as predetermined variables in Equation 4 because in this research, current agency costs and current risk-taking are conceptualized as being affected by past ownership structure.

The empirical results of Equation 4 are presented in column 2 of the table below. To make a convenient comparison, the previous results of Equation 1 are added in the column 1 of this table.

Notes: *This table reports the results of dynamic system GMM regressions of firm performance in Equation 4 after controlling for the effects of agency costs and risk-taking (column 2). It examines how firm performance is directly affected by ownership structure, agency costs, risk-taking, and other control variables. The results of Equation 1 are also re- represented in column 1 to compare with Equation 4. Endogenous variables are lagged government ownership, lagged insider ownership, and lagged foreign ownership. Predetermined variables are agency costs, risk-taking, financial leverage, firm size and lagged firm performance. Exogenous variables are Big4audit, time dummies and industry dummies. When ROA is regressed, in the transformed equation, the lags 2 of endogenous variables and lags 1 of predetermined variables are used as instruments. In the level equation, the first lags of differenced endogenous variables and the contemporaneous differenced predetermined variables are used as instruments. When Q is regressed, in the transformed equation, the lags 1 to lags 2 of endogenous variables, and the contemporaneous lags to lags 1 of predetermined variables are used as instruments. In the level equation, the lags 2 of the differenced endogenous variables and the first lags of differenced predetermined variables are used as instruments. The parameters are estimated using two-step procedures for dynamic system GMM. The robust standard errors using the Windmeijer correction for small-sample are included in parentheses.*

In regression with ROA, agency costs are found to have a significantly positive relation with ROA at the 5% level: an increase by 1 in asset utilization ratio is associated with nearly 0.049% increase in ROA of the same year. Hence, the third condition for potential mediation effect of agency costs is met. However, the third condition for risk-taking is not met, suggesting that risk-taking does not meditate the effect of ownership structure on ROA.

As stated earlier, the fourth condition for the mediated effect is that the direct effects of predictor variables on the outcome variables are reduced or no longer significant when mediator variables are controlled for. The results in column 2 of ROA regression show that when agency costs and risk-taking are added to Equation 4, the direct positive effects of lagged government ownership becomes insignificant while that of lagged insider ownership is still significant but smaller. Taken together, there is evidence that agency costs fully mediate the effect of lagged government ownership on firm performance while partially mediate the effect of lagged insider ownership on firm performance.

In regression with Q, it is found that both mediator variables have quite strongly and significantly positive association with Q. An increase by 1 in utilization ratio and risk-taking is associated with an increase of 0.1 and 0.7 in Q, respectively. The direct effect of lagged insider ownership on Q found in Equation 1 becomes quite weak and insignificant when agency costs and risk-taking are added. This is evidence of a full mediating effect of agency costs on lagged insider ownership-firm performance relationship; meanwhile, risk-taking may mediate the effect of lagged foreign ownership on Q.

The explaining powers of all other controlling variables are not changed in both columns. Accordingly, accounting firm performance ROA is negatively affected by financial leverage and positively by lagged ROA; and Q is positively affected by lagged Q.

In short, it can be concluded that there is a full agency costs-mediated relationship between lagged government ownership and ROA, partial agency costs-mediated relationship between lagged insider ownership and ROA, full agency costs-mediated relationship between lagged insider ownership and Q, and potential risk taking-mediated relationship between lagged foreign ownership and Q.

6.5. ***Robustness tests***

Several additional regressions are conducted to check for robustness of the coefficients

of all variables of interest as the followings:

1) Using another measure of accounting firm performance, that is return on equity (ROE), and re-testing Equation 1 and Equation 4. The results show that the total effects of lagged government ownership and lagged insider ownership remain significantly positive to ROE; and the direct effects of agency costs and risk-taking on firm performance are similar to those obtained with ROA.

2) Using another measure of agency costs and re-testing Equation 2 and Equation 4.

Following Chen, X and Yur-Austin (2007), adjusted short-term debt ratio (AC2) is employed as an alternative proxy of agency costs, which is calculated as the market value of equity divided by book value of equity and multiplied by short-term debt ratio. It indicates the likelihood of engaging in underinvestment, ‘which is a situation where a firm foregoes positive net present value projects’. A high value of AC2 means a low likelihood of underinvestment; hence this ratio is expected to have similar signs as asset utilization ratio. The results of Equation 2 using AC2 shows that lagged government ownership and lagged insider ownership are significantly associated with AC2, which are the same as those obtained with utilization ratio. When Equation 4 is re-tested using AC2, consistent results are obtained: AC2 is significantly positively related to ROA and Q.

3) Removing insignificant control variables and re-testing Equation 3. As reported Table 5, firm growth and financial investment do not significantly explain risk- taking; hence they are dropped from Equation 3. The re-testing results do not change in terms of the significantly positive and negative effect of lagged insider ownership and lagged firm performance on risk-taking, respectively.

In short, the above additional tests indicate that the effects among variables of interest, namely ownership structure, agency costs, risk-taking and firm performance are robust.

7. Discussion and Conclusions

As for the potential mediating role of agency costs, it is well established that agency

costs emerge as a consequence of the agency conflicts within firms, and a certain structure of ownership can be utilized to reduce the agency problems (Agrawal & Knoeber 1996; Jensen & Meckling 1976). Hence, prior studies on the issues suggests that there are robust links between equity ownership and agency costs, and in turn, agency costs is related to firm performance (Ang, Cole & Lin 2000; Davidson & Singh 2003).

As expected, the results in this study suggest that agency costs fully mediate the positive effect of lagged government ownership on ROA, partially and fully mediate the positive effect of lagged insider ownership on ROA and Tobin's Q respectively. The empirical evidence is consistent with Le and Buck (2011) in terms of a positive contribution of government ownership via agency costs to improving performance of listed firms. Thus, a universally negative view of government ownership is challenged.

The results for insider ownership support the 'alignment of interest effect' (Jensen & Meckling 1976; Morck, Shleifer & Vishny 1988; Shleifer & Vishny 2008). In particular, the positive effects of previous-year insider ownership on current-year ROA occur via both indirect and direct channel. In the context of transitional and merging countries like Vietnam, therefore, government ownership and insider ownership can be employed as corporate governance mechanisms to mitigate the agency conflicts within listed firms and hence to enhance firm performance.

In terms of the second channel, corporate risk-taking, this research does not find evidence of the link between government ownership and risk-taking. However, the evidence for insider ownership and risk-taking is as expected and opposite to the assumption of 'risk-averse preference' of insider ownership (Himmelberg, Hubbard & Palia 1999). Specifically, insider shareholders in Vietnamese stock markets tend to prefer and take risks. The 'higher risk-higher return' assumption (Drever, Stanton & McGowan 2007;

Gordon, Loeb & Tseng 2009) is not supported for the relation between risk-taking and ROA, but it is confirmed for the relation between risk-taking and Q.

Foreign shareholders are found to be risk-adverse investors. The tendency to avoid risks of foreign investors may be due to their short-term view of investment in frontier stock markets, particularly when they do not have controlling stakes in the firm. Since the higher level of risk-taking in this year is estimated to be followed by an increase in Tobin's Q in next year, therefore, it is likely that risk-taking mediates the negative effect of foreign ownership on market performance of listed firms. It should be noted that this mediating effect of risk-taking is not certain because the total effect of foreign ownership on firm performance is not significant to be mediated as reported at step 1 of regression (Equation 1). At least, it can be said there are signs of the negative impact of foreign ownership in Vietnam's stock market and this is consistent with the evidence found in Phung and Le (2013), suggesting that foreign investors do not contribute to improving firm performance due to ownership restriction.

To conclude, while prior literature almost ignores the indirect channels in ownership structure-firm performance relationship, this paper provides evidence to confirm that agency cost and risk-taking are two 'missing links' in this association, and the mediation effect of agency costs is stronger than that of risk-taking. By adopting mediation approach, this paper sheds lights on the mechanisms by which government ownership, insider ownership and foreign ownership can affect firm performance. Hence, it is recommended that the intervening role of agency costs and risk-taking in equity ownership-firm performance relation be accounted for in further research on the issue. Research on Vietnam's stock markets can also benefit from the estimated influence of control variables employed in this paper.

Abstract
The study explores the scales of human resource management (HRM) practices in the context of Vietnam. The study investigates the relationships between HRM practices and business performance. Data were collected from 388 companies, using a questionnaire survey. The research showed that HRM practices in Vietnam can be measured through 7 dimensions with tested construct validity. Except four traditional functions of HRM such as recruitment-selection, training-development, performance appraisal, and compensation, HRM practices in Vietnamese context involve three more advanced functions: leading change, motivation and talent management. This result implies that HRM practices in Vietnam are following the world trend in HRM practices. It indicates that HRM practices in Vietnam are beyond traditional functions of HR department and closer to the change agent role and hand-in-hand with line managers in talent management. Another finding is about the important role of HRM practices the firm's business performance. Particularly, HRM practices can explain 43% of variation in business performance.

Keywords HRM practices, business performance, Vietnam.

Abstract
The high ranking manager in a corporation is the major financial decision-maker; therefore the attitude of this manager toward the corporation's debtors influences the amount of the firm's trade credit. This research investigates the influence of the high ranking manager's power and the use firm's trade credit (i.e., accounts payable and accounts receivable).The sample is collected from the listed companies in Taiwan Stock Exchange OTC market between 2005 and 2011. Managers' power is divided into four categories and four types of governance to analyze the managerial index. The research results show that different high ranking managers' power has a different effect on corporations' final trade credit. Managers' power indirectly affects the rights of stockowners and increases turnover and profit through trade credit. This shows that the attitude of the high ranking manager affects trade credit decisions, as well as cost control and debtor relationship maintenance.

Keywords *trade credit, managers' power, governance type.*

I. Introduction

Company bonds and bank loans have always been the main financing channels for domestically- listed and OTC companies. However, apart from these channels, companies delay paying creditors based on the previous trade credit. This is known as trade credit, and since trade credit is often accompanied by early payment deduction benefit, it has a dramatic influence on the company's profit. Especially in recent years, with enhanced economic prosperity, many domestic corporations are finding it more difficult to obtain financing, which leads to many good credit companies providing and using trade credit to lower their sales cost and delay payment. Poor credit or poorly-operated corporations that find it more difficult to borrow from the bank can use trade credit to increase their cash flow and even maintain a continued partnership with suppliers.

The supply of trade credit is short-term credit suppliers provide to purchasers. In other words, the goods are delivered to the purchaser first and the supplier agrees that the purchaser can make payment later. With the development of the economy, corporations emphasize self-credit, so that the trust between them increases. Trade credit has gradually been accepted and used in order to more actively trade and maintain a good relationship, since it lowers the financing costs of corporations compared to a bank loan. Elliehausen and Wolken (1993) explain that trade credit accounts for 20% of non-financial corporation debt and 35% of total assets; moreover, Rajan and Zingales (1995) point out that trade credit is 17.8% of the total assets of American companies. Furthermore, Kohler et al. (2000) also mention that, in British companies, trade credit reaches as high as 55% of the sales amount. According to the above authors, there is a certain relationship between trade credit and the operational performance of companies.

An extension of trade credit acts as a financing tool (Ferris, 1981). Smaller and newer companies in the market are unlikely to obtain a loan from the bank, and the ratio of trade credit rises at this point. Further research shows that the demanding party views trade credit as being a financing tool with zero interest and discounts if the payment is settled within the given period. This has more advantages than bank financing. In the perfectly competitive market theory, a company can have lower interest rates if it mortgages its goods to the financial organization; however, in actual trading, the company tends to use trade credit because it can obtain more information about competitors with lower supervising costs. A company can understand the operation of its clients from the number and time the order was placed with the information asymmetry theory. Therefore, it knows which clients need to be followed up. This information would be relatively expensive if it had to be acquired from a financial organization.

Pringle (1974) maintains that a company uses trade credit like a flow reserve, which has a preventative function. Trade credit can turn future uncertain purchasing income into a predictable future cash flow; therefore, when having a flexible future cash flow, a company can make better use of the excess capital. Profit maximization companies have a better chance than unstable companies of obtaining funds from financial organizations (Schwartz, 1974). Therefore, for this reason, companies with better conditions and profits are more willing to provide trade credit as a financing tool for smaller and newer companies. In this way, the pressure of finding financing resources of many small companies and factories is resolved and this increases the overall social productivity and efficiency.

Apart from performance and salary contracts, power also affects the decision-making of the Chief Executive (CEO) in terms of corporate financing and trade credit when developing important strategies such as investment and financing. Liu & Jiraporn (2010) believe that, in a risk aversion hypothesis and reputation hypothesis, in order to consider their own reputations, managers tended to make decisions in favor of debtors and stockholders when facing financial risk that cannot be predicted and dispersed. However, in a self-interest hypothesis and lack of opinion diversification hypothesis, more powerful managers will pursue their self-interest and sacrifice that of stockholders and debtors; or in the absence of an open major decision-making process, managers would take a decision that might further harm the interests of debtors or make a wrong decision. Therefore, managers with different levels of power will have different effects on the value of their corporations.

In addition, the operational models of corporations are different in eastern and western countries. In western countries, companies adopt a professional management operation, while in eastern countries; most companies are run by one family or a few families. In the research of Astrachan and Shanker (2003), when appointing a CEO, Asian family businesses are more likely to inherit the position than in western countries. Moreover, the CEO has a more central decision-making power in Asian corporations than in western ones, and the company structure tends to be more centralized. This means that Asian corporations tend to appoint an heir or CEO from the family, and he holds a certain power, which means that many important decisions are made for his convenience. In view of this, the research has an empirical platform that is different from western culture in order to understand the power of a CEO and categorize the type of governance to observe the influence of corporate performance and value. Leuz, Nanda & Wysocki (2003) also propose that, when power is centered in the hands of high ranking staff or stockholders, they have the material influencing power and can manipulate the accuracy of the earnings and financial statements so that the debtors do not know the actual cash flow information and bear a higher risk of bankruptcy.

Moreover, the relationship between high ranking managers and corporation performance is supported by previous literature. For example, previous literature explains that the factors that influence corporate performance are company characteristics, industry characteristics, and market characteristics (Faulkender, 2005); however, the development, decision-making and strategic execution are decided by managers. Therefore, the behavior and decisions made by corporate managers is one of the main factors of the final results and performance. Bebchuk, Cohen & Ferrell (2009) propose that the more centralized power high ranking managers have in terms of decision-making, the more influence they have on company performance, which causes a decrease in the corporation's value. Since the corporation's value decides the weighted average fortune variable of the stockholders and debtors, the power of the CEO also affects their rights.

In recent years, listed and OTC companies that are bound by government regulations and investment acts, have placed more value on protecting the interests of stockholders. However, with more information, it is easy to reflect the company's current situation in the stock or bond markets. Therefore, if the CEO controls the sales cost, turnover, sales amount, or trade credit, he can exploit the interests of the debtors and stockholders by transferring their assets to himself. This illustrates how the power of the CEO influences a corporation's trade credit and affects the operation and profits without stockholders being aware.

When making financing and trade credit decisions, the strength of the power influencing the interests of the debtors can be divided into a risk aversion hypothesis and reputation hypothesis, which favors their interests, and a self-interest hypothesis and lack of opinion diversification hypothesis, which contravenes their interests. According to Liu & Jiraporn (2010), the decision-making of a high ranking manager with greater power indicates a lack of diversified opinion hypothesis so that the debt capital cost of the company would be higher. In contrast, if a high ranking manager has weaker power, he tends to maintain the interests of the debtors and stockholders under the influence of risk aversion or market reputation when using trade credit to avoid the likelihood of bankruptcy.

The power index of the manager, namely, structural power, ownership power, expert power, or prestigious power, should be structured to understand the influence of the power of the CEO in domestic corporations in terms of corporation trade credit. As mentioned in the previous paragraphs, this is the obvious difference between the operation of western and Asian corporations, and the type of corporate governance will be discussed later in the paper. Therefore, the objectives of this research are as follows:

I. To determine the influence of the power of the CEO on corporate trade credit.

II. To determine the influence of the type of corporate governance on corporate trade credit.

II. Research method

The purpose of the research is to discuss the influence of high ranking managers on the supply and demand of corporate trade credit. The aim is to understand whether investors' decision of the power structure of the high ranking manager and the supply and demand of trade credit reflects the corporation's market value. In order to achieve this aim and make a contribution, a high ranking manager power index is established, together with the theory and empirical base of trade credit and the category of corporate governance by discussing them from the perspective of the literature and analyzing them with the appropriate statistical variables and methods as empirical evidence of the conclusion and suggestions. The process, methods, and steps of the empirical research are described below.

1. The measurement of trade credit parameters

Accounts receivable (AR) and accounts payable (AP) are used as the supply and demand of trade credit, which mainly occurs during the trading process. Therefore, the amount of the trade credit provided is influenced by the turnover.

(I) Sales (S) is the control variable of trade credit supply. In contrast, sales cost (C) is the control variable in a trade credit demand model. A change in operation will cause a change in sales (ΔS) and sales cost (ΔC). In terms of the trade credit supply, if the sales change more, it means that the sale of products increases so that the accounts receivable increases. Therefore, a change in sales is positively related to accounts receivable; in contrast, when discussing trade credit demand, a change in sales cost should positively relate to accounts payable.

(II) Company scale (lnA): The logarithm of the total assets of the company is taken to measure its scale. From the financing point of view, big companies are more capable of providing more TC; on the other hand, the quality confirmation theory suggests that smaller companies need more TC than big companies to ensure product quality. However, in terms of the willingness of TC providers, big companies tend to have a better reputation and when they have more assets; a good reputation will bring more investment opportunities. Therefore, if a small company has a greater demand for TC but has yet to establish a reputation; it is unlikely to have this investment opportunity.

(III) Inventory (I): Inventory and accounts receivable are current assets in accounting, and the two are substitutable from a financial perspective. If a company has high inventory, it must lower the supply of TC. From another angle, the inventory is the company' s asset. Therefore, when the inventory is high, it will be used as collateral for the TC supplier. At this point, a company with a high inventory should increase its demand for TC. In summary, a high inventory company will increase its TC demand and decrease its TC supply. In other words, inventory and accounts receivable are negatively related and positively related to accounts payable.

(IV) Retained earnings (RE): When a company has more retained earnings, it has more assets. This means it has more ability to provide more TC. The TC provider will also consider the internal funds of the TC demander. Therefore, a company with more retained earnings is more likely to be provided with TC. In short, retained earnings have a positive effect on the supply and demand of TC.

2. The measurement of managers' power index

The structural power index of high ranking managers is established by the definition of Liu & Jiraporn (2010). This research defines a high ranking manager as the General Manager of a corporation. If a corporation has no General Manager, it is the CEO and Chief Operating Officer in that order. If none of these exist, it is defined as the person in the highest decision-making position. The managers' power indices are shown below.

(1) CEO Ownership (CO): This means the share of the high ranking management team's total issuing shares (percentage).

(2) CEO Expertise (CE): This is the previous position taken by the General Manager. If he participates in the high management team, including this one, the score is one. If he has no managerial position, the score is at least one.

(3) CEO Reputation (CR): This means whether or not the General Manager has any other managerial position or a seat on the Board. Each position adds one point. If he has no other position, the score is zero.

(4) CEO Pay Slice (CPS): This is the salary of the General Manager in the high management team. The salary announced in the annual report of each company prevails, excluding other income.

3. Governance category

In this paper, the governance category is divided as the following four types:

(1) Family (F): At least two family members have a position on the Board or have reached the standard of manager (manager and above) as revealed in the annual report. Second-tier relatives are generally the standard in the annual report. The Director of the Board and General Manager are family members with more than 50% of the seats on the Board. A family corporation often has relative or absolute share advantages; the seats on the Board are an absolute advantage. This research divides corporate governance as shown below.

(2) Association (A): Run by different families. This type of corporation has more dispersed stock rights. No single group has the absolute advantage; therefore, most decisions must have the consent of stockholders and the Board is formed of more than 2 groups.

(3) Government (G): In 1989, the Executive Yuan established a Privatization of state businesses promotion team" to release shares and sell assets to lower the position of the government. Although the government owns less than 50% shares, it has substantial controlling power of the Board and the appointment of personnel.

(4) Manager (M): This mainly applies to the electronic industry which hires managers with a professional background and capability as members of the Board. They even participate in the operation or occupy important positions to create profits for the company.

4. Multiple regression model analysis

The purpose of the research is to discuss whether or not the power of managers and the type of governance of a company have different influences on the usage of TC. According to research by Choi and Kim (2005), accounts receivable (AR) is used as the dependent variable in the TC supply model and accounts payable (AP) as the dependent variable in the TC demand model. In the process of TC, the amount of TC is closely related to the company's scale and annual trading figures. Therefore, sales are taken as the operational variable in the TC supply model and cost of sales is the operational variable in the TC demand model.

This research basically emphasizes the influence of TC on the power index of high ranking managers; therefore, the independent variables are selected in accordance with Long (1993), Petersen and Rajan (1977), Choi and Kim (2005). Capturing the explanatory variable in TC should satisfy the influential variables mentioned in the TC theory. Therefore, defined from the previously mentioned TC, the operational variable is the changing amount of sales, the changing amount of cost of sales, the inventory, and retained earnings to explain the TC situation. The regression model of TC demand is defined as:

$$\boldsymbol{AP_i} = \alpha_0 + \alpha \ \ln \boldsymbol{A} + \alpha_2 \Delta \boldsymbol{C_i} + \alpha_3 \boldsymbol{I_i} + \alpha_4 \boldsymbol{RE_i} + \varepsilon_i \qquad (1)$$

The regression model of TC supply:

$$\boldsymbol{AR_i} = \alpha_0 + \alpha \ \ln \boldsymbol{A} + \alpha_2 \Delta \boldsymbol{S_i} + \alpha_3 \boldsymbol{I_i} + \alpha_4 \boldsymbol{RE_i} + \varepsilon_i \qquad (2)$$

In other articles that discuss TC, which mainly define it as short term financing or cash flow, quarterly information was used as the basis for analysis. This is because quarterly data was sufficient to assess the usage of the TC of the corporation in each phase. However, current research focuses on the influence of high ranking managers on TC; therefore, annual information was used in order to more precisely observe the power of the manager to influence TC for all manager indices and the same time standard of TC. Thus, the related variables in TC research are acquired from annual data in the annual report, and in this way, the managers' power index is combined. Therefore, unlike the sales income and cost of sales, which are one quarter late, our model is one year late. The manager model for TC demand is:

$$AP_i = \alpha_0 + \alpha \ \ln A + \alpha_2 \Delta C_i + \alpha_3 I_i + \alpha_4 RE_i + \alpha_5 CO_i + \alpha_6 CE_i + \alpha_7 CR_i + \alpha_8 CPS_i + \varepsilon_i \qquad (3)$$

The manager model for TC supply is:

$$AR_i = \alpha_0 + \alpha \ \ln A + \alpha_2 \Delta S_i + \alpha_3 I_i + \alpha_4 RE_i + \alpha_5 CO_i + \alpha_6 CE_i + \alpha_7 CR_i + \alpha_8 CPS_i + \varepsilon_i \qquad (4)$$

Finally, the governance type of Asian companies is different from that of western countries. Besides discussing the manager indices, the method of forming high ranking managers is further investigated to discuss TC from another aspect. The establishment of a corporate governance model still uses the important variables for TC, namely, the changing amount of the sales, the changing amount of cost of sales, the inventory, and retained earnings. Then, the corporation governance type is divided into four different categories, namely, association, government, manager, and family. These four categories have three dummy variables and then the two types with the lowest proportion are set as control groups for cross-reference. Thus, there will be two other models. The type of corporate governance in the TC supply model is:

$$AR_i = \alpha_0 + \alpha_1 \ln A + \alpha_2 \Delta S_i + \alpha_3 I_i + \alpha_4 RE_i + \alpha_5 CO_i + \alpha_6 CE_i + \alpha_7 CR_i + \alpha_8 CPS_i + \alpha_8 DJ + \varepsilon_i, J = 1,2,3 \qquad (5)$$

The type of corporate governance in the TC demand model is:

$$AP_i = \alpha_0 + \alpha_1 \ln A + \alpha_2 \Delta C_i + \alpha_3 I_i + \alpha_4 RE_i + \alpha_5 CO_i + \alpha_6 CE_i + \alpha_7 CR_i + \alpha_8 CPS_i + \alpha_8 DJ + \varepsilon_i, J = 1,2,3 \qquad (6)$$

III. Empirical results and analysis

1. Descriptive statistics

The study selected domestic listed and OTC companies from 2005 to 2011, excluding financial businesses, insurance, logistics, and travel industries that mainly collect cash, to study their supply and demand of TC. There are 7466 effective samples.

CO, CE, CE, and CPS are the highest ranking management power indices, and the variable establishment was mentioned in the previous section. It is worth noting that the prestigious power in the high ranking management power indices is in accordance with the position or service on the Board, supervising Board, consultant, and director of other companies. Therefore, the power value of high rank managers of different corporations greatly differs from that announced on the financial statement and further makes the standard deviation higher than other management variables.

Finally, the descriptive statistical analysis of accounts receivable and accounts payable, lnA, △S, △C, RE, and I are shown in the table as the supply and demand of corporation TC, the change in sales, the change in the cost of sales, the current retained earnings, and the inventory respectively. The four dummy variables are the corporate governance types. It is worth noting that the average value of family governance in Taiwanese corporations is 0.62, which means that more than 60% of them are governed by family members.

2. Multiple regression analysis

This research seeks to determine the influence of prominent high ranking managers on TC. This is consistent with previous literature (Finkelstein, 1992; Bebchuk et al., 2009), which points out that the proportion of the total salary of high ranking managers in the operational team explains the effect of structural power on the corporation's performance. However, the negative relationship between the salary of high ranking managers and the supply of TC means that when high ranking managers have more salary power, this will cause a decrease of corporate TC whether from the supply or demand perspective. Finally, the TC position will be less. It has a positive relationship with prestigious power and expert power, which means that when high ranking managers have more power in these two aspects, corporate TC increases. This shows that the prestigious and expert power of high ranking managers positively help TC. The ownership power of professional managers shows no prominent results.

Hill and Wayne (2012) point out in their article that the increment of corporate TC supply helps to increase the reward of corporate debtors. This means that accounts receivable and the reward of debtors have a positive relationship. When high ranking managers have more shares, they have more power in the final pay-off and surplus distribution. In the TC supply model, it is found that, when high ranking managers possess company shares, TC is relatively positive but not prominent. This means that, when company shares increase, high ranking managers have an effect on TC, but in the agency theory, this is an agency issue. The main cause of the agency issue is the final distribution rights of self-interest and the company receiving a surplus, leading to less prominent TC usage. In the previous agency theory, if a high ranking manager makes decisions to harm the interests of clients and favor his own interests in an effective market, he must not have a good position at the next stage. Therefore, in the reputation index, it was found that, when a high ranking manager has a higher reputation, he can make a TC supply which favors the debtors or clients so that he can have a better managerial position in the future. According to the reputation hypothesis, when a manager builds a certain credit relationship with outsiders or banks and corporations, he will be careful not to harm the interests of investors and debtors.

The salary index of high ranking managers shows that there is a prominent negative relationship, whether in the supply or demand of TC. When establishing the salary index, it means that the higher the high ranking manager's salary is in the team, the more powerful his decision-making. In the lack of opinion diversification hypothesis, a group decision helps the diversification and diversity of the corporation; however, when the decision-making power is more centralized, more wrong decisions are possible, which will further harm the investment value of the corporation's debtors and clients. Further investigation found that, in the agency theory, if a corporation attracts funds from outside investors by issuing equities, the agency of the corporation may harm the interests of the stockholders by increasing self-interest. This theory is different from the TC situation of the manager in the model.

Having discussed the power indices of high ranking managers, the management indices are retained in the following models. These are substituted with the dummy variables of the types of corporate governance for a regression test. It was found from two control groups that the manager type was the one that most used TC; the association type and family type had no prominent advantages or disadvantages, and the government type was the one that least favored TC. The results are prominently related to the above hypothesis. In terms of the association type, more people in the decision-making team have less centralized issues, which mean that they tend not to make the wrong decisions. This is because some people may have more shares in the team, while others may have none; as a result, the decision-making is more neutral. This means that whether in the supply or demand of TC, the decision will not only not harm the debtors and stockholders, but also not overly erode the assets of the clients for self-interest. In government-type corporations, the proportion possessed by the government is higher. Therefore, the position of the high ranking manager is politically-related. Therefore, this position may be stabilized as it is supported by political power. Therefore, high ranking managers in government tend to harm the clients for self-interest. There is no prominent willingness to use TC supply and demand. In manager-type corporations, the manager must make a prominent performance to be able to extend the term. This is consistent with the reputation hypothesis that states that, in order to have a better relationship with outsiders and better public credit, the TC supply and demand is increased in corporate operations for maximized interest. Finally, in family types of governance, one certain family or specific members of the family hold absolute majority shares so that outsiders cannot enter the managerial level. It is found from the agency theory that agency issues occur if the agent is the internal shareholder with a high proportion of the stock. This is because if the family manager holds too many shares, he will make a better TC financing decision. However, if the profit of the shares of a family manager is insufficient to cover his consumption, he may make a TC decision that impairs the corporation.

IV. Conclusion

With the rapid development of the prosperity cycle, banks are more cautious when financing corporations; therefore, the difficulty in obtaining a loan to fund operations causes incremental trade credit. The main point of the research is the influence of the CEO on corporate trade credit. Ownership, education and expertise are the points considered. Types of corporate governance are divided into government, association, manager, and family.

The usage of corporate trade credit is found to be different under different CEO power indices. In the model of CEO and trade credit demand and supply, based on a lack of opinion diversification hypothesis, it was found that, if the salary slice of CEOs is higher than that of the salary of the decision-making group, they are not favor of using trade credit. This is because, if their decision-making power is stronger, CEOs are not inclined to consider the fortune of debtors or commissioners, but themselves. An article by Hill and Wayne (2012) mentioned that incremental trade credit helps to reward the debtors, and this coincides with this index. However, the index shows no prominent results with the ownership of the CEOs. This is because the agency problem cannot be eliminated in the agency theory when the agent processes the funds or shares. Past reputation and the expertise of the CEO have a prominent positive influence on trade credit. In the reputation hypothesis and agency theory, CEOs do not harm the clients in order to have a better position. Therefore, when making a credit decision, they tend to favor the debtors. The category of corporate governance fits the agency issue in the agency theory. CEOs in government and family-type corporations do not compete in the management market; therefore, they tend to choose a decision in trade credit that is adverse to that of the debtors. CEOs in managerial corporations consider the position of the next manager or expertise of the managers and choose a trade credit decision favoring the clients. The management team in an association corporation consists of family and managerial characteristics. Therefore, there may be differences in the final decision of trade credit if it unknown whether the decision favors the debtors or not.

Abstract

Many believe that increased investment in capital expenditure is what causes the long-run underperformance of initial public offerings (IPOs) and seasoned equity offerings (SEOs). We argue that such underperformance is caused by the agency costs of managerial discretion on free cash flow, rather than capital expenditure per se. The results of an empirical examination of a sample of 418 private placements by firms on the Taiwan stock markets confirm our hypothesis. We show that the increase in issuers of placements in capital expenditures is associated with better long-run performance, whereas issuers without any investment in capital expenditures have non-positive or significantly negative abnormal returns.

Keywords: *Private placements; Capital expenditures; Long-run performance.*

JEL Codes: G14, G30, G32

1. Introduction

In the last decade, private placements have become an important alternative to public offerings for public firms to raise equity capital. According to the Sagient Research PlacementTracker database, there were 14,079 private investment in public equity (PIPEs) transactions by U.S. public firms in the period 2001-2010, with total proceeds of US$ 421 billion. In comparison, the number of seasoned equity offerings (SEOs) in the corresponding period was 4,065, with a total new capital of US$700 billion.[1]

Existing studies show that SEOs have, on average, a negative announcement return and poor long-run performance.[2] In contrast, private placements tend to have a positive return around the announcement day and non-negative long-run performance.[3] Although the new issue puzzles relating to public offerings and private placements are well documented, few studies have addressed the topic with respect to the difference in the long-run performance of SEOs and private placements. In this paper, we shed light on the role of capital expenditure on post-issue performance, highlighting the relationship between capital expenditure and the long-run performance of private placements.

In a perfect capital market, the value of a firm should be unrelated to the amount of its investment in capital expenditures. However, Loughran and Ritter (1997) and Fu (2010) find that SEO firms tend to increase their capital expenditures rapidly after equity issuance. They conclude that there is a negative relationship between capital expenditures

[1] The statistics on SEOs are from Thomson Financial Securities Data Company's (SDC) new issue database.

[2] Studies that discuss the announcement return and long-run performance of SEOs include Loughran and Ritter (1995, 1997); Spiess and Affleck-Graves (1995); Corwin (2003); Walker and Yost (2008); and Fu (2010).

[3] Studies on private placements include Hertzel, Lemmon, Linck, and Rees (2002); Krishnamurthy, Spindt, Subramaniam, and Woidtke (2005); Wu, Wang, and Yao (2005); Barclay, Holderness, and Sheehan (2007); Wruck and Wu (2009); and Shiu and Wei (2013).

and long-run performance. More recently, Li, Livdan and Zhang (2009) propose the rational overinvestment hypothesis, and argue that managers of IPO and SEO firms have various incentives to grow their firm beyond its optimal size. Because the marginal rate of return on capital is decreasing, increased investment leads to lower marginal rates of return and results in post-issue underperformance. To test the overinvestment hypothesis, Lyandres, Sun, and Zhang (2008) construct an overinvestment risk factor by going long on low-investment stocks and short on high-investment stocks, and show that the overinvestment risk factor successfully explains the long-run underperformance of new issues. They conclude that managers of SEO firms invest too much in capital expenditure or R&D because of the low cost of capital and high agency cost of managerial discretion.

Unlike firms conducting SEOs, which are subject to the agency costs of free cash flow, with such costs increasing as new equity is issued,[4] issuers of private placements are often poorly managed and financially distressed, and cannot access public markets to raise the needed capital (Chen, Dai, and Schatzberg, 2010). In addition, their capital costs are higher than those of their industrial peers are. Thus, the agency costs of managerial discretion are less important for issuers of private placements. Moreover, capital expenditure can significantly increase the firm's placement value because it can bring new business, resulting in a turnaround for the issuer. Consequently, we hypothesize that a positive relationship exists between capital expenditures and the post-issue performance of private placements, in contrast to SEOs.

A pre-issue price run-up reflects a valuable growth opportunity or an overvaluation. Because firms in financial distress are often unable to access public markets, they may

[4] McLean (2011) finds that the propensity to save issuance proceeds as cash has increased significantly over the past three decades. Although some of the issuances are motivated by precautionary savings, the issuances of new shares by health firms also result in managerial discretion over the free cash flow.

resort to target investors through private placements. We posit that firms with financial constraints have various incentives to raise equity capital. If the issuing firms have valuable growth opportunities and specific plans for the proceeds, they would state "investment" as their primary use of capital. In the process of gradually converting growth options into assets in place, these firms may use the proceeds primarily to invest in capital expenditures or R&D. We hypothesize that because of valuable investment opportunities and lower managerial discretion, issuers of private placements with greater capital expenditure tend to have better long-run performance than their industry peers.

On the other hand, if the issuing firms desire to relieve financial constraints, they may state "recapitalization" as their goal and use the proceeds to repay debts or increase their investment in working capital. In cases where managers do not have specific plans and merely take advantage of overvaluation to issue private equity, they tend to state their intended use of proceeds as "general corporate purposes".[5] These two types of issuers tend to spend their proceeds on other accounts, rather than invest in capital expenditure. The impact on the issuer's firm value is twofold. The positive effect is that an issuance of new shares provides substantial cash infusion, which could lower the discount rate of financially distressed firms (Fama and French, 1992). The negative effect is that because the post-issue assets in place are less risky than the pre-issue growth options, the post-issue return will decline (Carlson, Fisher, and Giammarino, 2006). In considering both effects on the firm's value, we hypothesize that issuers of private placements without an investment in capital expenditure will have no excess or negative long-run abnormal returns.

[5] Since the regulation requires disclosure of the intended use of the proceeds, and the competent authority will audit the ultimate use of such proceeds, these regulations force managers of issuing firms to state truthfully their intended use of the proceeds.

To empirically examine our hypothesis, we investigate a sample of 418 placements made on the Taiwanese stock markets between January 2002 and December 2010. The competent authority in Taiwan requires the issuers of private placements to disclose detailed information, including the intended use of the capital raised and the names of target investors. We use the information provided by the firms in complying with this disclosure requirement to classify placements into three categories: investment, recapitalization, and general purpose. We then examine the announcement returns and post-issue stock performance for the three categories. The empirical results support our predictions.

Three main findings emerge from our analysis. First, the ultimate use of proceeds in the years following the placements is generally consistent with the intended use of capital stated in the announcement. That is, issuers in the *investment* category actually increase investment in capital expenditures in the years following the issuance, while issuers in the other two categories do not. This is probably a result of the likelihood of post-audit regulation by the competent authority. It also validates our classification.[6]

Second, the motivation for placement issuance varies depending on category. We follow the methodologies proposed by Rhodes-Kropf, Robinson, and Viswanathan (2005) and Hertzel and Li (2010) to decompose the pre-issue market-to-book ratios into misevaluation and growth opportunity components. Placements in the *investment* category are associated with higher growth opportunities. Thus, firms making such placements increase investment in capital expenditure to take advantage of valuable growth options in the hope of achieving a turnaround. In contrast, placements in the

[6] In a related study, Brown and Floros (2012) find that issuers use funds from PIPEs in cash reserve and R&D rather than capital expenditures. This finding is similar to our sample of placements in the *recapitalization* category and contrasts with placements in the *investment* category.

general purpose category are more likely to be motivated by overvaluation. Managers of issuers in this category do not have specific plans.

Third, post-issue performance varies greatly among these three categories. Placements in the *investment* category have a significantly positive abnormal return over the two- and three-year period following the issuance. In contrast, placements in the *recapitalization* category do not have excess long-term returns. Worse still, placements in the *general purpose* category underperform in relation to their industrial peers. The outperformance of placements in the *investment* category over those in the *general purpose* category is still robust in both insider and non-insider groups. Overall, the empirical findings presented support our hypothesis that investment in capital expenditures significantly increases the firm value of private placements.

Our empirical results complement the debate on the overinvestment of equity issuance. Although several studies, as discussed earlier, document that overinvestment of IPO or SEO firms is the driving force behind long-run underperformance, recent studies suggest a different view. Hertzel and Li (2010) argue that firms with greater growth opportunities tend to invest more in capital expenditures and R&D after issuance but firms with greater mispricing tend to decrease long-term debt or increase cash holdings. Their findings show that the latter, not the former, experience lower post-issue performance. In a study closely related to ours, Autore, Bray, and Peterson (2009) examine the relationship between the intended use of proceeds in SEOs and their subsequent long-run performance. They find that issuers that state *recapitalization* or *general purpose* as their objective experience poor performance, but issuers that state *investment* as their objective do not underperform. The authors do not check whether the ultimate use of proceeds is consistent with the stated purpose. Their sample is also contaminated by the agency costs of managerial discretion. However, their results are qualitatively similar to ours.[7] Both of the findings in this paper and those in Autore et al. (2009) provide strong evidence against the overinvestment hypothesis. Our findings suggest that the adverse effect of overinvestment on firm value is not from investment per se, but rather from the agency cost of managerial discretion on the proceeds from SEOs.[8]

This study also contributes to the existing literature on private placements. In examining the market reaction and long-run performance, Krishnamurthy et al. (2005), Barclay, Holderness, and Sheehan (2007), Wruck and Wu (2009), and Shiu and Wei (2013) have confirmed the role of insiders on performance. In addition to the status of target investors, our findings confirm that the intended use of proceeds from placements is also an important determinant of long-run performance. Investing proceeds in capital expenditures significantly increases the firm value of private placements.

The remainder of this paper is organized as follows. Section 2 introduces private placements in Taiwan. Section 3 describes the data used in this study. The main empirical results and findings are presented in Section 4. A robust check of these results and findings is undertaken in Section 5. Finally, the conclusions drawn from this study are presented and summarized in Section 6.

2. Private placements in Taiwan

Prior to 2002, public offerings were the only choice for public firms in Taiwan to sell their primary shares through seasoned equity offerings. Since some firms with poor

---

[7] Although the general findings in Autore et al. (2009) are similar to ours, the report of no abnormal performance on *investment* purpose is worth noting. They examine 880 SEOs in U.S. during the period 1997-2003. Most of the issuers are health public firms.

[8] Li (2011) finds that the positive R&D-return relationship exists only among financially constrained firms. Similarly, we find that the capital expenditures positively predict returns only among issuers of private placements, which are often financially constrained.

operating performance or illiquid stocks were financially constrained during the Asian financial crisis in 1997 and the dotcom crash in 2000-2001, they were unable to access public markets to raise external capital. To solve the problem, the Securities and Exchange Act was amended in January 2002 to allow public firms in Taiwan to choose between public offerings or private placements in conducting SEOs. Because of their flexibility and cost saving, private placements gained market shares soon after the amendment Act and become an important capital-raising source for Taiwanese public firms from 2005 onwards. For example, in 2006 there were 65 private placements by all public firms in the Taiwan stock markets, raising total equity capital of NT$ 84 billion, compared to 70 public seasoned offerings raising a total of NT$ 108 billion. By 2008, when the global financial crisis affected the capital markets, the number of private placements increased to 66 (raising NT$ 34 billion in equity capital) but the number of public offerings decreased to 17 (raising NT$ 14 billion in equity capital).

An issuance of primary shares, whether through public offerings or private placements, cannot be made without shareholder approval, which ultimately requires a two-thirds majority of all votes at a shareholders' meeting. When a firm chooses a public offering, it is obligated to register the issue with the competent authority prior to the sale. Immediately after receiving approval from the authority, the underwriters and the issuing firms can then prepare for the sale of their primary shares to the public. In contrast, when a firm conducts a private placement, it is not required to register with the competent authority in advance.

Prior to the issuance of a private placement, the issuing firm should place the capital-raising proposal on the voting agenda at the shareholders' meeting. In addition, the firm has to disclose the planned amount of capital to be issued, as well as the intended use of the proceeds. Once approval is obtained, the issuing firm contacts the private investors. Securities are generally sold to maximum of 35 knowledgeable investors, including banks, insurance companies, pension funds, incorporated entities, the firm's directors and managers, and other retail investors and institutions approved by the competent authority. When the placement deal is closed, the issuing firm publishes an announcement about the transaction in the "Material Information" bulletin in the Market Observation Post System (MOPS). Those investors acquiring the securities of the private placements are subject to restrictions on the resale for a period of three years.

3. Data

3.1 Sample

To construct the sample for this study, we search the Material Information in the MOPS for private placements announced in the Taiwan stock markets between January 2002 and December 2010. The dataset lists detailed features of each deal, including the announcement date, the intended use of proceeds, the offer price, the total number of shares sold in the placement, the number of investors, the names of the investors, the number of shares purchased by each investor, and the relationship between the issuer and the investors. This produces a total sample of 532 issues. We exclude placements by financial firms, resulting in the elimination of 21 observations.[9]

We then obtain the financial variables from the Taiwan Economic Journal (TEJ) Finance database, the daily price from the TEJ Equity database, and the names of the board directors and the ownership data from the TEJ Company database. Due to the unavailability of these financial variables, stock prices, and ownership data, two

[9] The elimination of financial firms results in smaller firms size and proceeds for our sample issuers, compared to earlier studies using a similar dataset (e.g., Shiu and Wei (2013)).

additional observations are excluded. Furthermore, 58 firms make two or more issuances between two consecutive shareholder meetings; hence, an additional 91 observations are excluded from our analysis.[10] This process leaves us with a final sample of 418 private placements, which is used in most of our empirical analyses.

Table 1 displays the distribution of our sample. Panel A presents the frequency distribution of the sample firms by year. There are only four placements in the first year, accounting for 1% of the total sample. The number of placements increases over time until 2007, and then slightly declines with the financial crisis in 2008.

<Table 1 is inserted about here>

Panel B of Table 1 presents the frequency distribution of the sample firms by industry. Among the 418 sample firms, electronic firms made up 242 of the placements accounting for 58 percent of the total sample. This distribution is generally consistent with the industry structure, with information technology and related firms dominating Taiwan's stock markets.

3.2 Characteristics of the issuing firms

In this section we present descriptive statistics on several firm characteristic variables for our sample of private placements. All variables are the annual or the year-end figures in the preceding year of issue. We define these variables in the following discussion.

Our proxies for firm size are total book assets and market capitalization. The proxy for operating performance is the return on assets, which is calculated as the earnings before interest and taxes (EBIT) divided by total book assets. The proxy for internal cash

[10] If a firm announces multiple issues in the period between two consecutive shareholder meetings, these multiple issues are regarded as tranches of a private placement. Therefore, we aggregate the proceeds from the multiple issues as the proceeds of a single placement.

flow is the cash flow ratio, which is measured as earnings before interest, taxes, depreciation, and amortization (EBITDA) divided by total book assets. Our proxies for liquidity are cash ratio and NWC ratio, which are calculated as the ratio of cash and cash equivalents to total book assets, and the ratio of non-cash net working capital to total book assets, respectively. We compute the total debt ratio as a proxy for financial leverage. We calculate investment in capital expenditures (CAPEX ratio) and research and development expense (R&D ratio) relative to total book assets. We also calculate the controlling ownership as a proxy for the extent of corporate control. Finally, we compute the market-to book ratio, where both the market and book values are measured at the end of the preceding year,[11] as a proxy for investment opportunities and/or mispricing, which we discuss later.

We report the mean and median values of firm characteristic for our sample firms in Table 2. For purpose of comparison, we also report values for the issuing firm's industry peers, which are calculated using all non-placement-issuing firms in the same industry during the same period. We test differences across the private placements and non-issuing sample using the t-statistic (in mean) and non-parametric Wilcoxon rank-sum test (in median).

<Table 2 is inserted about here>

Table 2 highlights that private placements are likely to be made by poorly managed firms that tend to be financially constrained. For the placements sample, the mean cash flow ratio is -7.7% with a median of -1.4%, suggesting the internal source of cash flow is a deficit. In sharp contrast to issuing firms, the typical industry peer has a mean cash flow

[11] We also compute the market-to-book ratio for each deal using market information prior to the announcement day (the market value is measured 10 days prior to the announcement, and the book value is measured at the end of the year preceding the announcement). The results are qualitatively unchanged.

of 9.5% with a median of 10.1%. The difference in the cash flow ratio between issuing and non-issuing firms is statistically and economically significant. Issuing firms also have lower returns on assets than do their benchmark firms. In addition, firms in our sample tend to use more debt, maintain less liquidity, and be more R&D intensive than their industry peers. Interestingly, the issuers of placements have higher mean values of capital expenditures and market-to-book ratios but lower median values than their industry peers, indicating that the distributions of these two variables are rightly skewed.

3.3 Characteristics of the deals

Table 3 presents summary statistics for private placement deals in our sample, showing that the mean gross proceeds are NT$ 490 million, with a median of NT$ 161 million (approximately US$ 14.9 million and US$ 4.9 million respectively).[12] The mean number of new shares issued, as a percentage of the total shares outstanding after the issue, is 24.9% with a median of 18.1%. When compared to other studies, the proceeds and the fraction of shares sold in our private placements sample are slightly larger than U.S. placements. For example, Wruck and Wu (2009) report that the mean (median) gross proceeds are $15.3 million ($3.0 million) and the mean (median) fraction of shares sold is 11.39% (7.24%) in their sample.

<Table 3 is inserted about here>

We calculate the beta and idiosyncratic risk, respectively, as a proxy for a firm's systemic risk and specific risk. The beta is derived from the market model (of daily returns) in the 230-day period beginning 240 days prior to the announcement, while the idiosyncratic risk is calculated as the standard deviation of the residuals from the market

[12] The exchange rate during our sample period is in the range of NT$ 35.11 (February 2002) to NT$ 30.01 (March 2008) per US$ 1. For simplicity, we use the exchange rate of NT$ 33 per US$ 1.

model. As indicated in Table 3, the mean market-to-book ratio is 2.03 with a median of 1.24. The mean (median) beta is 0.65 (0.69) and the mean (median) idiosyncratic risk is 3.72% (3.36%).

On average, the private placements are sold at a discount of 23.5% (measured relative to the market price ten days after the announcement) or 18.1% (one day prior to the announcement). The average discount in our sample is similar to the discount of 18.70% reported in Barclay et al. (2007) and the 19.44% reported in Krishnamurthy et al. (2005). However, it is much higher than the 11.33% (measured by the share price ten days after the announcement) or the 6.79% (one day prior to the announcement) discount reported in Wruck and Wu (2009).

3.4 Classification by stated use of funds

In this section, we introduce our method for classifying our sample of 418 placements into three categories based on the stated use of proceeds posted in the "Material Information" bulletin. We also provide descriptive statistics on firm and deal characteristics for the three categories.

In their announcement of private placements, if issuers indicate that they intend to use the proceeds for investments in R&Ds or capital expenditures, acquisitions, or business expansions, these placements are classified in the "investment" category (120 placements or 29% of our sample). If issuers state that they intend to use the proceeds to repay outstanding debt or bank loans, or to increase working capital, these deals are placed in the "recapitalization" category (229 placements or 55% of our sample). If the issuing firms state that proceeds of placements have multiple purposes and at least two purposes are in the "recapitalization" and "investment" categories, or if the announcements do not specifically identify the intended use of the proceeds,[13] then these placements are classified in the "general purpose" category (69 placements or 17% of our sample). The summary statistics on firm and deal characteristics for the three categories are presented in Table 4.

<Table 4 is inserted about here>

Table 4 shows that, although poor operating performance and financial constraints are universal across all three categories, issuing firms that state "recapitalization" and firms that state "general purpose" have a poorer return on assets, higher leverage, larger relative offer size, and lower net working capital ratio than firms that state "investment". Firms that state "general purpose" are larger and have higher discounts on private shares than firms in the other two categories.

4. Empirical results

4.1 The ultimate use of the proceeds

We classify all sample firms into three categories based on their intended use of funds. It is interesting to note how the issuing firms actually use their funds raised in the private placements of equity. In this section, we investigate the ultimate use of capital for the three categories.

To address the issue, we follow the methodology proposed by Kim and Weisbach (2008), who study how firms use the capital raised in the initial public offerings (IPOs) and seasoned equity offerings (SEOs) in subsequent years. For our sample of 418 private placements, we examine the cumulative changes in cash holdings (Δ Cash), non-cash net working capital (Δ *NWC*), capital expenditures (Σ *CAPX*), R&D (Σ *R&D*), and

---

[13] In such a case, the intended use of the proceeds is recorded as "general corporate purpose".

reductions in long-term debt (Σ *LTD reduction*) in the subsequent four years following the issuance. For each of five measures of possible use of the funds raised in the placements, we estimate:

$$Y = \beta_1 \cdot \ln[(\text{proceeds}/TA_0)+1] + \beta_2 \cdot \ln[(\text{other sources}/TA_0)+1] + \beta_3 \cdot \ln[TA_0] + Year + Industry + \varepsilon \quad (1)$$

where $Y = \ln[((V_t - V_0)/TA_0)+1]$ if the measure is one of "real accounts" (*Cash*, *NWC*) or $Y = \ln\left[\left(\sum_{i=1}^{t} V_i / TA_0\right)+1\right]$ if the measure is one of "nominal accounts" (*CAPEX*, *R&Ds*, and *LTD reduction*), and t=1, 2, 3, 4 years after the placements.

In the regression, β_1 measures the cumulative impact of funds raised in placements on their use in the following years, after controlling for other sources of capital inflows and the initial base of total assets. We also consider the year and industry fixed effects in our model specification. In Table 5, we only report the estimate of β_1 for the sake of brevity.

As shown in the table, the β_1 for the *investment* sample in the regressions of increase investment in capital expenditures ($\Sigma CAPX$) is significantly positive at the 1% level. Further, we find that issuers initially keep large amounts of proceeds in cash and net working capital in the year immediately after the issuance of private placements, and then substantially increase investment in capital expenditures over the next three years. Nevertheless, issuers in this category do not increase their R&D expense.[14]

[14] In Taiwan, the Statute for Upgrading Industries (SUI) provides an incentive for business investment in research and development by providing a credit against corporate tax liability for qualified company research expenses. In practice, however, firms in our sample do not have incentives to claim their R&D expenses for two reasons even if they actually spent on research and development activities. First, there is uncertainty regarding the criteria governing the entitlement to deduct R&D expenses. This point is made in the article by PwC: http://www.pwc.tw/en/challenges/taxation/indissue0260.jhtml. Second, our sample firms tend to have substantial accumulated losses and receive little value from the investment credits.

the β_1 for the *recapitalization* sample in the regressions of cumulative changes in cash holdings (Δ Cash) and non-cash net working capital (ΔNWC) is significantly positive at the 1% level. However, none of the coefficients on reductions in long-term debt (Σ*LTD reduction*) is significantly different from zero, indicating that issuers in the *recapitalization* category pile up funds in cash and net working capital rather than repay long-term debt. This finding is consistent with the view of Erel, Jang, and Weisbach (2015), who argue that firms being financially constrained tend to hold more cash on their balance sheet. Moreover, the coefficients in the regressions of capital expenditure and R&Ds are positive, with some being significantly different from zero, showing that firms in this category also slightly increase investments in real activities.

<Table 5 is inserted about here>

Finally, for the *general purpose* sample, the long-term debt temporarily declines in the year after issuance and reverts to its original level later. Firms in this category do not use funds in specific accounts except that they keep a moderate proportion of proceeds in the accounts of cash and net working capital. It reflects the fact that *general purpose* issuers do not have specific plans.

Overall, the results in Table 5 show that the ultimate use of proceeds in each category is consistent with the stated use of funds. This could be attributed to the regulatory requirement for post-audits of the proceeds. It also justifies the classification of our placements sample into *investment*, *recapitalization*, and *general purpose* categories.

4.2 Investment opportunities and mispricing

The summary statistics reported in Table 2 show that the issuers in our sample have a higher mean ratio of pre-issue market-to-book than their industry peers. High market-to-book ratios may be viewed as a sign of overvaluation, or as a sign of valuable investment opportunities (Rhodes-Kropf et al., 2005). In examining the motivation of equity issuance, Hertzel and Li (2010) decompose market-to-book ratios into two components: misevaluation and growth opportunities. They find that issuing firms are both overvalued and have greater growth opportunities relative to non-issuing firms.

We follow the methodologies proposed by Rhodes-Kropf et al. (2005), and Hertzel and Li (2010) to decompose the pre-issue market-to-book ratios of our private placements. The market-to-book ratio can be expressed as follows:

$$\frac{M}{B} \equiv \frac{M}{V} \times \frac{V}{B} \tag{2}$$

where M is the market equity, B is the book equity, and V is the fundamental value of equity. Taking the logarithms of both sides (represented by lower case letters), the equation can be written as follows:

$$m - b \equiv (m - v) + (v - b) \tag{3}$$

In equation (3), the decomposition of market-to-book ratio relies on an estimate of fundamental value, v. For each observation, Rhodes-Kropf et al. (2005) further decompose the market-to-book ratio for firm i at time t into three components as follows:

$$m_{it} - b_{it} = \left[m_{it} - v(\theta_{it};\alpha_{jt})\right] + \left[v(\theta_{it};\alpha_{jt}) - v(\theta_{it};\alpha_{j})\right] + \left[v(\theta_{it};\alpha_{j}) - b_{it}\right] \tag{4}$$

where valuation measure v is defined as a function of θ_{it} (the specific accounting information for firm i at time t) and α (a vector of accounting multiples for firm i in industry j). Specifically, α_{jt} is the vector of industry j accounting multiples at the time t, and α_j is the vector of industry j long-run multiples.

The first part on the right-hand side of equation (4), $m_{it} - v(\theta_{it};\alpha_{jt})$ represents the difference between the market value and fundamental value of equity where fundamental value is conditioned on the firm-specific accounting data, θ_{it}, and the contemporaneous industry *j* accounting multiples. Rhodes-Kropf et al. (2005) argue that this difference can capture the extent to which the firm is misvalued relative to its contemporaneous industry peers, referred to as firm-specific errors (FSE). The second component $v(\theta_{it};\alpha_{jt}) - v(\theta_{it};\alpha_j)$, which is referred to as time-series sector error (TSSE), is the difference between the full time series valuation and the industry specific valuation. This component captures the extent of misvaluation specific to the industry. The final component, $v(\theta_{it};\alpha_j) - b_{it}$, referred to as long-run value-to-book (LRVTB), measures the difference between firm value and book value where firm value is conditioned on the vector of long-run industry *j* accounting multiples.

To estimate $v(\theta_{it};\alpha_{jt})$ and $v(\theta_{it};\alpha_j)$ we use the third model proposed by Rhodes-Kropf et al. (2005) that includes book value of equity (*b*), net income (*NI*), and market leverage ratio (*LEV*) as the θ_{it} (this approach is also used in Hertzel and Li (2010)). Market equity is estimated as a simple linear model of the accounting variables as follows:

$$m_{it} = \alpha_{0jt} + \alpha_{1jt} b_{it} + \alpha_{2jt} \ln(NI)^{+}_{it} + \alpha_{3jt} I_{<0} \ln(NI)^{+}_{it} + \alpha_{4jt} LEV_{it} + \varepsilon_{it} \qquad (5)$$

where $(NI)^{+}$ is the absolute value of net income, $I_{<0}$ is an indicator variable when net income is negative, and *LEV* is computed as:

$$LEV = 1 - \frac{\text{Market equity}}{\text{Market equity} + \text{Book assets - Deferred taxes - Book equity}} \qquad (6)$$

We regress equation (5) annually for each of the 11 industries for the years from

1995 to 2009, to yield the estimates of their accounting multiples (i.e., $\hat{\alpha}_{0jt}$, $\hat{\alpha}_{1jt}$, $\hat{\alpha}_{2jt}$, $\hat{\alpha}_{3jt}$, and $\hat{\alpha}_{4jt}$).[15] The first component of equation (4) (FSE) for each firm is the residual of the equation (5). To calculate the second and third components, we have to estimate the long-run industry multiples. For each industry, we average all multiples over the available years prior to the issuance of the private placement.[16] The accounting variables (b_{it}, NI_{it}, LEV_{it}) with the estimates of long-run industry multiples ($\overline{\alpha}_{0jt}$, $\overline{\alpha}_{1jt}$, $\overline{\alpha}_{2jt}$, $\overline{\alpha}_{3jt}$, and $\overline{\alpha}_{4jt}$) are fitted into the equation (5) to compute the estimate of $v(\theta_{it};\alpha_j)$.

Table 6 presents the mean and median of the three components of the market-to-book ratios for the three categories. The table shows that the mean (median) FSE for the *general purpose* sample is 0.206 (0.262), and is significantly higher than 0.084 (0.031) in the *recapitalization* category and 0.048 (0.100) in the *investment* category. On the other hand, firms in the *investment* category have significantly higher pre-issue LRVTB ratios than do firms in the other two categories. The mean (median) LRVTB in the *investment* category is 0.479 (0.471), which is twice 0.192 (0.169) in the *recapitalization* category and 0.198 (0.184) in the *general purpose* category.

<Table 6 is inserted about here>

The findings in Table 6 show that firms in the *investment* category have high pre-issue LRVTB ratios, and are more likely to have valuable investment opportunities.

---

[15] The results are quantitatively similar to those reported in Rhodes-Kropf et al. (2005) and Hertzel and Li (2010). The time series average of coefficients and then averaged across 11 industries is 0.960 (with a standard error of 0.169) for α_0, 0.836 (se=0.024) for α_1, 0.213 (se=0.035) for α_2, -0.032 (se=0.007) for α_3, and is -1.020 (se=0.394) for α_4. The average adjusted R^2 is 0.915.

[16] We also compute the long-run industry multiples using full time series of values, which is used in Rhodes-Kropf et al. (2005), to estimate the TSSE and LRVTB components. The results are qualitatively unchanged. However, as discussed in Hertzel and Li (2010), this methodology suffers the problem of forward-looking information that is not available to investors at the time placements are issued.

They issue new shares to private investors to raise funds for investment in capital expenditures. In contrast, firms in the *general purpose* category have high pre-issue FES ratios, suggesting that the issuance of equity is more likely to be motivated by overvaluation.

4.3 Market reactions

Previous studies show that the market reaction to firms conducting SEOs is negative around the announcement day (e.g., Corwin, 2003; Walker and Yost, 2008). The information asymmetry, which is the assumption of analytical framework of the pecking-order model by Myers and Majluf (1984), is one of the most successful hypotheses offered to explain the negative market reaction to the equity issuance. Myers and Majluf argue that when a firm announces an issue of risky securities, outside investors believe these risky securities to be overvalued and adjust their valuation of the firm to reflect the new information. However, the pecking order theory are challenged by the phenomenon of a positive market reaction to private placements (e.g., Krishnamurthy et al., 2005; Wu, Wang, and Yao, 2005; Wruck and Wu, 2009; Shiu and Wei, 2013). To explain the positive reaction, some studies extend the Myers and Majluf model. For example, Wu and Wang (2005) asserts that the positive effect of asymmetric information about corporate growth opportunities offsets the adverse selection effect from asymmetric information about the assets in place, thus leading to a positive announcement return.

We use the market model to calculate the announcement period abnormal return. The market model is estimated, in the period from day -120 through day -11, with a regression of the firm's daily stock returns on the market return. We use the cumulative abnormal returns (CARs) in two different windows to capture the stock price reactions to the announcement of the private placements: CAR [-1, 3] (cumulative abnormal returns over the 5-day interval beginning 1 day prior to the announcement, with day 0 being the initial announcement day of the private placement) and CAR [-1, 10]. The announcement period abnormal returns are reported in Table 7.

<Table 7 is inserted about here>

As reported, the mean (median) CAR [-1, 3] for all placements is 3.86 percent (1.84 percent), and the mean (median) CAR [-1, 10] is 7.44 percent (2.73 percent). All of these abnormal return measures are significant. In our sample, the information effect of announcing a placement is stronger than the findings in previous studies. For example, Krishnamurthy et al. (2005) report a mean CAR [-3, 0] of 2.21 percent, and Wruck and Wu (2009) measure a mean CAR [-3, 0] of 2.02 percent. Wu, Wang, and Yao (2005) also document a mean CAR [-1, 1] of 3.51 percent for their sample of private placements in Hong Kong.

In proceeding to examine the abnormal returns in the three categories, we find that the positive market reaction to the announcement of private placements do not materially differ between the three intended use of capital types.

4.4 Long-run stock performance

Earlier studies document that private placements underperform, compared to benchmarks, in the long run. For example, Hertzel, Lemmon, Linck and Rees (2002) report a three-year abnormal return of -45.15 percent, while Krishnamurthy et al. (2005) find an abnormal return of -38.39 percent, and Wruck and Wu (2009) document an abnormal return of -25.27 percent. Here, we are interested in understanding whether different stated intentions for use of capital can be associated with a variation in long-run stock performance.

The medium-term abnormal returns in the [11, 480] period and the long-term abnormal returns in the [11, 720] period are a proxy for the post-issue long-run stock performance.[17] We adopt two approaches to measure such performance. The first approach is the cumulative abnormal returns, where the abnormal return is computed by subtracting the value-weighted return of all firms in the same industry from the return of the issuing firm. The second method is the calendar time abnormal return, which involves regressing the portfolios' daily excess return against the four factors of Fama and French (1993, 1996) and Carhart (1997). For each calendar day in our sample period, we form an equally weighted portfolio of all placements in the post-issue period [11, 480] or [11,720]. We also form the portfolios of placements classified by the stated use of capital type. The four-factor model can be stated as follows:

$$R_{i,t} - RF_t = \alpha + \beta_{RMRF} RMRF + \beta_{SMB} SMB + \beta_{HML} HML + \beta_{PR1YR} PR1YR_t + \varepsilon_{i,t} \quad (7)$$

where $R_{i,t}$ is the return on portfolio i at day t, RF_t is the risk free rate,[18] $RMRF_t$ is the daily excess return on the Taiwan-listed value-weighted market portfolio, SMB_t is the return on the factor-mimicking size portfolio, HML_t is the return on the factor-mimicking book-to-market equity portfolio, and $PR1YR_t$ is the return on the factor-mimicking portfolio for a one-year return momentum. The constant term α is Jensen's alpha and β_{RMRF}, β_{SMB}, β_{HML}, and β_{PR1YR} are the factor loadings of $RMRF$, SMB, HML, and $PR1YR$, respectively.

Table 8 reports the summary statistics for the long-run performance of private placements. Panel A presents CAR results. The first row reports the medium-term and

[17] We use 480 days and 720 days to approximate the two-year and three-year period, respectively, after the placement.

[18] Because there is no actively traded T-bond market in Taiwan, we use the one-month time deposit rate offered by the Bank of Taiwan as a proxy for the risk-free rate.

long-term CARs for the entire sample of placements. In contrast to the previous studies, we find that the average of the long-run abnormal returns for all placements is insignificant. As shown, the mean CAR [11, 480] is -1.97 percent (median of -0.97 percent), while the long-term CAR over the [11, 720] window is also insignificantly different from zero, with a mean of -1.41 percent (median of 2.59 percent). Although the mean and median CARs are close to zero, we find a large number of placements exhibit extremely high or extremely low long-run abnormal returns. For example, in the [11, 720] window, almost a quarter of the placements have CARs in excess of 60 percent, whereas one-sixth of placements suffer losses exceeding 60 percent.

<Table 8 is inserted about here>

The second to fourth rows of Panel A show that the long-run stock performance varies across the different types of placements. We find that the average abnormal returns of placements in the *investment* category are significantly positive (11.11 percent in the period [11,480], and 18.04 percent in the period [11,720]), whereas placements in the *general purpose* category are significantly negative (-26.79 percent and -18.97 percent, respectively). The long-run performance for placements in the *recapitalization* category lies between the other two types and the average abnormal returns are not significantly different from zero (-1.34 percent and -6.31 percent).

We also test the difference in the mean and median abnormal returns between the placements in the *general purpose* category and those in the other two categories. With reference to the CAR [11, 480], the placements that state *investment* as the intended use of capital significantly outperform the placements in the *general purpose* category by 37.90 percent (median of 12.17 percent). The placements in the *recapitalization* category also have a significantly superior performance of 25.45 percent (median of 7.43 percent).

All of the differences are statistically and economically significant. Similarly, in the long-term window [11,720], the *investment* placements also significantly outperform the *general purpose* placements.

Panel B of Table 8 presents the Fama-French and the Carhart four-factor model results based on the daily and implied returns in the [11, 480] and [11, 720] windows, respectively. Slightly different from the results in Panel A, the alpha for the entire sample of placements is 0.029 percent and 0.030 percent. Both results are significantly different from zero. The implied abnormal return over the [11, 480] period is 14.33 percent, while it is 23.63 percent over the [11, 720] period. For the placements classified according to the intended use of capital, the alphas for the *investment* category are all significantly positive, while the ones for the *recapitalization* category are insignificantly positive. In contrast to the *investment* and *recapitalization* categories, the alpha on *general purpose* placements is significantly negative. Similar to the result reported in Panel A, the *investment* placements and *recapitalization* placements significantly outperform the *general purpose* placements in the four-factor model.

Using a multivariate model that controls for other factors such as deal and firm characteristics, we further analyze the influence of the intended use of capital on the post-issue performance of placements. The dependent variable in the first and second equations is the medium-term abnormal return, CAR [11, 480], while the dependent variable in the third and fourth equations is the three-year abnormal return, CAR [11, 720]. The independent variables are as follows: the two intended uses of capital dummies (*Investment dummy* and *Recapitalization dummy*) for the placements (the *general purpose* category has been omitted); the fraction of new shares sold in the placement (*Fraction placed*); the ownership of controlling shareholders prior to issuance (*Controlling* *ownership*); the private placement discount (*Discount_2*), which is calculated as the issuing price relative to the closing price on the day prior to the announcement; the market capitalization of the issuing firm (*Ln_cap*; the logarithm of market cap); *return on assets*; *debt ratio*; *beta*; *idiosyncratic risk*; *prior return*; *announcement return*; and the year dummies. The results for the regression of the long-run stock performance are reported in Table 9.

<Table 9 is inserted about here>

As shown in Table 9, when controlling for other factors, placements in the *investment* and *recapitalization* categories both have better post-issue performance than the placements in the *general purpose* category. Particularly, the coefficient on the *Investment dummy* is 39.92 (t-statistic = 3.68) for the medium-term excess return regression and 36.87 (t-statistic= 3.18) for the long-term ones, indicating that the long-run outperformance of the *investment* placements when compared to the *general purpose* placements is not only statistically significant but also economically significant. These results confirm the earlier findings and are consistent with our argument that placements in the *investment* category are more likely to have valuable opportunities while placements in the *general purpose* category do not.

For the firm and deal characteristic variables, we find that the coefficients for *Ln_cap* are significantly negative, suggesting that smaller firms tend to have better long-run performance following the placements. The coefficients for *Controlling ownership* are significantly positive and the ones for *Discount_2* are significantly negative. These findings indicates that issuers with a higher controlling ownership and is less diluted at issuance have better long-run performance. Interestingly, the coefficients on *Announcement return* are significantly negative, implying a reverse relationship between the market reaction and long-run performance. Recalling that abnormal returns of placements around the announcement day are positive for all three categories, the result on reverse relation indicates that investors do not correctly assess the signal of the intended use of capital when placements are announced.

5. Robustness test

Our empirical findings show that private placements in the *investments* category tend to have greater valuable opportunity and issuers subsequently increase investment in capital expenditures. Most importantly, these placements are associated with a long-run outperformance when compared to their industry peers. In contrast, placements in the *general purpose* category do not have specific investment plans and the issuance of placements is more likely to be motivated by overvaluation. These placements are associated with poor long-run performance. These findings are consistent with the view that the intended use of capital stated in the placements does matter for the post-issue long-run performance.

Our results, however, can also be explained by competing hypotheses. Earlier studies have confirmed the role of insiders in private placements and found that placements sold to insiders tend to have better announcement returns and superior post-issue performance than placements sold to outsiders. Either the managerial incentive hypothesis (Wruck, 1989; Krishnamurthy et al., 2005; Wruck and Wu, 2009; Shiu and Wei, 2013) or the certification hypotheses (Hertzel and Smith, 1993) is offered to explain the phenomenon. If the outperformance (underperformance) of placements in the *investment* (*general purpose*) category is merely a manifestation of managerial incentive or certification, we would observe that placements in the *investment* category concentrate in insider placements while placements in the *general purpose* category involve more non-insider placements. We conduct robustness tests, as explained below, to examine the validity of the competing hypotheses.

To distinguish the participating investors as insiders or non-insiders, we collect the names of the private investors in the deal of placement and the relation of the investors with the issuers. Participating investors are regarded as insiders if they are controlling shareholders, directors, or managers. If an investor is a relative or a family member of the controlling shareholder, this investor is also categorized as a controlling shareholder. In each deal, if the dominant investor is insider (non-insider), then this placement is classified as "insider placement" ("non-insider placement"). Among 418 placements, we classify 200 deals as "insider placements", 208 deals as "non-insider placements", and 10 deals are undetermined.

Panel A of Table 10 reports the cross-tabulation of intended use categories and participating investor categories for 418 placements. Although earlier results show that the outperformance of placements in the *investment* category is in sharp contrast to the underperformance of placements in the *general purpose* category, both categories have more insider placements and less non-insider ones than the placements in the *recapitalization* category. It suggests that our findings are not driven by the managerial incentive or certification hypothesis.

<Table 10 is inserted about here>

Panel B of Table 10 reports the summary statistics of several variables for the insider and non-insider placements. Non-insider placements have higher FSE (the value in median is significantly different from zero) than insider placements. However, the difference in LRVTB between two investor type placements is insignificant. The result suggests that overvaluation and valuable growth opportunity in the pre-issue period is not an important consideration, or perhaps is not discerned, by insiders in deciding in which placements to participate. For the offering price, non-insider placements have a smaller discount than insider placements, implying that self-dealing is not supported in our sample. For the post-issue performance, insider placements have better long-run performance than non-insider placements. The differences in CAR[11, 480] and CAR[11, 720] between these two investor-type placements are highly significant. The result is consistent with the prediction of monitoring or managerial incentive hypotheses.

In cross tabulation, if the outperformance (underperformance) of placements in the *investment* (*general purpose*) category is merely a manifestation of managerial incentive or certification, the difference in the long-run performance between the insider and non-insider placements would be significant and the difference between placements in the *investment* category and those in the *general purpose* category would become insignificant. In cross tabulation, we calculate the medium-term (CAR[11, 480]) and the long-term stock performance (CAR[11,720]) for those placements. The results are shown in Panel C of Table 10.

The results from Panel C of Table 10 indicate that the non-insider placements actually weaken the long-run stock performance of the placements. However, the difference in the performance between the placements in the *investment* category and those in the *general purpose* category are still significant. For example, for the sample of insider placements, the placements in the *investment* category outperform the average placements in the *general purpose* category by 38.20 percent (a median of 18.49 percent) in the long-term. Similarly, for the non-insider placements, the average (median) difference in the CAR[11,720] is 33.50 percent (41.04 percent). All of these differences are economically and statistically significant.

To further control for the investor type and other deal and firm characteristics, we add a new independent variable, the *Insider dummy* (a dummy variable for the insider placements), and repeat the multivariate analysis conducted in Table 9. The new results are reported in Table 11. As shown in the Table, the coefficient on Insider dummy is positive and in regression (2) the one is significantly different from zero, suggesting that the insider placements outperform non-insider placements in the post-issue period. More importantly, all of the coefficients on the *Recapitalization dummy* and the *Investment dummy* are positive and most of them are significant. The regression results are qualitatively similar to the cross tabulation results.

<Table 11 is inserted about here>

The above analyses show that our results are not driven by the monitoring or managerial incentive hypothesis. Rather, the empirical results are more consistent with our hypothesis that when the placements are announced, issuers tend to state an investment in capital expenditure if they have a valuable growth opportunity. We find that placements in the *investment* category ultimately increase their investment in capital expenditure and experience outperformance post issue when compared to their industry peers. On the other hand, if the issuing firms are motivated by overvaluation, they tend to state *general purpose* in their announcements.

6. Conclusions

Over the past few years, private placements have become an important way for public firms to obtain equity capital relatively quickly and inexpensively. The advantage of flexibility and cost-saving in private placements is very appealing for small- and mid-cap public firms.

In this paper, we investigate a sample of 418 placements made on the Taiwanese stock markets between January 2002 and December 2010. These issuers of placements are characterized by poor performance with financial constraints. Since regulation requires disclosure of the intended use of funds raised in private placements, this provides us an opportunity to classify all placements into three categories (recapitalization, investment, and general purpose) and to examine the association of investment and the long-run performance of private placements.

Our empirical results show that managers of issuers ultimately use the funds in the accounts in a manner consistent with the stated purposes in the announcement when issued. This is probably attributable to the post-audit requirements by the competent authority. In the decomposition of pre-issue market-to-book ratios, we document that placements in the *investment* category have higher growth opportunities than those in the other two categories, and placements in the general purpose category are more likely to be motivated by overvaluation. Finally, the post-issue performance varies greatly among these three categories. While placements in the *investment* category have significantly positive long-run abnormal returns, and placements in the *general purpose* category have poor long-run performance, the ones in the *recapitalization* category are reported as having no abnormal returns. Our results are robust after controlling for deal characteristics, firm characteristics, and types of participating investors.

For the outperformance of placements in the *investment* category, we argue that the agency problem of managerial discretion on free cash flow is overcome by the emergence of the growth opportunities. Issuers significantly increase investment in capital expenditure to take advantage of valuable investment opportunities in the hope of making a turnaround. The underperformance of placements in the *general purpose* category indicates that these issuers do not have specific plans for the proceeds. Rather, they only take advantage of the overvaluation to issue new equity, and accumulate funds in less-risky accounts, such as cash, cash equivalents, and net working capital. This results in a lower post-issue return. For placements in the *recapitalization* category, an issuance of new equity provides substantial cash infusion for the issuers. The benefits from relieving financial distress risk can offset the decrease in value when growth options are converted into assets in place, where assets in place are less risky than growth options. This results in placements in the *recapitalization* category that do not have abnormal returns in the long run.

Table 1 Distribution of Private Placements

The sample comprises 418 private placements made by firms on the Taiwan stock markets from January 2002 to December 2010. Panel A presents the frequency distribution of sample firms by cohort year. Panel B reports the frequency distribution of sample firms by industry.

Panel A: Frequency distribution of sample firms by cohort year

Cohort Year	Number of placements	% of sample
2002	4	1.0
2003	15	3.6
2004	15	3.6
2005	42	10.0
2006	61	14.6
2007	76	18.2
2008	62	14.8
2009	77	18.4
2010	66	15.8
Total	418	100.0

Panel B: Frequency distribution of sample firms by industry

Industry	Number of placements	% of sample
Food	2	0.5
Plastics	4	1.0
Textiles	11	2.6
Electric Machinery	16	3.8
Biotechnology and Medical Care	15	3.6
Iron and Steel	13	3.1
Electronic	242	57.9
Building Materials and Construction	62	14.8
Shipping and Transportation	3	0.7
Trading and Consumers' Goods	14	3.3
Others	36	8.6
Total	418	100.0

Table 2 Descriptive Statistics of Firm Characteristics

This table presents descriptive statistics for the characteristics of the sample firms and their industry peers. The sample comprises 418 private placements made by firms on the Taiwan stock markets between January 2002 and December 2010. All of the variables are the annual or the year-end figures in the preceding year. *Cash flow ratio* is earnings before interest, taxes, depreciation, and amortization (EBITDA) divided by total book assets. *CAPEX ratio* is capital expenditures divided by total book assets. *R&D ratio* is the ratio of research and development expenditures to total book assets. *Return on assets* is the net income divided by total book assets. *Cash ratio* is the ratio of cash and cash equivalents to total book assets. *NWC ratio* is the ratio of non-cash working capital (current assets minus current liabilities minus cash and cash equivalents) to total book assets. *Debt ratio* is the ratio of long-term debt plus short-term debt to total book assets. *Market cap* is the stock price times the number of shares outstanding. *Market-to-book* is defined as the ratio of market cap to book value of equity. *Controlling ownership* is the ownership of the controlling family. The last column reports *p*-values for two-tailed tests of differences in the mean (t-statistics) and median (Wilcoxon z-statistics) between issuing firms and their industry peers.

Variable	Issuing firm	Industry peers	Difference	*p*-Value
Cash flow ratio (%)				
Mean	-7.655	9.521	-17.180	0.000
Median	-1.370	10.080	-11.450	0.000
CAPEX ratio (%)				
Mean	4.204	2.703	1.500	0.000
Median	2.061	3.146	-1.085	0.067
R&D ratio (%)				
Mean	4.592	1.943	2.650	0.000
Median	2.460	2.334	0.127	0.000
Return on assets (%)				
Mean	-14.010	4.509	-18.520	0.000
Median	-6.441	4.543	-10.984	0.000

Table 3 Summary Statistics for the Deal of Private Placements

This table presents descriptive statistics for the deal. The sample comprises 418 private placements made by firms on the Taiwan stock markets between January 2002 and December 2010. *Gross proceeds* is the total dollar amount of the placements. *Fraction placed* is the fraction of the offered shares relative to the total shares outstanding after the sale. *Market-to-book* is the market-to-book value, where the market value is measured 10 days prior to the announcement, and the book value is measured at the end of the year preceding the date of announcement. *Beta* is calculated from the market model in the 230-day period beginning 240 days prior to the announcement, and *Idiosyncratic risk* is calculated as the standard deviation of the residuals from the market model. *Discount_1* and *Discount_2* are calculated as the (P1-Po)/P1, where Po is the offering price and P1 is the market price. For *Discount_1* (*Discount_2*), the market price is the share price 10 days after the announcement (1 day prior to the announcement).

	Mean	Std Dev	Median
Gross proceeds (NT$ million)	490	2,142	161
Fraction placed (%)	24.901	18.765	18.083
Market-to-book	2.031	6.126	1.243
Beta	0.654	0.384	0.687
Idiosyncratic risk (%)	3.721	1.186	3.359
Discount_1 (% relative to 10 days after announcements)	23.459	26.312	24.016
Discount_2 (% relative to 1 day prior to announcements)	18.084	25.918	19.940

Table 4 Firm and Deal Characteristics by Intended Use of Funds Categories

This table presents the summary statistics for firm and deal characteristics of private placements classified by the stated intended use of funds. The sample comprises 418 private placements undertaken by firms on the Taiwan stock markets between January 2002 and December 2010. Placements are categorized as recapitalization (*N*=229), investment (*N*=120), and general purpose (*N*=69). For the definition of firm and deal characteristics, please refer to Tables 2 and 3.

	Intended use of funds categories		
	Recapitalization	Investment	General purpose
Number of placements	229	120	69
(%)	54.785	28.708	16.507
Return on assets (%)			
Mean	-17.595	-6.958	-14.375
Median	-9.394	0.349	-4.116
NWC ratio (%)			
Mean	8.027	27.669	8.235
Median	9.659	27.597	6.635
Debt ratio (%)			
Mean	59.811	44.374	57.377
Median	59.921	44.390	59.068
Total Assets (NT$ million)			
Mean	5,683	4,204	14,280
Median	1,661	1,552	2,098
Fraction placed			
Mean	26.660	21.069	25.729
Median	20.183	15.074	17.525
Market-to-book			
Mean	2.066	1.964	2.033
Median	1.121	1.473	1.488
Discount_1 (% relative to 10 days after announcements)			
Mean	23.097	22.291	26.688
Median	24.051	24.591	23.109
Discount_2 (% relative to 1 day prior to announcements)			
Mean	17.143	17.936	21.460
Median	19.918	20.000	20.000

Table 5 Ultimate Use of Private Placements Inflows

The table presents estimates from regressions of changes in accounting in the subsequent years on the private equity proceeds and other sources of funds. The sample comprises 418 private placements undertaken by firms on the Taiwan stock markets between January 2002 and December 2010. Placements are categorized as recapitalization (N=229), investment (N=120), and general purpose (N=69). Proceeds are the total dollar amount of funds raised in the placements. TA_0 is the total book assets in the preceding year (t=0). *Cash* is the cash and cash equivalents. *NWC* is non-cash working capital (current assets minus current liabilities minus cash and cash equivalents). *CAPEX* is capital expenditures, and *LTD reduction* is reduction in long-term debt. The numbers in column t-stat are heteroskedasticity-adjusted t-statistics. Coefficients with statistical significance of 10% or less are highlighted in bold-faces type. The regression model can be stated as follows:

$$Y = \beta_1 \cdot \ln[(\text{proceeds}/TA_0) + 1] + \beta_2 \cdot \ln[(\text{other sources}/TA_0) + 1] + \beta_3 \cdot \ln[TA_0] + Year + Industry + \varepsilon$$

where dependent variable $Y = \ln[((V_t - V_0)/TA_0) + 1]$ for "real accounts" (*Cash*, *NWC*), and

$Y = \ln\left[\left(\sum_{i=1}^{t} V_i / TA_0\right) + 1\right]$ for "nominal accounts" (*CAPEX*, R&Ds, and *LTD reduction*).

Categories	t	Dependent variable: Δ*Cash*		Δ*NWC*		Σ*CAPX*		Σ *R&D*		Σ*LTD reduction*	
		β_1	t-stat.	β_1	t-stat.	β_1	t-stat.	β_1	t-stat.	β_1	t-stat.

Table 6 Decomposition of Market-to-Book Ratios

This table presents the summary statistics of the market-to-book ratios and the three components for issuers of placements. The sample comprises 418 private placements undertaken by firms on the Taiwan stock markets between January 2002 and December 2010. Placements are categorized as recapitalization (N=229), investment (N=120), and general purpose (N=69). Ln_MB is the logarithm of market-to-book ratio, which is defined as the ratio of market cap to the book value of equity. The three components are firm-specific error (FSE), time-series sector error (TSSE), and long-run value-to-book (LRVTB). *p*-Values are for two-tailed tests of differences in the mean (t-statistics) and median (Wilcoxon z-statistics) between categories. Statistics with p-values of 0.10 or less are highlighted in bold-faced type.

		All issuers	Recapitalization	Investment	General purpose	Diff	*p*-Value	Diff	*p*-Value	Diff	*p*-Value
			(1)	(2)	(3)	(1-2)		(1-3)		(2-3)	
Ln_MB	Mean	0.252	0.165	0.389	0.302	**-0.224**	**(0.010)**	-0.137	(0.200)	0.087	(0.475)
	Median	0.218	0.114	0.387	0.397	**-0.273**	**(0.002)**	-0.283	(0.150)	-0.010	(0.344)
FSE	Mean	0.094	0.084	0.048	0.206	0.036	(0.515)	**-0.122**	**(0.078)**	**-0.158**	**(0.029)**
	Median	0.070	0.031	0.100	0.262	-0.069	(0.744)	**-0.231**	**(0.018)**	**-0.162**	**(0.047)**

	Median	-0.114	-0.129	-0.115	-0.076	-0.014	(0.695)	-0.052	(0.560)	-0.038	(0.305)
LRVTB	Mean	0.275	0.192	0.479	0.198	**-0.286**	**(0.000)**	-0.005	(0.933)	**0.281**	**(0.000)**
	Median	0.265	0.169	0.471	0.184	**-0.302**	**(0.000)**	-0.015	(0.827)	**0.288**	**(0.000)**

Table 7 Announcement Abnormal Returns

This table presents the mean and median announcement returns, CAR[-1, 3] and CAR[-1, 10]. The sample comprises 418 private placements undertaken by firms on the Taiwan stock markets from January 2002 to December 2010. Placements are categorized as recapitalization (N=229), investment (N=120), and general purpose (N=69). We use the market model to calculate the announcement period abnormal return. The market model is estimated, in the [-120, -11] period, with a regression of the firm's daily stock returns against the market return. The numbers in parentheses are *p*-values.

	CAR[-1, 3] (%)		CAR[-1, 10] (%)	
	Mean	Median	Mean	Median
All placements	3.855	1.842	7.440	2.731
	(0.000)	(0.000)	(0.000)	(0.000)
Recapitalization	4.001	1.934	8.016	4.679
	(0.000)	(0.000)	(0.000)	(0.000)
Investment	2.951	1.981	6.357	1.479
	(0.002)	(0.008)	(0.000)	(0.002)
General purpose	4.945	0.914	7.409	1.938
	(0.001)	(0.017)	(0.002)	(0.023)

Table 8 Long-Run Stock Performance

The sample comprises 418 private placements undertaken by firms on the Taiwan stock markets between January 2002 and December 2010. Long-run stock performance variables are computed over two different periods: medium-term abnormal return is measured in the [11, 480] period and long-term abnormal return in the [11, 720] period. Panel A presents the CARs for all placements and placements categorized as recapitalization (N=229), investment (N=120), and general purpose (N=69). Abnormal returns are computed by subtracting the value-weighted returns of all firms in the same industry from the return of the corresponding issuing firm. We test for the difference between two placement categories using the t-test for the mean, and the Wilcoxon sign rank test for the median. Panel B presents the alphas from daily Fama-French and Carhart four-factor model, and the implied medium-term and long-term abnormal returns. The implied median-term abnormal return is calculated as $(1+alpha)^{470}-1$, and the implied long-term abnormal return as $(1+alpha)^{710}-1$. *p*-Values are for two-tailed tests and are reported in parentheses below the mean or median values. Statistics with *p*-values of 0.10 or less are highlighted in bold-faced type.

Panel A: Cumulative abnormal returns for private placements

	Medium-term abnormal return CAR [11, 480] (%)		Long-term abnormal return CAR [11,720] (%)	
	Mean	Median	Mean	Median
All Placements (N=418)	-1.965 (0.583)	-0.972 (0.566)	-1.409 (0.718)	2.590 (0.913)
Recapitalization (N=229)	-1.339 (0.786)	-1.552 (0.505)	-6.309 (0.242)	-3.044 (0.350)
Investment (N=120)	**11.113** **(0.057)**	**3.189** **(0.081)**	**18.039** **(0.009)**	**12.882** **(0.017)**
General purpose (N=69)	**-26.789** **(0.006)**	**-8.980** **(0.016)**	**-18.971** **(0.043)**	**-23.071** **(0.081)**
Recapitalization *minus* General purpose	**25.450** **(0.015)**	**7.428** **(0.042)**	12.662 (0.252)	20.028 (0.150)
Investment *minus* General purpose	**37.901** **(0.000)**	**12.169** **(0.002)**	**37.010** **(0.001)**	**35.954** **(0.002)**

Panel B: Calendar time portfolio abnormal returns for private placements

	Medium-term abnormal return Alpha [11, 480] (%)		Long-term abnormal return Alpha [11, 720] (%)	
	Daily	Implied	Daily	Implied
All Placements (N=418)	**0.0285** **(0.032)**	14.331	**0.0299** **(0.009)**	23.629
Recapitalization (N=229)	0.0272 (0.132)	13.657	0.0149 (0.348)	11.189
Investment (N=120)	**0.0530** **(0.006)**	28.279	**0.0584** **(0.000)**	51.386

Recapitalization *minus* General purpose	**0.0927** **(0.057)**	40.159	**0.0602** **(0.025)**	38.698
Investment *minus* General purpose	**0.1185** **(0.002)**	54.773	**0.1037** **(0.006)**	78.894

Table 9 Determinants of Long-Run Stock Performance

This table presents the regression results of the long-run stock performance for private placements undertaken by firms on the Taiwan stock markets between January 2002 and December 2010. The dependent variable in regression models (1) and (2) is medium-term stock performance, which is measured by CAR [11, 480], and the dependent variable in the models (3) and (4) is long-term stock performance, which is measured by CAR [11, 720]. Abnormal returns are computed by subtracting the value-weighted return of all firms in the same industry from the return of the corresponding issuing firm. *Recapitalization dummy* and *Investment dummy* are indicator variables that are equal to 1 if the placements are categorized as recapitalization or investment purpose, respectively. *Fraction placed* is the fraction of the offered shares relative to total shares outstanding after sale. *Controlling ownership* is the ownership of the controlling family before the placement. *Discount_2* is the private placement discount and is calculated as the $(P_1\text{-Po})/P_1$, where Po is the offering price and P_1 is the share price one day prior to the announcement. *Ln_cap* is the logarithm of the market value of shares outstanding, measured 10 days prior to the announcement. *Return on assets* is the net income divided by the total assets in the preceding year; *Debt ratio* is the book-debt ratio, which is measured as the total debt divided by the total assets at the end of the year preceding the announcement; *Market-to-book* is the market-to-book value, where the market value is measured 10 days prior to the announcement, and the book value is measured at the end of the year preceding the announcement; *Beta* is calculated from the market model in the 230-day period beginning 240 days prior to the announcement; and *Idiosyncratic risk* is calculated as the standard deviation of the residuals from the market model. *Announcement return* is measured by CAR[-1, +10]. *FSE* (firm-specific error) and *LRVB* (long-run value-to-book) are the components of the Ln_MB, which are reported in Table 5. The numbers in parentheses are White (1980) heteroskedasticity-adjusted t-statistics. Coefficients with *p*-values of 0.10 or less are highlighted in bold-faced type.

Table 10 Contingency Analysis: Intended Use of Proceeds *versus* Investor Type

This table presents the contingency analysis of the placements categorized by the intended use of proceeds and by the dominant investor type. The sample is comprised of 418 private placements made by firms on the Taiwan stock markets between January 2002 and December 2010. Panel A displays the cross tabulation of the intended use of proceeds (Recapitalization, Investment, and General Purpose) and dominant investor type (insider and non-insider) for 418 placements. Panel B reports the summary statistics of the placements classified by dominant investor type. For the definition of variables, please refer to Table 9. Panel C presents the mean and median of the long-run stock performance. We test the difference between two investor type placements using the t-test for the mean and the Wilcoxon sign rank test for the median. p-Values are for two-tailed tests and are reported in parentheses. Statistics with p-values of 0.10 or less are highlighted in bold-faced type.

Panel A: Cross tabulation of the intended use of capital and investor type for 418 placements

RELATIONS AMONG COMPONENTS OF KNOWLEDGE MANAGEMENT ORIENTATION AND MARKET ORIENTATION

Minh-Chuong, Truong
School of Industrial Management
University of Technology, Hochiminh City, Vietnam
tmchuong@hcmut.edu.vn

Abstract

Knowledge management orientation and market orientation are the two concepts forming a mechanism for market shaping and response making, hence, creating organizational performance. This mechanism has been empirically tested. However, in view of managerial practices, managers of firms need to know how this mechanism operates in practice. To answer this question, understanding the relations among components of knowledge management orientation and market orientation is demanded. Thus, the objective of this study is to recognize these relations and to propose managerial implications basing on these relations. The study reviewed background theories to establish a set of ten hypotheses on these relations, and tested them with data extracted from enterprises in Hochiminh City with quantitative approach. The results showed that the knowledge receptivity played a driving force role to increase knowledge absorption, sharing, organizational memory. Knowledge receptivity and organizational memory caused strong positive impacts on responsiveness of market orientation. Some managerial implications are proposed basing on these relations.

1. Introduction

Knowledge management and market orientation is the two concepts creating organizational performance.

Knowledge management with the aim of increasing the organizational knowledge for higher competitive advantage is paid more attention. Basing on the resource based view of the firm, the knowledge based theory of the firm has been established (Grant, 1996). According to this theory, the knowledge is at individual person working in the enterprise. And, the role of the manager is to integrate the individual knowledge into the organizational knowledge. The firm enhances the organizational knowledge via the absorption of new knowledge from the environment. To integrate the individual knowledge as well as new knowledge into the existing organizational knowledge, the firm should have some practices to perform such functions as knowledge absorption, sharing, storing. It should also build up knowledge receptivity behaviors in the staff to increase the knowledge absorption and sharing (Wang et al., 2009). From the organizational knowledge, responses to the environment will be select, implement to create enterprise performance. Thus, firms having knowledge management are believed to create higher performance than the ones without knowledge management.

Market orientation is, in view of behavioral perspective, organizational behavior in generating and sharing market intelligence, and making response to the market (Kohli & Jaworski, 1990). Market orientation helps the organization catching quickly changes in the market and customers 'need, then sharing internally the information of change to create response to meet the changes. As such, market orientation generates high organizational performance.

The knowledge management and market orientation are studied separately and forming two fields of research. However, some recent studies have argued that the two concepts are not separated, but, combined to explain more on organizational performance.

In view of sense making theory, the firm should have a mechanism to interpret the data from the environment to shape the environment understanding, from then, to make responses to the environment (Weick et al., 2005). This mechanism is composed of knowledge management orientation as a cognitive system and market orientation as response system. Knowledge management orientation is an inside-out capability and market orientation is an outside-in capability of the firm. This mechanism was tested empirically to generate the organizational performance (Wang et al., 2009). However, in view of managerial practices, components of knowledge management orientation and market orientation are managerial practices. Thus, the understanding of relations among these components is of importance because it helps to improve managerial practices for organizational performance improvement.

As such, the objective of this study is to build up and empirically test a model presenting the relations among these components. Theoretical background for the model building, research method and results are presented in the followings.

2. Theoretical background and hypotheses

Knowledge management orientation (KMO) is the firm's relative propensity to build on its achieved wisdom as well as the propensity to share, assimilate, and be receptive to new wisdom (Wang et al., 2009). It encourages new knowledge absorption from the market, internal knowledge development, knowledge sharing, storing, positive receptivity of the knowledge. The four components of KMO are: Knowledge absorption (KA), knowledge sharing (KS), organizational memory (OM) and knowledge receptivity (KR).

Knowledge absorption (KA) is the firm's capability to recognize the value of external knowledge and assimilate it, share it and apply it to the commercial end (Cohen & Levinthal, 1990). KA increases the organizational knowledge and creates innovations from the improved organizational knowledge (Nonaka, 1994; Nonaka & Toyama, 2003). The organization will look for external new knowledge which can be integrated with the existing organizational knowledge and can solve the problem faced by the organization to absorb (Nickerson & Zenger, 2004; Nonaka & Toyama, 2003). Therefore, KA is directed basing on the knowledge integration and problem solving.

Knowledge sharing (KS) is the firm's ability to transfer knowledge, skills, technology among departments or individuals in the firm (Kim & Lee, 2006; Tsai, 2002). KS distributes knowledge and creates knowledge flows within the firm and individuals. The sharing could be vertically from managers to staff and vice verse or horizontally among the staff. It could be conducted by the organizational regulations or social interactions.

Organizational memory (OM) is an organizational mechanism to capture, store and disseminate knowledge for decision making (Huber, 1991). Explicit knowledge is coded, classified, stored and delivered to the staff with the support of IT system. OM can store tacit knowledge in forms of beliefs, knowledge, frame of reference, models, values and norms, organizational myths, legends, stories, routines, procedures, scripts to name a few (Moorman & Miner, 1997).

Knowledge receptivity (KR) is the openness and the ease of absorption to the ideas inside and outside of the organization. This is the extent to which a firm encourages ideas and judge them on a fair effective basis (Wang et al., 2008).

Market orientation (MO) is the organizational capability to meet the changes of customers' needs and create competitive advantages for the organization. MO could be defined in behavioral approach or cultural approach. In cultural approach, MO is an organizational culture to generate effective behaviors for high values to the customers and organizational performance (Narver & Slater, 1988). In behavioral approach, MO is the organizational behaviors to monitor continuously market to recognize changes in consumers' needs and make response to meet the changes. MO in this approach is composed of three components, namely, intelligence generation (IG), dissemination (ID) and responsiveness to the market (Re) (Kohli & Jaworski, 1990). MO has impacts on innovation, then, on organizational performance (Jaworski & Kohli, 1993).

Relations among the components of KMO:

As the organization has knowledge absorption, the new knowledge will be absorbed and classified, coded to store in organizational memory (Nonaka & Toyama, 2003). The organization selects the knowledge to absorb to solve its business problems in accordance with the need of the staff in the problem solving team. Hence, the absorbed knowledge accelerates the knowledge sharing (Nickerson & Zenger, 2004). Therefore, the two first hypotheses H1 and H2 are:

The knowledge absorption has positive impact on the organizational memory (H1) and the knowledge sharing (H2)

When the staff of the organization have knowledge receptivity, the staff values new knowledge, looks for new knowledge to absorb and adopt the new knowledge for sharing and innovation making. Hence, knowledge receptivity increases the level and speed of knowledge absorption, sharing (Davenport & Prusak, 1998). In addition, when having knowledge receptivity, the staff requires knowledge to act on and they need the knowledge available for sharing. They are also willing to contribute their knowledge to the others and the organization. Then, knowledge receptivity causes the development of organizational memory to store all organizational common knowledge, all knowledge contributed by the staff and make the organizational knowledge available for sharing (Davenport & Prusak, 1998). Hence, the hypotheses are presented as followings:

The knowledge receptivity has positive impact on knowledge absorption (H3), knowledge sharing (H4), organizational memory (H5).

Relations among components of market orientation

The three components of market orientation have relations with each other (Kohli & Jaworski, 1990). When having market orientation, the market intelligence collected from the environment will be encouraged to share internally for common understandings. The more market intelligence collected the more intelligence sharing. When having market intelligence shared, the staff can make more effective response to the market. Hence, two hypotheses are proposed as followings:

Intelligence generation has positive impact on intelligence dissemination (H6) and intelligence dissemination has positive impact on market response (H7)

Relations between KMO and MO components

Market orientation exists on the continuum characterized by the degree to which organizations acquire, disseminate and respond to the market information (Sinkula, 1997). Thus, components of knowledge management orientation and market orientation have some relations.

Organizational memory is a baseline for the operation of the organization. It defines the products, the market, business processes, customer data… As a market oriented organization, the staff looks for market intelligence. They base on their internal knowledge stored in organizational memory to give directions for market intelligence collection (Weick 1995). They compare the new market intelligence with the existing one stored in the organizational memory to recognize changes in the market need. When facing problems, the staff of the organization look back to the organizational memory for the knowledge to solve the problem. If the existing knowledge is not enough to solve the problem, they will look for new knowledge from the environment (Nickerson & Zenger, 2004). Thus, organizational memory functions as a baseline for looking new knowledge from the market. Hence, a hypothesis is presented as following:

H8: Organizational memory has positive impact on intelligence generation

Responses the organization makes to the market depend upon the formulation of the market changes, alternative solutions proposed. In order to do so, the discussions among the related staff are conducted. The related staff should have opened minds and receptivity to receive new perspectives from the others to consider and to contribute their opinions to the final solution (Baker & Sinkula, 1999). As such, another hypothesis is as following:

The knowledge receptivity drives the responsiveness in market orientation (H9).

In the same way, as the organization has knowledge management orientation, the staff have good behaviors in knowledge sharing by contributing their knowledge into the organizational memory for others sharing or working with each other (Nonaka & Noboru, 1998). With the knowledge sharing oriented staff, market intelligence, after collected, will be disseminated internally for discussion and response making. Then, another hypothesis is formulated as

Knowledge sharing has positive impact on intelligence dissemination (H10).

From the above hypotheses, a model presenting the relations among components of knowledge management orientation and market orientation is shown in Figure 1.

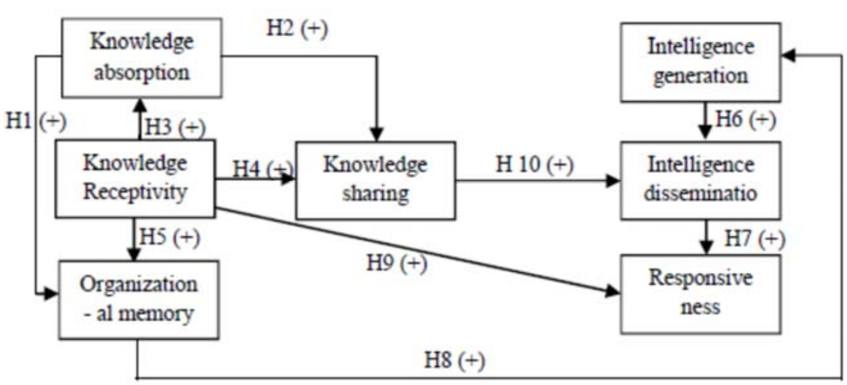

Figure 1: Model of relations among components of KMO and MO

3. Method

3.1. Research method:

Quantitative research method is used in this study. The research process is composed of two steps: First, testing the content, convergent validity, reliability of the measurement scales, then, the structure of the measurement scales with exploratory factor analysis (EFA) and, second, testing the measurement model, structural model with confirmatory factor analysis (CFA) in combination with structural equation modeling. The statistical softwares used to treat data were SPSS 20 and AMOS 5.0

3.2. Data collection

Data were collected from enterprises in Hochiminh City, Vietnam. The sampling procedure was convenient. The tool for data collection was questionnaire sent by post to the firms in accompany with a cover letter presenting the study contents and an empty envelop with stamp on it for the enterprises' reply. The questionnaires were required to be filled out by managers of the enterprises. Telephone calls to the mangers were also conducted to encourage them to fill the questionnaires and to provide the correct information. In all, 2012 questionnaires were sent out to the enterprises and there were 314 fulfilled-out questionnaires got back. Feedback ratio was 15.6%.

3.3. Measures

Components of Knowledge management orientation (KMO)
The measurement scales of KMO components were developed and tested by Wang &et at., (2009). However, due to the differences in the development of market economy between United Kingdom and Vietnam, and to assure of the validity of the concept measurement, the measurement scales of Wang & et al., (2009) were not used directly in this study. Just the list of indicators extracted by Wang &et. al., (2009) from previous studies was used as preliminary indicators of the scales and tested for their content and face validity (Crook et al., 2010; Netemeyer et al., 2003)

To test the face and contents validity of the measurement scales, interviews with seven managers were conducted. They were required to explain their understanding of the indicator descriptions and agreeing on the presence of the indicators in the measurement scales. Any of their adjustments were recorded for scale correction.

After face and content validity assessment, the measurement scale of knowledge absorption was composed of 3 indicators, knowledge sharing with 3 indicators, organizational memory with 4 indicators and knowledge receptivity with 5 indicators.

Components of Market orientation
Components of market orientation scale MARKOR of Kohli & Jaworski (1990) were used in this study. These scales were developed and tested in various contexts by many studies and given valid results. These scales were intelligence generation, intelligence dissemination and responsiveness. In the same way with KMO component scale testing, face and validity test for the components of MARKOR scale were conducted. The final measurement scales were intelligence generation with three indicators, intelligence dissemination with three indicators and responsiveness with four indicators.

All of the indicators in the measurement scales are scored with 5 point Likert scale from the lowest acceptability scored as level 1 to the highest acceptability scored as level 5.

After testing face and contents validity, all of the scales were pre-tested with a small sample of thirty managers in Hochiminh City. The data collected from this small sample were tested with EFA for measurement scale structures and Cronbach's Alpha for their reliabilities. The results of the pretest showed that the interviewees understood the indicator descriptions clearly, the measurement scales were relevant to the concepts, unidimensional. As such, the scales were ready for full scale sample collection.

4. Analysis and results

4.1. Sample descriptive statistics

Data were collected conveniently from list of enterprises in districts and industrial zones in Hochiminh City. There are 314 enterprises of which 42.0% was manufacturing, 21.0% was trading and 24.0% was service and 12.1% trading-service firms filling out the questionnaires. The employee number was varied from less than 10 persons occupying 17.5%, from 11 to 50 persons- 31%, from 51 to 100 persons –19.7%, from 101 to 200 persons – 18.8% and more than 200 persons – 12.8%. All of the enterprises started their operations more than 3 years before the date of data collection.

4.2. Measurement testing

Full scale data collected were treated with EFA for measurement scale structure. The scales' reliabilities were tested with Cronbach's Alpha. Some indicators were deleted from the original measurement scales due to their low factor loadings and/or cross loadings on other scales. Remaining indicators for measurement scales are presented in Appendix 1. After adjusting the measurement scales, they are re-analyzed with EFA and Alpha. Results showed that the scales were acceptable in structure, having unidimensionality, convergence validity (with factor loading of over 0.605), averaged variance extracted of over 59.31%, and reliability with Cronbach's Alpha of over 0.631. Details of the results are presented in Table 1.

These scales were ready for confirmatory factor analysis (CFA) with structural equation modeling. Results of CFA for each measurement scale are presented in Table 1. Most of standardized regression weights were over 0.70 except KA13 and KS 16 at 0.587. Variances extracted were over 0.57, composite reliabilities were higher than 0.68. These showed that each measurement scale was unidimensional, convergent, and assured of internal consistency (Hair et al., 2010). Details of CFA for each scale are presented in Table 1. As such, a measurement model composed of all measurement scales was also built and tested with CFA for their scale structures, convergence, discriminant analysis and their fitness to the data. Criteria for the fitness were χ^2/DF <3, CFI>0,9, TLI >0,9 and RMSEA<0,05 (Kline, 2010).

The results showed that the measurement model was well fitted with the data with $\chi2$ = 1031,711 DF=480, $\chi2$ /DF= 2,149, CFI=0,901, TLI=0,898, RMSEA=0,061. The structure of each measurement scale was unidimensional and convergence (with factor loading of over 0.648). The 95% reliability range of correlation coefficients between any pair of the scales in the measurement model did not cover unit. This was a proof of the discrimination among the measurement scales (Gerbing & Anderson, 1988). The results are shown in Table 2. Thus, the scales were acceptable for the structural model testing.

Table 1: Results of each measurement scale test with exploratory and confirmatory factor analysis

	EFA analysis					CFA Analysis		
	KMO of observed items	Factor loadings	Averaged Variance extracted	Item-to-total coefficients	Cronbach 's Alpha	Standardized regression weight	Variance extracted	Composite reliability
Knowledge absorption (KMO=.627)			62.70%		0.631		57.20%	0.680
KA13	.692	.605		.4738		.587		
KA14	.519	.844		.5233		.814		
KA15	.518	.868		.5753		.842		
Knowledge sharing (KMO=.672)			59.31%		0.721		57.16%	0.696
KS16	.740	.618		.5271		.588		
KS17	.662	.852		.6411		.825		
KS18	.671	.819		.5902		.802		
Organizational memory (KMO=.725)			81.54%		.887		78.92%	.907
KM19	.727	.902		.7780		.898		
KM20	.672	.930		.8314		.915		
KM21	.796	.876		.7321		.852		
Knowledge receptivity (KMO=.713)			71.95%		.803		66.71%	.799
KR23	.705	.853		.6587		.832		
KR24	.710	.850		.6551		.816		
KR25	.726	.841		.6402		.802		
Intelligence generation (KMO=.705)			74.29%		.820		72.37%	.803
IG28	.675	.882		.675		.878		
IG29	.675	.883		.675		.871		
IG30	.792	.820		.792		.801		
Intelligence dissemination (KMO=.698)			74.34%		.826		71.27%	.835
IS31	.670	.877		.7076		.858		
IS32	.801	.808		.6039		.802		
IS33	.645	.899		.7440		.871		
Responsiveness (KMO=0.769)			63.06%		.798		60.83%	.811
IR34	.627	.794		.5761		.782		
IR35	.627	.836		.6444		.815		
IR36	.692	.750		.5633		.741		

From then, a structural model was built and tested with CFA and structural equation modeling. The structural model was well fitted with the data with $\chi2$ = 366.733 DF=17. $\chi2$/DF= 2.157. CFI=.934. TLI=.918. RMSEA=.061. As such, results computed from the structural model were accepted.

Table 2: Discriminant analysis of the measurement scale

			Correlation estimate	Standard errors	95% reliability range		C.R.	P
					Upper level	Lower level		
KA	<-->	IG	.125	.036	.197	.053	3.456	***

Re	<-->	ID	.229	.042	.313	.145	5.460	***

Hypothesis testing

The regression coefficients computed from the structural model analysis are presented in Table 3 and Figure 2. All of the regression coefficients were significant statistically with C.R>1.96. P<0.05 and positive (Byrne. 2010).

Table 3: Regression coefficient between components of KMO and MO

Components			Regression coefficients		Standard error	C.R.	P
			Unstandardized	Standardized			
KA	→	OM	.261	.217	.076	3.426	***
KA	→	KS	.226	.245	.072	3.132	.002
KR	→	KA	.377	.429	.069	5.432	***
KR	→	KS	.474	.587	.068	6.931	***
KR	→	OM	.708	.669	.077	9.146	***
KR	→	Re	.246	.240	.096	2.563	.002
IG	→	ID	.279	.537	.057	4.864	***
ID	→	Re	1.237	.638	.056	4.827	***
OM	→	IG	.366	.382	.083	4.410	***
KS	→	ID	.102	.157	.041	2.410	***

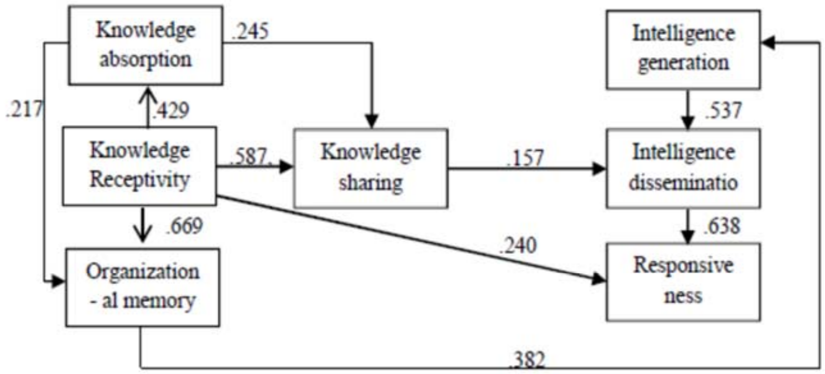

Figure 2: Standardized regression coefficients

These regression coefficients pointed out significant positive relations among these components. Therefore, the ten hypotheses stated above were supported by the data.

5. Discussions

Relations among components of knowledge management orientation (KMO)

Results showed that the four components of KMO have interrelations with each other. Knowledge receptivity played a central role. It had a strongest relation with organizational memory (β=0.669), then, with knowledge sharing (β=0.587), and knowledge absorption (β=0.429). This means that the opened mind and positive behavior to new knowledge are driving force to increase the new knowledge absorption to the organization, sharing existing and new knowledge within the organizational staff. The knowledge receptivity increases the knowledge flow within the organization, hence, increases the knowledge to be stored in the organizational memory.

Knowledge absorption has impacts on organizational memory (β=0.217) and knowledge sharing (β=0.245). Knowledge receptivity impacts organizational memory via direct path and indirect path through knowledge absorption. The path analysis was applied to estimate this integrated impact giving the result of 0.762. In the same way, knowledge receptivity causes impacts on knowledge sharing directly and indirectly via knowledge absorption. This integrated impact is 0.692. This means that the knowledge receptivity explained 76.2% of variance of the organizational memory and 69.2% of variance of knowledge sharing.

Relations among components of market orientation

Results show that intelligence generation has impact on intelligence dissemination (β=0.537) and intelligence dissemination increases responsiveness (β=0.638). These results were in confirmation with some other research (Kohli et al.. 1993)

Relations among components of knowledge management orientation and market orientation

It is very interesting in this study that relations among components of knowledge management orientation and market orientation are recognized.

Knowledge receptivity has positive impact on responsiveness (β=0.240). When having knowledge receptivity, the staff always value, look for knowledge and direct their behavior in sharing knowledge, integrating existing knowledge with new knowledge (Nonaka. 1994; Wang et al.. 2008). Hence, the knowledge is fully distributed within the organization. Innovative opinions are also encouraged to present and judged equally. All brings innovative solutions to the organization, and, a higher probability of having good responses to the market.

The organizational memory accelerates the intelligence generation (β=0.382). The intelligence generation is a directed activity. It bases on the vision, belief of the organization in serving customers and using organizational routines, procedures to look for changes in market, customer demands. The data, information stored in the organizational memory could be analyzed for earlier recognition of customer demand changes and the collection of market data will be conducted for confirmation of this recognition. This is the way the organization shapes the market before making response to the market.

The knowledge sharing drives the intelligence sharing knowledge (β=0.157). The behavior of knowledge sharing will be applied to all kinds of knowledge including market intelligence.

To understand more of the impact of the four components of knowledge management orientation on responsiveness – the action made to the market - path analysis was applied.

The impact of knowledge receptivity to responsiveness is integrated from the direct impact KR→Re and indirect impact KR→ID→Re. Since intelligence dissemination is influenced by knowledge receptivity through two indirect impacts: KR→KS→ID and KR→OM→IG→ID, the total impact of knowledge receptivity to intelligence dissemination was computed and equals 0.246. The indirect impact of knowledge receptivity to responsiveness was 0.157. Hence, the total impact of knowledge receptivity to responsiveness was 0.397. These results show a strong impact of knowledge receptivity to intelligence dissemination and responsiveness.

In the same way, organizational memory influences on responsiveness via the path OM→IG→ID→Re. The path analysis results in this impact strength of 0.131.

The influence of knowledge absorption to responsiveness is integrated from the impacts of KA→OM→Re and KA→KS→ID→Re. The total impact is 0.053. This result shows that the absorption of new knowledge has very limited impact on the responsiveness. Similarly, the impact of knowledge sharing to responsiveness is through KS→ID→Re and equals 0.100.

In all, the knowledge receptivity explained 24.6% variance of intelligence dissemination and 39.7% variance of responsiveness. The organizational memory explained 13.1% , the knowledge sharing explained 10.0% and the knowledge absorption explained only 5.3% variance of responsiveness.

The results show that responses made to the market depend much upon knowledge receptivity, then, on organizational memory, finally, on knowledge sharing. The absorption of new knowledge from the environment has very limited impact on the responses.

These results could be explained by the fact that most Vietnamese enterprises are of small and medium size (SME) and established by entrepreneurs who have internal locus of control, are flexible to change and accept risks of changes for the enterprise development (Nguyen et al.. 2008). They have knowledge receptivity and set up themselve as a symbol of knowledge receptivity for the staff to follow. Hence, they share their knowledge to the staff and set up routines, procedures – a type of organizational memory - to perform the task and encourage the staff to follow. They encourage the staff to present new opinions to do something and put the opinions into the organizational memory for sharing. As such, knowledge receptivity is the main driving force for the other components of knowledge management orientation, particularly, organizational memory and knowledge sharing. The investment of IT system in organizations will be ineffective if there is no staff's knowledge receptivity.

Because of having internal locus of control the entrepreneurs often try to sustain and develop their enterprises with the existing knowledge stored in organizational memory. They do not pay much attention to the new knowledge in the environment to absorb. Hence, organizational memory has more impact on responsiveness than knowledge absorption and knowledge sharing. Due to low level of new knowledge absorption, Vietnamese enterprises have low level of technologies, less innovation as compared with other enterprises in the region (Swierczek & Ha. 2003; World-Bank. 2010)

Managerial implications of the results

The results suggest following managerial implications for the management of the enterprises:

Knowledge receptivity plays a driving force role for knowledge management orientation and responsiveness. The knowledge receptivity should be built in the enterprises to develop knowledge sharing, organizational memory and making response to the market. The knowledge sharing behavior has also impact on responses to the market. Hence. the positive behaviors to receive and share new knowledge are encouraged. The culture of knowledge receptivity and sharing should be set up.

The organizational knowledge should be recorded in organizational memory. The organizational vision, mission should be established and encapsulated in organizational routines, procedures and processes. Knowledge should be classified, coded and recorded in organizational memory. The staff should be encouraged to access the organizational memory for intelligence generation and making responses to the market. In turn, the intelligence collected should also be put into the organizational memory for its development. These will increase the effectiveness of response to the market.

The knowledge absorption, although important in principle, is not focused by the enterprises. It causes shortage of new knowledge in general market, technologies, legal regulations…These shortages make the enterprises have few innovations, low competitiveness. The knowledge absorption should be improved to overcome these weaknesses.

. Conclusion

Knowledge management orientation is a high level concept composed of knowledge absorption, sharing, receptivity and organizational memory. Market orientation is also a high level concept structured from intelligence generation, dissemination and responsiveness. The integration of the two concepts creates a mechanism for market recognition, response making and organizational performance. However, the relations between the components of the two concepts are not recognized. Hence, managerial practices basing on integration of these concepts for organizational performance improvement are not built up. Therefore, this study aimed at recognizing these relations and proposing managerial implications from these relations for organizational performance. The study built up and tested a model of these relations basing on data from enterprises in Hochiminh City with the quantitative approach. The results showed that the components of the two concepts had close relations with each other. Knowledge receptivity was the driving force to increase knowledge absorption, sharing and organizational memory.

Intelligence generation had positive impact on intelligence dissemination, and, in turn, the intelligence dissemination had positive influence on responsiveness. The four components of knowledge management orientation had positive impacts on the components of market orientation, particularly, the responsiveness. Knowledge receptivity explained 39.7%, organizational memory explained 13.1% and knowledge sharing explained 10% variance of responsiveness. Some managerial implications of the results have been proposed.

Since the sampling frame of this study was enterprieses in Hochiminh City, the results are not surely applicable to other provinces in Vietnam where there are differences in economic development and managerial practices. The convenient sampling also impacts on the results. Hence, studies with sampling frame in other provinces and randomly sampling should be replicated to reconfirm these results.

Appendix 1

Measurement scales in this study

Measurement scale	Indicator name	Indicator description
Knowledge management orientation		
Knowledge absorption	KA13	Enterprise absorbs outside knowledge to perform its activities
	KA14	Enterprise uses IT to look for new information about market and environmental changes
	KA15	The sharing of new knowledge generates new opinions to improve the business
Knowledge sharing	KS16	Enterprise has an IT system and a place for the staff to meet and share knowledge as well as learn with each other.
	KS17	Knowledge is fully shared vertically and horizontally
	KS18	All members share knowledge with other members having the same interest
Organizational memory	KM19	Enterprise has a system to classify and code opinions. knowledge for storage and re-use.
	KM20	Enterprise analyzes systematically projects. works performed to record experiences and best practices.
	KM21	Enterprise maintains very often information system and continuously update information stored in it
Knowledge receptivity	KR23	Organizational culture supports discussions and encourages new opinions.
	KR24	All new opinions are encouraged to present and judged fairly
	KR25	Enterprise values and judges all opinions basing on the opinion contents not on the persons suggesting the opinions.
Market orientation		
Intelligence generation	IG28	Enterprise meets customers at least once a year to look for new products or services that customers need in the future
	IG29	Enterprise recognizes quickly changes in customer need.
	IG30	Enterprise invites customers at least once a year to evaluate its product quality
Intelligence dissemination	IS31	The marketing staff of the enterprise spend time to discuss future need of customers with staff of the other functions.
	IS32	When an important thing happens to a key customer of a business territories. the whole trading unit will be informed of it in very short time.
	IS33	Data on customer satisfaction are shared very often to all level of the trading unit.
Responsiveness	IR34	Enterprise makes quick response to changes in the competitors' prices
	IR35	Enterprise always responses to changes in customers needs.
	IR36	Enterprise reviews periodically its efforts in product development to make sure that the product meeting customers' demands.

Evaluating Senior and Junior Debts by Considering Default Urgency

Jin-Ray Lu
National Dong Hwa University, Taiwan
jinray@mail.ndhu.edu.tw

This article proposes a new perspective, the default urgency (DU), to evaluating both senior debts and junior debts. The default urgency describes firm's and claimant's degree of suffering default risk. We value subordinated debts and examine default cost, default probability, and default spread under a consideration of debt' default urgency. We find that senior debts' value is influenced by deep and shallow degrees of default urgency. However, junior debts' premium decreases and default spreads increase as a shallow degree of default urgency appears. Moreover, the default urgency changes full-payable probability, default probability, and bankruptcy probability.

***Key words**: default urgency, subordinated debt, default spread*

JEL classifications: G13, G23, G33.

1. Introduction

A corporate debt, issued by a firm for the purpose of raising funds, provides cash flows for the debt holders. The firm is obliged to redeem promised repayments at face value, along with interests, to the holders of corporate debts, with debt claimants having priority over other equity. A senior debt claimant takes priority over a subordinated debt claimant in the case of a conflict of interest among between claimants. As a firm's value remains low, the senior debt claimant first receives the promised repayment from the issuer, and the junior debt claimant then receives the residuals. If the firm value is low enough, the firm may go bankrupt and end up paying nothing to either debt holders. In other words, given different firm values and priority orders, the both the holders and issuers of corporate debts face different levels of default urgency with respect to the promised repayments.

In this study, we analyze corporate securities under a consideration of the default urgency. If the firm's value of assets is high enough, the firm has enough funds to pay the promised face values to the debt holders on maturity, in which case the claimants and firm can be said to be free from default urgency. Under other conditions, the firm's value of assets makes it possible for the firm to pay the senior debt claimants, but is insufficient to allow it to pay the junior debt claimants. This means there is shallow default urgency for the security claimants. Furthermore, if the firm's value gradually decreases, the firm more urgently pays debt claimants, even then the firm pays nothing to the junior debt claimants. In this type of situation, the firm has deep default urgency. Finally, under conditions where the firm's asset value approaches a very low point, the firm may go bankrupt and may end up not paying anything to either junior or senior debt holders. Therefore, the issue of *how much* the holders of corporate securities receive on maturity depends on a degree of default urgency.

We analyze four aspects from the perspective of default urgency. First, we solve subordinated debts' values. Second, we analyze firm's default cost. third, we also discuss default spreads. Finally, we analyze default probabilities in various degrees of default urgency. The default urgency describes a degree of how firm and claimants suffer from debt's default risk.

Under various degree of default urgency, firm's default costs differ. As a firm stays in a condition of shallow degree of default urgency, the default cost is lower than it is for a firm that stays in a condition of deep degree of default urgency. That is, if the junior debts are defaulted upon and the senior debts are paid by the firm, the default cost is lower. Otherwise, if the senior debts cannot be paid on maturity, the default costs tend to be higher because the firm has larger default urgency. The default costs affect the possibilities of debt holders receiving the promised repayments of corporate debts, and can further change the valuations of senior debts and junior debts.

Another major stream of theoretical analysis in the area of subordinated debts involves analyzing a default risk represented by a default spread (for example, Anderson and Sundaresan 1996, Nivorozhkin 2005a, Zhang et al. 2014). Given various conditions of default urgency for a firm, the degrees of default risk are markedly different for senior and junior debt claimants. For example, the holders of senior debts may have a low default risk as a firm stays in a condition of shallow default urgency, whereas they may have a high default risk if the firm stays in a condition of the deep default urgency. Specifically, we compare the default spreads between senior and junior debts under differential default urgencies to examine the impacts of default urgency on the default spreads of corporate debts. We expect that the spread is greater for a deep degree of default urgency.

We also analyze which conditions of default urgency are more likely to appear. That is, we discuss default probabilities in a shallow degree, a deep degree, a full-payable, or a bankruptcy under default urgencies. For example, in a certain interval, an increase in a firm's value may increase the probability of shallow default, and may decrease the probability of bankruptcy. Specifically, these probabilities may change the valuations of corporate debts, so it is important to analyze both the default probability and the bankruptcy probability in the valuations of corporate debts. In addition, the cost of default affects the intervals of various conditions under a given level of default urgency. For example, a high default cost may increase the bankruptcy stress and decrease the shallow default urgency, in which case the default cost changes the possibilities of default events or bankruptcy events occurring. The study thus solves and analyzes the full-payable probability, shallow default probability, deep default probability, and bankruptcy probability, in terms of a firm's value and the default costs.

A lot of financial literature has analyzed corporate securities, specifically focusing on subordinated debts, in terms of their valuations and designs (see, for example, Black and Cox 1976; Scott 1977; Stulz and Johnson 1985; Diamond 1993; Barclay and Smith 1995; Welch 1997; Chen, Jen, and Choi 1999; Belkhir 2013; and others). Black and Cox (1976) first analyzed subordinated debts using an option pricing theory, and derived a closed-form result for corporate bonds without a consideration of bankruptcy costs and default urgencies. Stulz and Johnson (1985) valued and analyzed the priority of corporate debts and found that the use of secured debt increased the firm values. Considering an asymmetry and financial distress, Welch (1997) explained the debt's claim priority. Diamond (1993) discussed a relation between a seniority and maturity of debt contracts, and found that a short-term debt was senior to a long-term debt. Chen *et al*. (1999) theoretically analyzed a determination of seniority structure of corporate debts and empirically examined a relation between the seniority structure of corporate debts and their characteristics. Numerous studies also argued that a structure of senior debts and junior debts affected its market values.

More recent studies of subordinated debt involve a wide integrated analysis taking account other financial issues (see, Nivorozhkin 2005a,b; Hackbarth and Mauer 2012; Belkhir 2013; Nguyen 2013; Miller et al. 2015; and others). Jointly analyzing the debt priority and optimal capital structures, Hackbarth and Mauer (2012) studied an interaction between financing and investment decisions. Belkhir (2013) examined a market discipline of bank risks to answer a question of whether banks implemented risk management policies that taking account a risk preference of subordinated debt claimants. A relevant study by Nivorozhkin (2005a,b) took account of a bankruptcy cost in the valuations of subordinated debts, and framed in the option pricing theory. They analyzed market disciplines and informational content of subordinated debts incorporating bankruptcy costs, respectively. Miller et al. (2015) employ a spread of subordinated debt as predictors of bank distress, and suggest that the spread is useful tool for warning systems during the financial crisis.

Our article differs from previous studies and contributes to financial literature in followings. Under a variety of default urgency, the bankruptcy or default probabilities and default costs are differential for the holders of corporate debts. Previous studies have not yet examined this practical fact. Specifically, the default costs under a condition of shallow default urgency should differ from those under a condition of deep default urgency. This study first explores the bankruptcy probability, deep and shallow default probabilities, and full-payment probability under different levels of default urgency.

In short, this study attempts to analyze the valuations of senior and junior debts, differential default costs, default spreads, and default and bankruptcy probabilities under different levels of default urgency. First, this study solves a closed-form result for the senior debts and junior debts, and analyzes debt values with respect to firm value and default costs. Second, since the default risks are different in these various conditions of default urgency, this study derives and discusses the default spreads of senior debts and junior debts, to compare these default spreads in terms of firm value and default costs. Third, probabilities of full-payment, shallow default, deep default, and bankruptcy are solved and analyzed under default urgency. Specifically, how the shallow and deep default costs change these probabilities is discussed.

The study is organized in four main sections. The section entitled "Valuations of Corporate Securities under default urgency" describes the theoretical models of the problem and solves closed-form results of security values and default spreads. We also derive the default probabilities and bankruptcy probabilities in this section. The second section, "Numerical Calibration", provides numerical examples for characterizing the debt values, default spreads, and default probabilities under a given level of default urgency. We also elaborate on the economic implications for these results. The third section, "Conclusion" summarizes main findings. Finally, the "Appendix" outlines how the valuations of corporate securities are derived.

2. Valuations of Corporate Securities under Default Urgency

We develop a continuous-time model to solve closed-form results for corporate equity, junior debt, and senior debt, considered under different levels of default urgency. This study also derives the default spreads of junior debt and senior debt, as well as the default probabilities associated with different levels of default urgency, in order to examine *how* the different default costs affect the valuations of corporate debts.

Framing the problem in a continuous-time model, this study makes the same preliminary assumptions as the previous works of Black and Scholes (1973), Merton (1974), Black and Cox (1976), Nivorozhkin (2005a,b). Dynamic process of the underlying firm's value (V) of the corporate securities is assumed to be generated by a geometric Brownian motion (GBM) process framed in a complete probability space (Ω,F,P) with filtration $\{F_t\}$, as follows:

$$dV(t) = \alpha S(t)dt + \sigma SdW \tag{1}$$

Where α and σ denote the instantaneous expected growth and volatility rates of the underlying firm value, respectively, while a stochastic variable W is assumed to follow a Wiener process with a mean value of zero and a standard deviation of one. In addition, a risk-free bond provides interest with a rate (r), in which the borrowing and lending rates are assumed to be equal and constant. Thus, the dynamic process of the risk-free bond price (B) is governed as follows:

$$dB(t) = rB(t)dt \tag{2}$$

The firm's values are shared by one equity-holder and two debt-holders at maturity date ($t = T$), where two debt claims on the firm's value are differentiated by their priorities, but share the same maturity date. The holder of senior debts (S) has first priority and the holder of junior debts (J) has a subordinate priority, while the holder of equity (E) is last in terms of priority.

If a firm does not make the promised repayments of the debts, the direct default costs can cause dead-losses for the firm's value. Specifically, if the firm defaults on making the final repayments (L) to the holders of junior debt but the firm makes the repayments (K) to the holders of senior debt, a shallow default condition arises, and a smaller default cost (c) reduces the firm's value. Furthermore, if the firm defaults on making the promised repayments to the holders of both kinds of debt, a deep default urgency condition arises, and the firm bears the burden of a larger default cost (b). That is, the default costs are different for shallow default conditions and deep default conditions within a framework of different degrees of default urgency. The default cost tends to become larger as the senior debt goes into default, compared to the cost when the junior debt goes into default. However, the default costs are still generally lower than the repayment values of the debts (i.e., $c < b < K, L$).

The amounts of the payoffs the claimants can expect to receive on maturity relating to both the firm's value and the default costs. When a firm's value is greater than the sum of the total debts' face values (K+L), both junior and senior debts can be paid off, and the equity-holder obtains the residual value. If the firm's value does not exceed the sum of the total debts' face values, but exceeds the sum (K+c) of the face value of the senior debt and the shallow default cost, the senior debt claimant can expect to obtain the full amount of the promised repayment and the junior debt claimant expects to obtain the residual value (V-K-c) after the firm pays the repayments (K) to the senior debt claimant and absorbs the dead loss of the default costs (c). In this case, the equity holder gets nothing. Furthermore, if the firm's value does not exceed the sum (K+c) of the face value of the senior debt and the shallow default cost, but exceeds the sum (b+c) of the shallow and the deep default costs, the junior debt claimant expects to receive nothing, while the senior debt claimant obtains the firm's residual value ($V - b - c$). In addition, as the firm's value is lower than the sum (b+c) of the shallow and the deep default costs, the firm's value is disposed to outside claimants (such as accountants, lawyers, staff, or government), and the holders of corporate securities receive nothing.

This study differentiates between four possible financial conditions for the firm, depending on the various degrees of default urgency. In stress condition *I*, on maturity, both senior and junior debts can be fully paid under a condition of sufficient firm value (i.e., K+L< V). In stress condition *II*, the firm cannot make full repayment to the holder of the junior debt, but can make full repayment to the holder of the senior debt, owing to the fact that the firm's value does not exceed the sum of the total debts' face values, but exceeds the sum of the face value of the senior debt and the shallow default cost (i.e., $K + c < V < K + L$). We can say that this represents a condition of shallow default urgency for the firm. In stress condition *III*, the firm stays in a deep default urgency condition, meaning that the junior debt claimant cannot receive any payoff, and the senior debt claimant obtains only a portion of the final promised repayment (i.e., $b + c < V < K + c$). In stress condition *IV*, the firm goes into bankruptcy. The default costs are different under the different degrees of default urgency, as a result of practical facts. We summarize the aforementioned descriptions of the four possible conditions in Table 1.

The values (E, S, and J) of the corporate securities upon maturity depend directly on the level of the firm's value, the promised repayments, and the amounts of the default costs. First, this study determines the equity values under the option pricing theory. The equity holders can receive residual values only if the firm's value is sufficient to make the repayments to the debt claimants on maturity, in which case the firm's financial situation falls under condition *I*. Otherwise, the equity-holders receive nothing under conditions *II*, *III*, and *IV*. The value of the equity on maturity is expressed as follows:

$$E(T) = \max(V(T) - (K + L), 0) \tag{3}$$

It is obvious that the equity value has same formula of a European plain vanilla call option on the firm value, with a strike price of $K+L$. Applying option pricing theory, the closed-form solution for the equity at time t is naturally derived as follows:

$$E(t) = V(t)N(d_1) - (K + L)e^{-r(T-t)}N\left(d_1 - \sigma\sqrt{T-t}\right) \tag{4}$$

where $N(d_i)$ is the cumulative density function of a standard normal distribution with a mean value of zero and a standard deviation of one, and where the cumulative range of probability is from negative infinity to d_i. Here d_1 is calculated as follows:

$$d_1 = \frac{ln\left(\frac{V(t)}{K+L}\right) + \left(r + \frac{1}{2}\sigma^2\right)(T-t)}{\sigma\sqrt{T-t}}$$

Thus, the valuation of corporate equity is the same as that of a European call option on the firm's value, with a strike price equaling the sum of the junior and senior debts' face values. The firm value, promised repayments, time to maturity and related factors can all influence the value of equity securities.

Next, this study values the junior debts, taking into account the levels of default urgency. At maturity date, if the firm's value is larger than the sum (*K*+*L*) of the outstanding debt repayments, which means all of the claimants stay in the full-payable condition, the junior debt claimant obtains full amount of the promised repayments. When the firm value is lower than the sum of the promised repayments (*K*+*L*) but exceeds the value of (*K*+*c*), the holder of junior debt obtains residual values after the firm pays the senior debt claimant and default costs, in which case the firm can be said to be in a condition of shallow default urgency. When the firm's value is lower than the value of (*K*+*c*), the holder of a junior debt will receive nothing. We can briefly summarize these results in mathematical form, as follows:

$$J(T) = \begin{cases} L, & K+L < V(T) \\ V(T) - K - c, & K+c < V(T) < K+L \\ 0, & others \end{cases} \tag{5}$$

Using the same techniques as we use for the valuation of corporate equity, this study solves a closed-form result for the junior debt, which we consider under default urgency, as follows.

$$J(t) = Le^{-r(T-t)}N\left(d_1 - \sigma\sqrt{T-t}\right) + V(t)[N(d_2) - N(d_1)]$$

$$-(K+c)e^{-r(T-t)}\left[N\left(d_2 - \sigma\sqrt{T-t}\right) - N\left(d_1 - \sigma\sqrt{T-t}\right)\right] \tag{6}$$

where

$$d_2 = \frac{ln\left(\frac{V(t)}{K+c}\right) + \left(r + \frac{1}{2}\sigma^2\right)(T-t)}{\sigma\sqrt{T-t}}$$

The valuation of junior debts under default urgency becomes more complicated than that of junior debts without default costs (See, Black and Cox 1976, and Nivorozhkin 2005a,b). In equation (6) the junior debts can be regarded in the same way as a portfolio of three call options on the firm's value with various strike prices. Specifically, the shallow default cost plays a role in the pricing of junior debts, in the case where a condition of shallow default urgency appears.

The possible payoff of the senior debts on maturity is determined as follows. The holders of senior debts can receive the full amount of promised repayments when the firm's value is larger than (K+c), in which case the firm remains under the conditions of fully-payable and shallow default urgency. However, the senior debt claimants can receive part of the promised repayments when the firm's value is between (K+c) and (V-b-c) on maturity, in which case the firm stays in a condition of deep default urgency. Thus, the value of senior debts can be written as follows:

$$S(T) = \begin{cases} K, & K + c < V(T) \\ V(T) - b - c, & b + c < V(T) < K + c \\ 0, & others \end{cases} \tag{7}$$

Using a procedure similar to the pricing of junior debt and equity, the closed-form result for senior debt is as follow:

$$S(t) = Ke^{-r(T-t)}N\left(d_2 - \sigma\sqrt{T-t}\right) + V(t)\left[N(d_3) - N(d_2)\right]$$

$$-(b+c)e^{-r(T-t)}\left[N\left(d_3 - \sigma\sqrt{T-t}\right) - N\left(d_2 - \sigma\sqrt{T-t}\right)\right] \tag{8}$$

where

$$d_3 = \frac{ln\left(\dfrac{V(t)}{b+c}\right) + \left(r + \dfrac{1}{2}\sigma^2\right)(T-t)}{\sigma\sqrt{T-t}}$$

This study derives three formulas of corporate securities under a consideration of different degrees of default urgency. Examining the values (4), (6), and (8), of equity and debts, we find that several parameters affect the valuations of corporate securities. The firm value (V), promised repayments (L and K), risk-free rate (r), time to maturity (T-t), return volatility of firm value (σ), and default costs (b and c) under default urgency can directly change the valuations of corporate securities. Specifically, the shallow default cost (c) can affect the premiums associated with both junior debts and senior debts, while the deep default cost (b) only affects senior debts, because how the junior debt claimants receive final repayments is independent of the level of deep default cost.

To examine the risk premiums of corporate debts under varying levels of default urgency, this study calculates the default spread, that is, the difference in yields between the corporate debts and a risk free bond. Thus, the default spreads of junior debt and senior debt at time t can be expressed as follows:

$$r^J(t)-r(t)=\left(\frac{-1}{T-t}\right)(\ln(N\left(d_1-\sigma\sqrt{T-t}\right)+\frac{V(t)}{L}e^{r(T-t)}[N(d_2)-N(d_1)]$$

$$-\frac{(K+c)}{L}\left[N\left(d_2-\sigma\sqrt{T-t}\right)-N\left(d_1-\sigma\sqrt{T-t}\right)\right]) \tag{9}$$

and

$$r^S(t)-r(t)=\left(\frac{-1}{T-t}\right)(\ln(N\left(d_2-\sigma\sqrt{T-t}\right)+\frac{V(t)}{K}e^{r(T-t)}\left[N(d_3)-N(d_2)\right]$$

$$-\frac{(b+c)}{K}\left[N\left(d_3-\sigma\sqrt{T-t}\right)-N\left(d_2-\sigma\sqrt{T-t}\right)\right]) \tag{10}$$

A high value of the default spread means that holding the asset is more risky, due to its default risk. In equations (9) and (10), the default spreads are influenced by firm value (V), default costs (b and c), and promised repayments (K and L). Because of the complexity of default spread expressions, this study further implements some numerical analyses to examine *how* the aforementioned factors change the default spreads. Specifically, the default spreads of corporate debts are expected to be different for varying levels of default urgency.

Given a level of default urgency, this study further derives the various probabilities for a firm depending on the firm's value with respect to the promised repayments and default costs. Under stress condition *I*, the firm's value is sufficient to pay the full values of all debts, and the debt claimants can be said to be free of default risk. Thus, we can derive a full-payable probability for the debt holders. Under stress conditions *II* and *III*, both shallow default probability and deep default probability are derived. Under condition *IV*, a bankruptcy probability is derived, because the firm does not make any repayment whatsoever to the debt holders. Therefore, the fully-payable probability (P_I), the shallow default probability (P_{II}), the deep default probability (P_{III}), and the bankruptcy probability (P_{IV}) are derived as follows:

$$P_I = \text{Prob}(K + L < V(T)) = N(d_1 - \sigma\sqrt{T-t}) \tag{11}$$

$$P_{II} = \text{Prob}(K + c < V(T) < K + L) = N(d_2 - \sigma\sqrt{T-t}) - N(d_1 - \sigma\sqrt{T-t}) \tag{12}$$

$$P_{III} = \text{Prob}(b + c < V(T) < K + c) = N(d_3 - \sigma\sqrt{T-t}) - N(d_2 - \sigma\sqrt{T-t}) \tag{13}$$

$$P_{IV} = \text{Prob}(V(T) < b + c) = 1 - N(d_3 - \sigma\sqrt{T-t}) \tag{14}$$

The above four probabilities, measuring the likelihood of default under varying levels of default urgency, vary with the firm's value, the default costs, and related factors. This study further discusses the sensitivities of these variables through several numerical examples.

3. Numerical Calibration

To analyze the value characteristics of corporate securities, the default spreads of junior debts and senior debts, and the default probabilities under varying levels of default urgency this investigation conducts a numerical analysis. This study gives a basic setting for the determinants, as follows: the initial firm value ($V(t)$) of \$70 million; the return volatility (σ) of firm values of 20%; the promised repayment amounts (K and L) of senior debt of \$30 million and of junior debt of \$40 million, respectively; the risk free rate (r) of 5%; the shallow default cost (c) of \$10 million; the deep default cost (b) of \$20 million; and the time to maturity (T-t) of 1 year. In this numerical example, the firm has a total promised repayment of $70 million on maturity.

3.1 Value Characteristics of Corporate Securities

The values of corporate securities tend to be higher if the firm value increases. This study displays the values of equity, junior debt, and senior debt, in terms of the firm value and time to maturity, in Panels A, B, and C of Table 2, respectively. We find that the equity value is positively related to the firm's value. The corporate equity can be viewed as a European call option on the firm's value, as per previous discussions by Black and Scholes (1973), Merton (1974), Black and Cox (1976), and others. In Panels B and C, the values of junior debts and senior debts are positive functions of the firm's value. That is, the debt holders tend to be more protected as the firm's value gradually increases. Specifically, as the firm's value approaches a high enough level, the debt values approach the amount of the promised repayments, i.e., the promised repayments of the senior debt and junior debt are $30 million and $40 million, on maturity.

Regarding the time to maturity, due to a time value being embedded in the call options, a long-life equity security is more valuable than a short-life equity security, as shown in Panel A of Table 2. However, the relationship between debt value and time to maturity is ambiguous for junior debts, as shown in Panel B. As the firm value reaches a high enough level (i.e., the junior debt is in-the-money or the firm stays in a condition of a very low default urgency), a short-life junior debt tends to be more valuable. Otherwise, when the firm's value is low (i.e., the junior debt is out-of-the-money or the firm stays in a condition of deep default urgency), a junior debt with a long maturity will have a high premium than a short-life debt, since a long-life debt has more time value. In addition, the value of a short-life senior debt is higher, compared to the value of a long-life senior debt, since the firm's value is high enough for the holders of senior debt in the interval over $K+c$ (= \$40 million).

Figure 1 graphically displays the numerical results discussed above. As previously mentioned, the presentation of the equity value resembles that of a plain vanilla call option with a strike price equal to the sum (i.e., $K+L$ = \$70 million) of the total repayments, as shown in Panel A of Figure 1. Panels B and C show the plots of the values of junior debts and senior debts, respectively, both of which vary with firm value and time to maturity. As the firm's value exceeds the sum of the total repayments, the junior debts reach a maximum in terms of their face value. As the firm's value drops below a threshold of ($K+c$ = \$40 million), the junior debts tend to be valueless. The senior debt also displays a similar presentation, which means the senior debt claimants receive a maximum of the promised payments (i.e., \$30 million) if the firm's value exceeds the strike level of \$40 million (= $K+c$), and the senior debt claimants receive nothing if the firm value is lower than the value of \$30 million (= $b+c$).

Next, this study further explores the impacts of the return volatility of the firm's value on the security values, as shown in Table 3. As the volatility rate is higher, the equity value becomes larger, but the values of both junior debts and senior debts tend to be lower. One rational explanation of this is as follows. A higher volatility rate leads to a wide variation in terms of the future possible results of firm values, and thus an increase of the volatility rate increases the possibility of higher firm values and increases the likelihood of payoffs being made to equity holders. However, the holders of corporate debts cannot receive the aforementioned over benefits from the increasing volatility rates, due to promised repayments remaining constant. In addition, a larger volatility rate also increases the default urgency as the firm's values goes downward, in which case the conditions of shallow-default urgency, deep-default urgency, or bankruptcy occur more frequently. Thus, the values of corporate debts are negatively related with the volatility rate of a firm's value.

Furthermore, this study also analyzes the effects of default costs, as shown in Table 4. We set a range of deep default costs from \$15 million to \$27 million and a range of shallow default costs from \$0 to \$12 million, since the default cost is lower in the condition of shallow default urgency. Panel A of Table 4 shows that the deep default cost (b) does not affect the pricing of junior debt, whereas the shallow default cost (c) has a negative impact on the valuation of junior debt. This is because a high shallow default cost will erode the payoffs of junior debts as the shallow default urgency appears, and because the junior debt has a subordinated priority on the firm's value as the deep default urgency appears. On the other hand, as shown in Panel B, both shallow and deep default costs have negative effects on the valuation of senior debts because an increase in the default cost reduces the payoffs to senior debt claimants. Figure 2 provides a graphical presentation of the relationships between the security values and bankruptcy costs. The main results hold true for the impacts of shallow and deep default costs on the valuations of both junior debts and senior debts.

In terms of the valuations of corporate securities under a consideration of different default urgencies, the shallow default urgency changes the junior debts' and senior debts' premiums, while the deep default urgency only affects the pricing of senior debts. As the results show, the valuation of corporate securities depends on the firm's level in a full-payable condition.

3.2 Default Spreads of Corporate Debts

With a numerical example, this study further analyzes the default spreads of senior debts and junior debts to examine *how* the default risks change in a variety of default urgency conditions. Given the same settings of the parameters, Table 5 shows that the default spreads of junior debts and senior debts gradually decrease along with a firm's value. A high firm value decreases the level of default urgency obviously. Specifically, the junior debts' default spreads are far larger than the senior debts' default spreads. That is, the junior debts have a higher default risk compared to the senior debts, since the junior debts are more likely to be defaulted by the firm, due to their subordinated status in the repayment priority order. In addition, a long-life junior debt has a low default spread, compared to a short-life junior debt, because the long-life junior debt has a higher possibility of receiving the full amount of the promised repayment. On the other hand, a long-life senior debt has a relatively high default spread, compared to a short-life senior debt. The reason is that the default risk is larger for the long-life senior debt, due to the uncertainty of the results regarding the firm's value.

Next, this study discusses *how* the default cost affects the default spread of corporate debts. In Figure 3, the default spreads of corporate debts are higher as the shallow and deep default costs are higher. That is, a high default cost can cause the holding of corporate debts to be risky, since the debt holders expect to receive little in the way of payoffs. In addition, as mentioned in the above discussions, a higher firm value releases the default urgency and thus diminishes the default spread of a corporate debt.

3.3 Probability Analysis

A firm's value, relative to the promised repayments and default costs, determines the level of the firm's default urgency. It is important for the holders of corporate securities to know the full-payable probability, shallow default probability, deep default probability, and full-bankruptcy probability under a given level of default urgency, since these probabilities also influence the pricing of corporate securities. This study further explores these probabilities with respect to firm value, due to the importance of security claimants understanding the probability distributions of defaults (i.e., the likelihood of *whether* they will receive repayment, or not).

In Figures 4-7, this study gives the same settings to the underlying parameters for the purpose of discussing the differential probabilities under given levels of default urgency. First, the default probabilities do not consistently vary with the firm values. Figure 4 displays four probability distributions based on the firm's value. The full-payable probability (P_I) increases with the firm's value, especially in the case of the firm's value exceeding the total promised repayments (K+L). The shallow default probability (P_{II}) shows a peak as the firm's value locates in a range from the value of K+c (= \$40 million) to K+L (=\$ 70 million). Besides, the possibility (P_{III}) of deep default urgency tends to be larger in the interval of (b+c, K+c). The bankruptcy probability (P_{IV}) steadily increases as firm value gradually declines. As a result, as firm value goes downward, the deep default urgency gradually increases as the firm value approaches the level of b+c, and the deep default urgency decreases and the bankruptcy stress increases as the firm value tends to be lower than the level of b+c. That is, if the firm value stays at a very low level, the firm has a high bankruptcy probability on maturity.

Second, the default cost causes different impacts on the default and bankruptcy probabilities. As shown in Figure 5, an increase in the shallow default cost can decrease the shallow default probability (P_{II}) with respect to the firm value. In fact, a higher shallow default cost decreases the probability that the firm value stays in the range (K+c, K+L), i.e., the range of shallow default urgency. The shallow default cost also has a similar impact on the deep default probability (P_{III}), as shown in Figure 6. However, when the firm value is higher, the shallow default cost can increase the deep default probability because the likelihood of the firm's value appearing in the interval (b+c, K+c), i.e., the range of deep default urgency, is higher. That is, the interval of deep default urgency also consistently moves along with the shallow default cost. In addition, as the deep default urgency occurs, the deep default cost has a negative effect on the deep default probability (P_{III}). Actually, a high deep default cost drives the firm to stay in a bankruptcy condition. That is, the firm easily bankrupts if the default cost increases, i.e., the bankruptcy probability (P_{IV}) increases over an interval of (0, b+c) as the default cost (b or c) increases. In this bankruptcy condition, the two debt claimants and the one equity holder receive nothing from the firm.

Third, the default and bankruptcy probability display various paths in different conditions of default urgency. Figure 7 gives a cumulative probability distribution for integrating full-payable, shallow default, deep default, and bankruptcy conditions depending on a variety of default urgencies. With respect to firm value, the sum of these four probabilities equals one, in which P_I, P_{II}, P_{III}, and P_{IV} gradually vary with the firm value. As the firm value is very low, the bankruptcy probability (P_{IV}) tends to be larger, and the other three probabilities tend to be lower. As the firm value gradually increases, the relative proportions of the deep default probability and the shallow default probability also increase, but the former performs a more sensitive change. If the firm value exceeds the level of K+c, the proportion of the deep default probability decreases, and the proportion of the shallow default probability increases, because there is a greater possibility that the promised repayments of senior debts can be made, whereas there is a lesser possibility that the promised repayments of junior debts can be made. Otherwise, if the firm value is high enough, the full-payable probability obviously increases with the firm value, and the bankruptcy probability and deep default probabilities immediately approach zero. That is, the default urgency is eliminated for the firm with a high value.

4. Conclusion

The holders of corporate securities bear different degrees of default urgency that vary with whether firm's values of asset are sufficient to pay claimants. We analyze default costs, default probabilities, and default spreads, under a consideration of default urgency. In actual fact, a firm has a different level of default urgency as it issues corporate debts with a subordinate priority scheme. As shallow level of default urgency appears, there is a high likelihood that the junior debts may be defaulted upon, but the senior debts are still secure in the sense that their holders will likely receive their promised repayments. On the other hand, as a deep degree of default urgency appears, the senior debts may also be defaulted upon. We value senior debts and junior debts under varying levels of default urgency. We also answer the question of *how* the level of default costs changes the debt values and give an analysis of bankruptcy probabilities and default probabilities.

We derive a closed-form result of security values under a consideration of different degrees of default urgency, and finds that the shallow default cost can affect the premiums of both junior debts and senior debts, while the deep default cost only affects senior debts. Second, the junior debts have a higher default risk compared to the senior debts, since the junior debts are more likely to be defaulted on. Specifically, the default spreads of corporate debts are higher as the shallow and deep default costs are higher. Third, the full-payable probability, shallow default probability, deep default probability, and bankruptcy probability vary with a variety of default urgency.

This article identifies default costs, probabilities, spreads, and debt valuation under a consideration of default urgency. Our findings offer new evidence about the valuations of senior and junior debts and provide a new perspective into default risk issues. We show that senior debts' or junior debts' default conditions drive from different conditions of default urgency for the firm and the security claimants.

Table 1 Security payoffs at the maturity date

Condition	Bankruptcy (IV)	Deep Default (III)	Shallow Default (II)	Full-payable (I)
	$V_T < b+c$	$b+c \le V_T < K+c$	$K+c \le V_T < K+L$	$K+L \le V_T$
Senior Debt	0	$V_T - b - c$	K	K
Junior Debt	0	0	$V_T - K - c$	L
Equity	0	0	0	$V_T - K - L$

Notes: This table describes security payoffs under default urgency at maturity date. V denotes firm value. L and K are the promised repayments to the junior and senior debt claimants, respectively. c and b are a shallow and a deep default cost, respectively, i.e., $c < b < K$ or L.

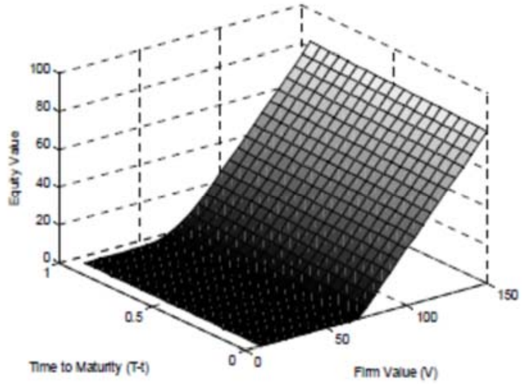
Notes: This table reports values of junior debts and senior debts in Panels A and B, respectively, varying with default costs. Parameters are set as follows: initial firm value V = \$70 million, face values of senior debts and junior debts of \$30 million and \$40 million, respectively, risk free rate of r = 5%, volatility rate of firm values of σ = 20%, and time to maturity of T - t = 2 years. Prices are expressed in units of millions.

Table 5 Default spreads varying with various firm values

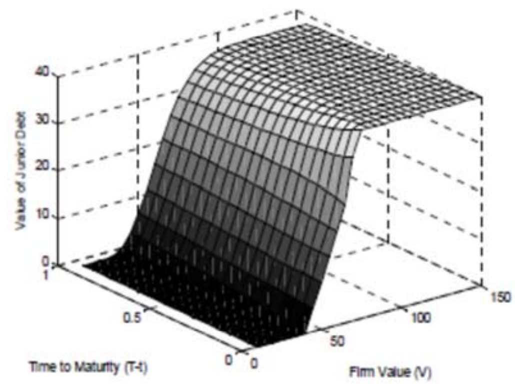
	Firm Value (V)					
Time (T-t)	\$60	\$65	\$70	\$75	\$80	\$85
Panel A : Junior Debts						
1.0	54.25%	36.54%	23.90%	15.15%	9.31%	5.55%
1.5	34.53%	24.30%	16.87%	11.54%	7.78%	5.17%
2.0	25.00%	18.16%	13.10%	9.39%	6.67%	4.71%
2.5	19.42%	14.45%	10.72%	7.93%	5.84%	4.29%
3.0	15.76%	11.95%	9.06%	6.86%	5.19%	3.92%
Panel B : Senior Debts						
1.0	1.12%	0.37%	0.12%	0.04%	0.01%	0.00%
1.5	1.74%	0.79%	0.35%	0.15%	0.06%	0.03%
2.0	2.04%	1.08%	0.56%	0.29%	0.15%	0.08%
2.5	2.17%	1.26%	0.72%	0.42%	0.24%	0.14%
3.0	2.19%	1.35%	0.84%	0.52%	0.32%	0.20%

Notes: This table shows default spreads of junior debts and senior debts in Panels A and B, respectively. Parameters are set as follows: face values of senior debts and junior debts of \$30 million and \$40 million, respectively, risk free rate of r = 5%, volatility rate of firm values of σ = 20%, deep costs of b = \$20 million, and shallow costs of c = \$10 million. Prices are expressed in units of millions.

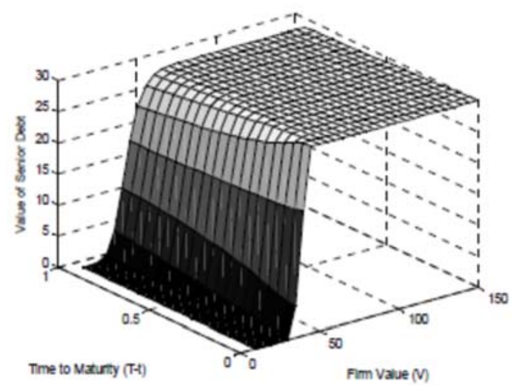
Figure 1 Security values varying with firm value and time to maturity



Panel A: Equity values



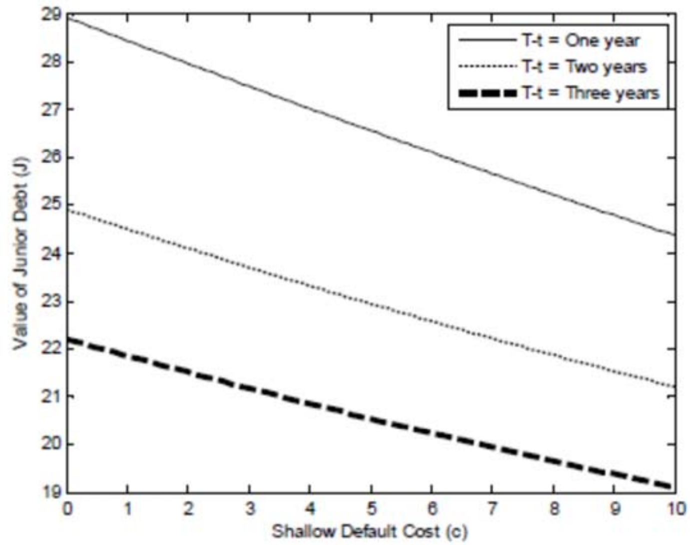
Panel B: Values of junior debt



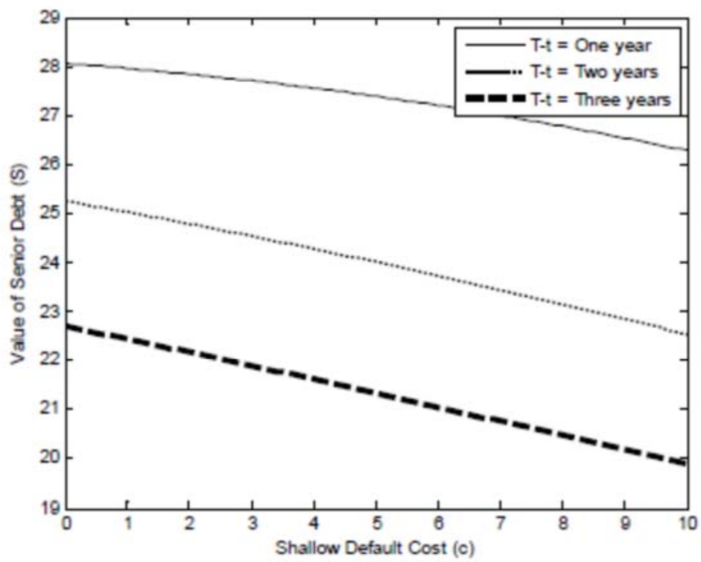
Panel C: Values of senior debt

Notes: This Figure displays values of equities, junior debts, and senior debts varying with various firm values and times to maturity. Parameters are set as follows: volatility rate of firm values of σ =20%, face values of senior debts and junior debts of \$30 million and \$40 million, respectively, risk free rate of r = 5%, deep default costs of b = \$20 million, and shallow default costs of c = \$10 million. Prices are expressed in units of millions.

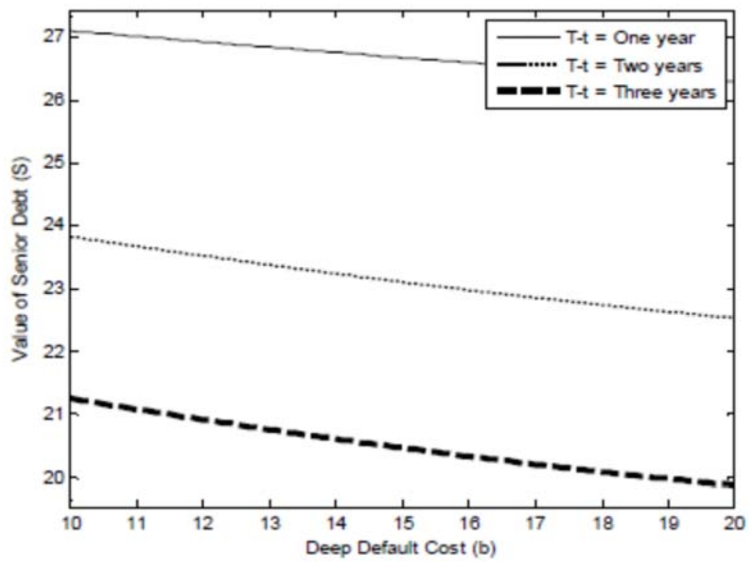
Figure 2 Security values varying with default cost and time to maturity



Panel A: Value variance of junior debt with shallow default costs



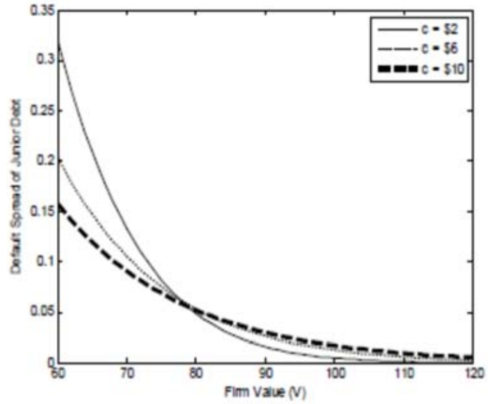
Panel B: Value variance of senior debt with shallow default costs



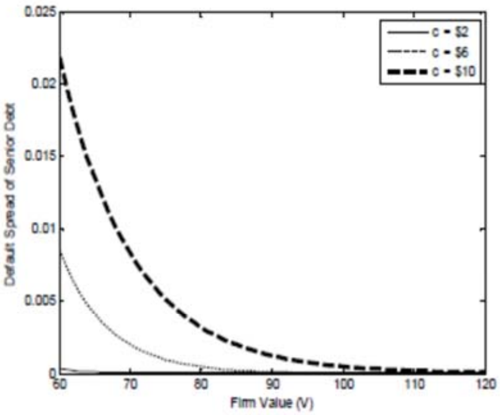
Panel C: Value variance of senior debt with deep default costs

Notes: This Figure presents values of junior debt and senior debts varying with default costs. Parameters are set as follows: initial firm value of V = \$70 million, face values of senior debts and junior debts of \$30 million and \$40 million, respectively, risk free rate of r = 5%, deep default costs of b = \$20 million, shallow default costs of c = \$10 million, and volatility rate of firm values of σ =40%. Prices are expressed in units of millions.

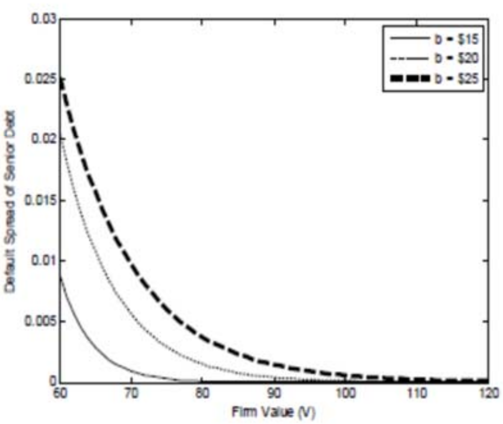
Figure 3 Default spreads varying with default costs



Panel A: default spreads varying of junior debt with shallow default costs



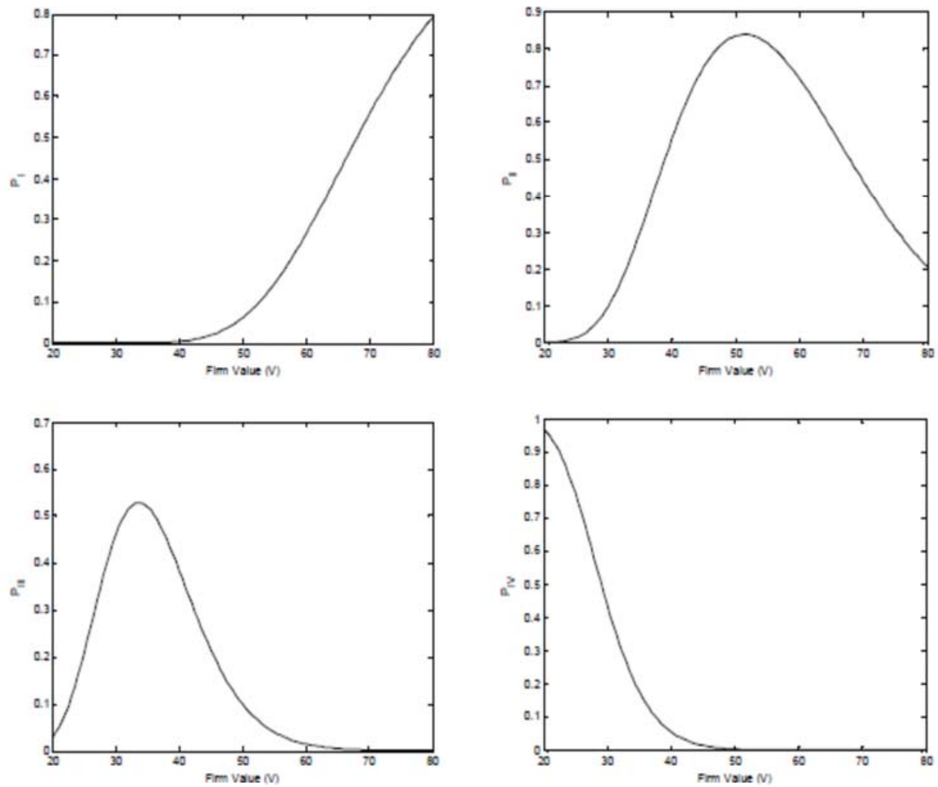
Panel B: default spreads varying of senior debt with shallow default costs



Panel C: default spreads varying of senior debt with deep default costs

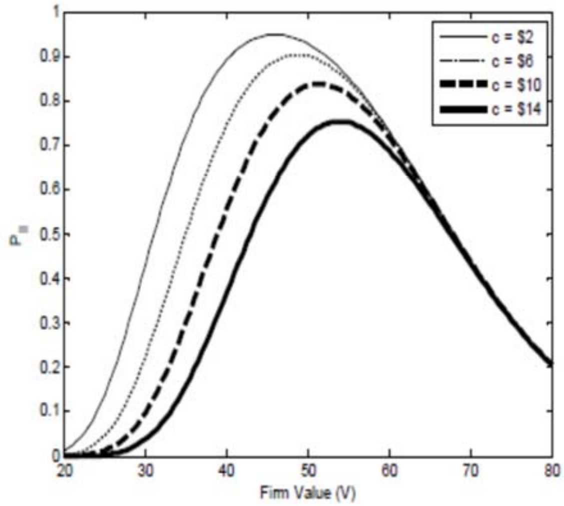
Notes: This Figure shows default spreads of junior debts and senior debts. Parameters are set as follows: face values of senior debts and junior debts of $30 million and $40 million, respectively, risk free rate of r = 5%, volatility rate of firm values of σ =40%, deep default costs of b = $20 million, and shallow default costs of c = $10 million. Prices are expressed in units of millions.

Figure 4 Probability analysis



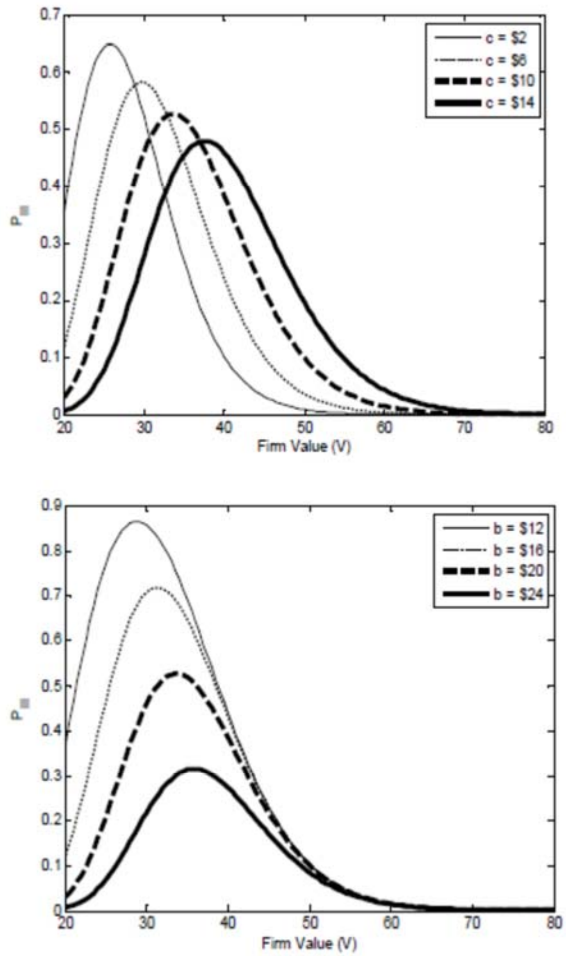
Notes: The Figure shows how full-payable probabilities, shallow default probabilities, deep default probabilities, and bankruptcy probabilities at maturity, vary with firm values. Parameters are set as follows: face values of senior debts and junior debts of \$30 million and \$20 million, respectively, risk free rate of r = 5%, volatility rate of firm values of σ =20%, deep default costs of b = \$20 million, and shallow default costs of c = \$10 million. Prices are expressed in units of millions.

Figure 5 Shallow default probabilities varying with shallow default cost



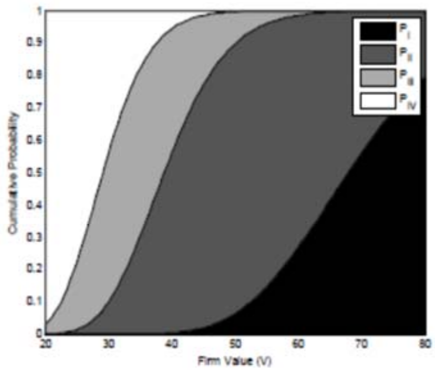
Notes: The Figure shows how shallow default probabilities at maturity vary with firm values, for examining the impacts of shallow default cost. Parameters are set as follows: face values of senior debts and junior debts of $30 million and $40 million, respectively, risk free rate of r = 5%, volatility rate of firm values of σ =20%, and deep default costs of b = $20 million. Prices are expressed in units of millions.

Figure 6 Probability in a deep degree of default urgency



Notes: The Figure shows how deep default probabilities at maturity vary with firm values, for examining the impacts of default costs. Parameters are set as follows: face values of senior debts and junior debts of \$30 million and \$40 million, respectively, risk free rate of r = 5%, volatility rate of firm values of σ =20%, deep default costs of b = \$20 million, and shallow default costs of c = \$10 million. Prices are expressed in units of millions.

Figure 7 Cumulative probabilities under default urgency



Notes: The Figure shows how cumulative full-payable probabilities, shallow default probabilities, deep default probabilities, and bankruptcy probabilities at maturity vary with firm values. Parameters are set as follows: face values of senior debts and junior debts of $30 million and $40 million, respectively, risk free rate of r = 5%, volatility rate of firm values of σ = 20%, deep default costs of b = $20 million, and shallow default costs of c = $10 million. Prices are expressed in units of millions.

Appendix

This appendix presents the result of equations (6) and (8) for the junior debts and senior debts, respectively. Based on option pricing theory, in a risk-neutral probability Q, under the default urgency the price of the junior debt at time t can be written as follows:

$$J(t) = e^{-r(T-t)} E^Q[J(T)]$$

$$= e^{-r(T-t)} E^Q[LI_1] + e^{-r(T-t)} E^Q[(V(T) - K - c)I_2]$$

$$= Le^{-r(T-t)} N\left(d_1 - \sigma\sqrt{T-t}\right) + V(t)[N(d_2) - N(d_1)]$$

$$-(K+c)e^{-r(T-t)}\left[N\left(d_2 - \sigma\sqrt{T-t}\right) - N\left(d_1 - \sigma\sqrt{T-t}\right)\right]$$

where E^Q denotes an expected value conditional on a risk-neutral probability measure Q, and where I_1 and I_2 are indicator functions for full-payable conditions and shallow conditions of default urgency, respectively, and are expressed as follows:

$$I_1 = \begin{cases} 1, & K + L < V_T \\ 0, & others \end{cases}$$

and,

$$I_2 = \begin{cases} 1, & K + c < V_T < K + L \\ 0, & others \end{cases}$$

Similarly, the valuation of the senior debt can be expressed as follows:

$$S(t) = e^{-r(T-t)} E^{Q}\left[S(T)\right]$$

$$= e^{-r(T-t)} E^{Q}\left[KI_0\right] + e^{-r(T-t)} E^{Q}\left[(V(T) - b - c)I_3\right]$$

$$= Ke^{-r(T-t)} N\left(d_2 - \sigma\sqrt{T-t}\right) + V(t)\left[N(d_3) - N(d_2)\right]$$

$$-(b+c)e^{-r(T-t)}\left[N\left(d_3 - \sigma\sqrt{T-t}\right) - N\left(d_2 - \sigma\sqrt{T-t}\right)\right]$$

where I_0 is an indicator function for a condition of default urgency as the firm value exceeds the strike price (K+c), and I_3 is an indicator function for the deep default condition, and they are expressed as follows:

$$I_0 = \begin{cases} 1, & V_T > K + c \\ 0, & others \end{cases}$$

and,

$$I_3 = \begin{cases} 1, & b + c < V_T < K + c \\ 0, & others \end{cases}$$

Abstract

The development of Industry Clusters (IC) now is a trend concerned to enhance the competitiveness of the industries in the world. The research objective is to review and synthesize current theories of IC development, then to explore key issues influencing the IC formation in Vietnam. A desk research and qualitative method through in-depth interviews with experts have been conducted in this exploratory study. Results find out seven key issues influencing IC development: the necessity of IC development, approaches to IC formation, conditions for development, IC governance structures, difficulties of SMEs participants, supporting policies of the government, and the role of related organizations. The study suggests recommendations for facilitating the development of IC in Vietnam.

Keywords: *Industry clusters, supporting industries, IC structure, SMEs, focal enterprise.*

1. INTRODUCTION

Industry Cluster is a topic of concern in both developed and developing countries because of its enormous impact on the effectiveness of the industry development. The governments and organizations of many countries in the world have developed this concept as a strong model to promote regional and urban economic growth. As a result, a large number of IC was initiated in the 1990s and this trend is increasing.

In Vietnam, the concept of IC has not been popular among enterprises. On the other hand, that the supporting industries (SI) in Vietnam is still underdeveloped is a major obstacle to the IC development. Currently, the majority of Vietnamese enterprises are not eligible to participate in the international supply chain of corporations and large enterprises investing in Vietnam.

Therefore, the objective of this paper is to review and synthesize current theories of industry clusters, then to explore key issues influencing the IC formation in Vietnam.

2. LITERATURE REVIEW AND RESEARCH METHODOLOGY

2.1 Literature review

2.1.1. Concept of industry cluster

Michael Porter is the scholar contributing the most to the development of the concept IC. According to Porter (1990), industrial clusters are groups of interconnected firms, suppliers, related industries, and specialized institutions that arise in particular location. This definition has two core requirements. Firstly, the firms in IC are linked in many ways such as vertical integration (network of supply, production and distribution) and cross-linking (supplemental products and services, etc.). Secondly, it is geographical concentration and linkage of firms. Porter's IC model emphasizes four factors: the limit of geography, the number of industries, interconnection of firm, and competitive advantage. There is a difference between the IC concept of Porter (1990) and industrial cluster of Vietnam (Table 1).

Table 1. Differences between IC of Porter (1990) and Industrial Cluster of Vietnam

Criteria	IC of Porter (1990)	Industrial Cluster of Vietnam
Objectives	– Develop linkages among enterprises in IC. – Enhance enterprises' competitive capabilities – Create workforce, high-quality goods and services	– Attract and relocate enterprises. – Improve infrastructure, promote production and business, and tackle environmental pollution.
Participants	– Suppliers – Manufacturers – Service organizations – Universities and research institutes	– Production and business enterprises – Industrial and handicraft enterprises – Small and medium enterprises (SMEs)
Linkages	– Strong and mutually supportive	– Weak and individually-performing
Scope	– Focus on the geographical concentration of related industries in the supply chain. – IC cannot be limited to a certain geographical boundaries.	– Focus on the geographical concentration of irrelative industries in the supply chain. – Industrial cluster is constrained by geographical boundaries.

2.1.2 Necessity of IC development

In the era of globalization and liberalization, the competitive advantages of a nation no longer result from the cheap labor force or abundant resources but from the creativity and improvement abilities. As can be proven in industrialized countries, IC has become an effective tool to strengthen the national and regional economy (Karaev et al., 2007). According to Arif and Sonobe (2012), the formation and development of IC has had crucial effects on the economy: (1) spillover effects of knowledge and technology contribute to sustainable economic development (2) the hierarchy and specialization of labor among enterprises, (3) the labor market easily attracts highly skilled workforce at low labor costs. In addition, firms in IC can get the benefits of collective efficiency such as shares of machinery and equipment, orders, marketing costs, market information, governmental lobby, etc.

On the other hand, industrial parks and industrial zones haven't yet taken advantage of geographical proximity. The linkages among enterprises are weak, and supports from organizations such as education, finance, research and development are not well. Therefore, the formation and development of IC will beneficially connect enterprises and organizations to create a synergy for innovation, operation efficiency and effectiveness, increased competitiveness, and global market involvement. Niu (2010) has pointed out that enterprise benefits greatly from their IC participation. They can improve the supply chain, business strategies, technology, and finance. Moreover, they can increase functions of products, improve product quality, improve customer services, extend longer life cycle of product profitability, stimulate innovation, create new products, open new markets, access to new technologies, and increase productivity.

2.1.3. Approaches to IC development

According Obadic (2013), there are two approaches used to develop IC: "top-down" and "bottom-up".

"Top-down" approach. This approach implies the active role of the government in creating the ICs. The government initiates the IC policies based on the country/region economic policies, directly selects focal enterprises for the development of clusters, and intervenes in many aspects to support IC. Then, the IC policies will be transferred to local community. However, according Obadic (2013), this approach will be less effective since it is not derived from actual situation, not observing the actual dynamics occurring in enterprises and organizations in IC.

"Bottom-up" approach. This approach involves the interaction between enterprises, organizations and a dynamic view of the changing needs of the clusters and the learning process (Borra and Tsagdis, 2008). In the case of the "bottom-up" approach, a motivation to create a cluster policy is from the business sector. The enterprises themselves are in need of improvements in order to enhance their competitive capability, so they actively link and cooperate with one another.

A typical case of "Top-down" approach is Gumi Industrial Park (GIP) (also called Gumi Cluster) - an electronics IC built by the Korean government. The focal firms of Gumi Cluster are LG Electronics and Samsung Electronics. According to Park et al. (2012), the South Korean government initiated the IC establishment. GIP is the IC that the Korean government has built over the years with the aim of developing the Korean electronics industry. In order to catch up with the leading countries in electronics industry, the Korean government has attracted American, Japan and European enterprises to invest in their manufacturing activities in Korea so that domestic enterprises could acquire hands-on learning. This IC strategically cooperates with private research centers and research institutions supported by the government.

As of the "bottom-up" approach, according to Ketels (2003), for a developing country like Thailand, they said that economic development is a multi-leveled collaborative process associated with the government, enterprises, education and research institutes, and supporting organizations. As a result, the government's role for the development of IC is in supporting the development of all ICs through consolidating and establishing the emerging clusters rather than trying to create entirely new clusters, and in developing the public-private partnership.

Two parallel approaches are applied in Europe (Obadic, 2013). For the "top-down" approach, all cluster policies are taken at the supranational level, and consequently form a single national policy. The national government spends a large amount of time on the design and coordination of IC policies, a common framework, and R & D programs while local governments enter the implementation phase. They also apply the "bottom-up" approach by listening to enterprises and local governments who are all virtually better stakeholders at evaluating and meeting each IC's specific needs.

2.1.4 Conditions for IC development

Karaev et al. (2007) suggest that preconditions for the development of IC are: geographical proximity, critical mass of firms, the appropriate business environment, and the trust building among members.

Geographical proximity

Geographical proximity creates competitive advantage for SMEs to collaborate and compete, since a host of linkages among cluster members results in a whole greater than the sum of its parts (Porter, 1998b). Geographical proximity results in enhanced communication and knowledge exchange among cluster members (Karaev et al., 2007). Proximity helps to establish co-operative linkages between companies through enhancing mutual learning and knowledge creation and knowledge can "spill over" between local firms due to the easier (informal) contact between them (Wolter, 2003). Although in the age of internet-based technologies geographical proximity loses importance because of the easier access to information, still some valuable, non-codified, but tacit, knowledge can be exclusively obtained within a cluster (Preissl and Solimene, 2003). Besides, geographical proximity reduces costs for transaction, transportation, insurance, and so on (Karaev et al., 2007).

Business environment

The ICs are affected by business environment, particularly the availability of raw materials and other facilities such as transport (road, rail) and communications, etc. In addition, competitors (local and global), and the cooperation of governmental agencies, enterprises, universities and other related organizations are considered parts of the business environment (Singh et al., 2013). According to Karaev et al. (2007), the appropriate business environment is the basis for the attraction of a large number of SMEs - a precondition for the IC formation. Without such an environment, it can be a major barrier to the implementation of the IC approaches.

Trust building

Ceglie (2003) has pointed out that factors such as trust building and constructive dialogue among cluster actors, exchanging of information, identifying common strategic objectives, agreeing on a joint development strategy and its systematic and coherent implementation are of paramount importance for building an efficient cluster. The trust among members helps them link together more closely. A high trust level also reduces costs for transactions, administrative procedures, and legal disputes. Raising the level of trust among cluster members is a strategic determination in the successful development of clusters. In addition, the presence of a global company or large enterprises in the cluster will facilitate the trust building for the participating enterprises.

2.1.5 Management structure of IC

According to Contreras et al. (2013), the automotive industry IC in Puebla (Mexico) is fully developed with representatives from three participants: upstream, mainstream and downstream. Besides, IC must be supported by other organizations such as related industries and supporting sectors, government, education, institutes for collaboration and associations (Figure 1).

For the case of IC in Indonesia, Tambunan (2009) argues that the economic benefits can only be achieved if IC developed internal and external networks well (Figure 2). Internal networks can be defined as business co-operations or links among enterprises inside the cluster, which can be in various forms, for example marketing, distribution, production, procurement of materials, training for workers, etc. External networks are business and other forms of relation between enterprises inside the cluster and actors outside the cluster such as large enterprises (LEs), suppliers of inputs, providers of business services, and so on (Ceglie and Dinni, 1999).

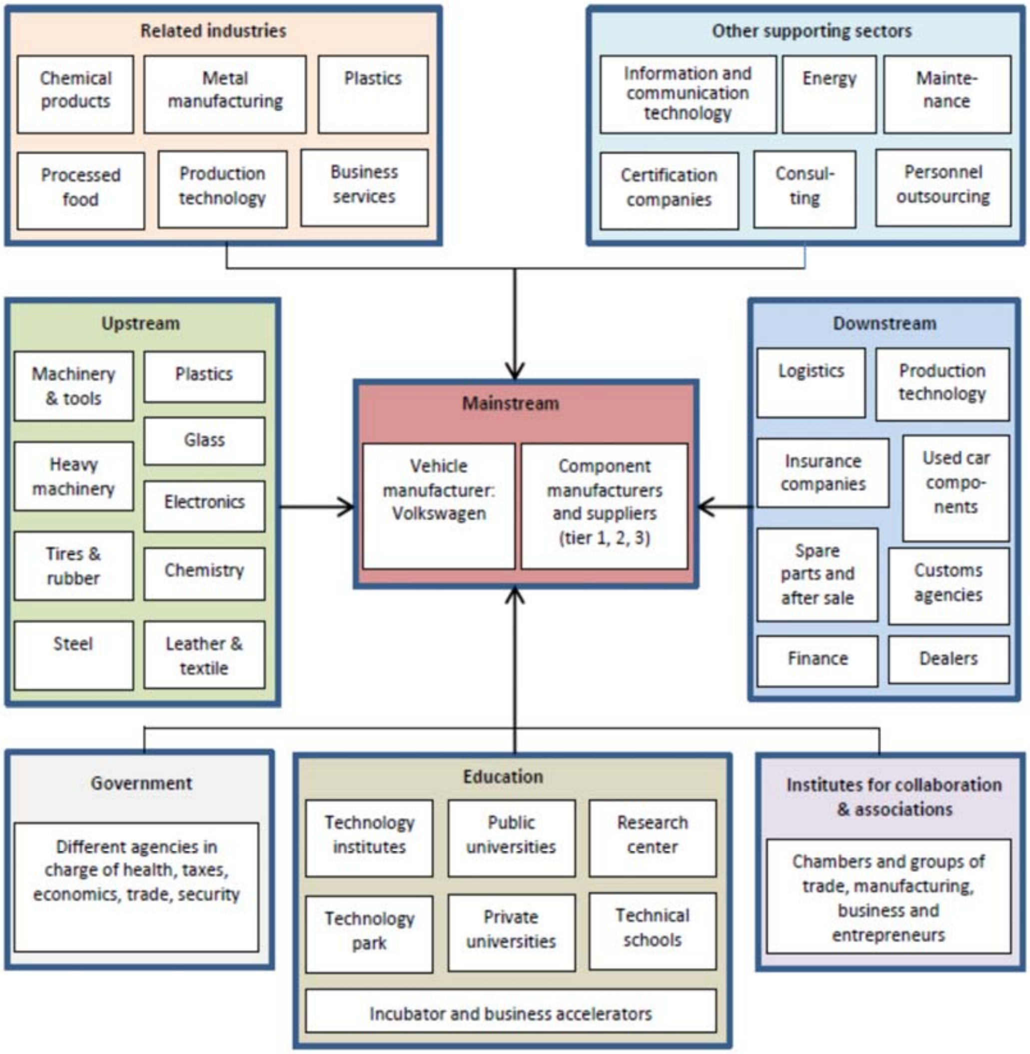

Figure 1. Automobile industry IC model in Mexico's Puebla (Contreras et al, 2013)

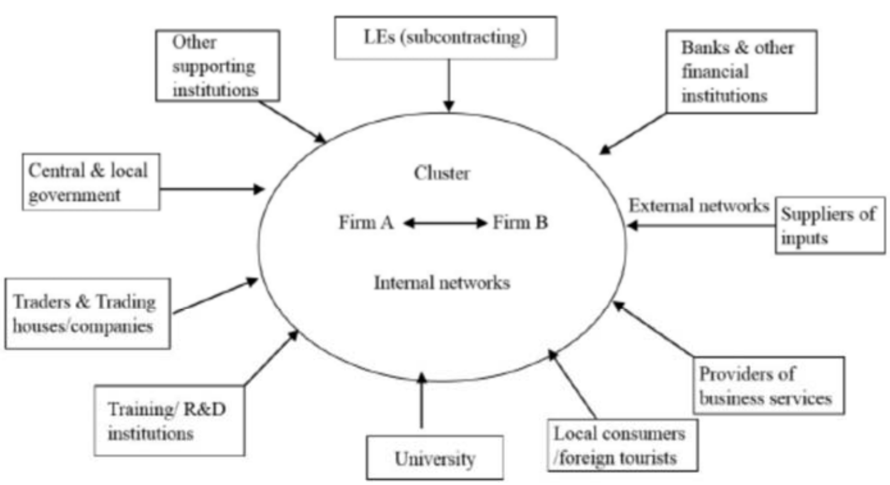

Figure 2. Internal and external networks of a small and medium industry cluster in Indonesia (Tambunan, 2009)

2.1.6. Difficulties of SMEs to participate in the development of IC

Trade liberalization and globalization processes have significantly increased opportunities and challenges for SMEs. SMEs have begun facing two main challenges: first, to transform themselves and increase their individual competitiveness (Fassoula, 2006), and second, due to their limited size to take advantage of synergy effects created by entering into cooperative relations with other SMEs and related partner institutions.

Tambunan (2009) argues that common limitations of SMEs are lack of capital, difficulty in procuring raw materials, lack of market information, difficulty in marketing and distribution, low technological capabilities, high transportation costs, communication problems, cumbersome and costly bureaucratic procedures, and the policies and regulations that generate market distortions.

2.1.7. Government's supporting policy for IC and SI

In developed countries, the governments' IC policies are usually planned at more levels than those of the developing countries, with a transnational and inter-regional way of thinking. Governments often have direct intervention policies for the IC development, whereas similar policies in developing countries are often meant to co-participation and support. According to Obadic (2013), in the EU member countries, the IC development policies have common orientations as follows:

- National or regional authorities focus on fostering innovation and improving knowledge and technology.
- The public and private funds aim to finance major programs for R&D cooperation and commercialization of research applications.
- A focus on developing a business cooperation and networking.
- They stimulate a firm ground promoting exchanges among cluster members, centers of research and education, financial institutions, government organizations and NGOs.

In Thailand, the role of government for IC is concretely expressed through the elements in the diamond pattern (Figure 3).

2.1.8. Roles of related organizations

Roles of universities and research institutes

To succeed, an IC must have a strong education and research. The renowned public and private universities and research centers can offer supports through technology parks, technology business incubators (Contreras et al, 2013).

Role of industry associations

For fast-growing countries, particularly Thailand, Ketels (2003) compared the old and new role of the Industrial Associations with the involvement of IC as shown in Table 2.

The role of banks, venture capital and other financial institutions

According to Liu et al. (2013), the non-governmental chamber of commerce can be a trusted intermediary between banks and enterprises. This organization can reduce the banks' lending risk, and help new business projects improve finance and investment. Family and friends, banks and financial and investing institutions play important roles in providing capital and finance to help enterprises maintain, develop and participate in IC.

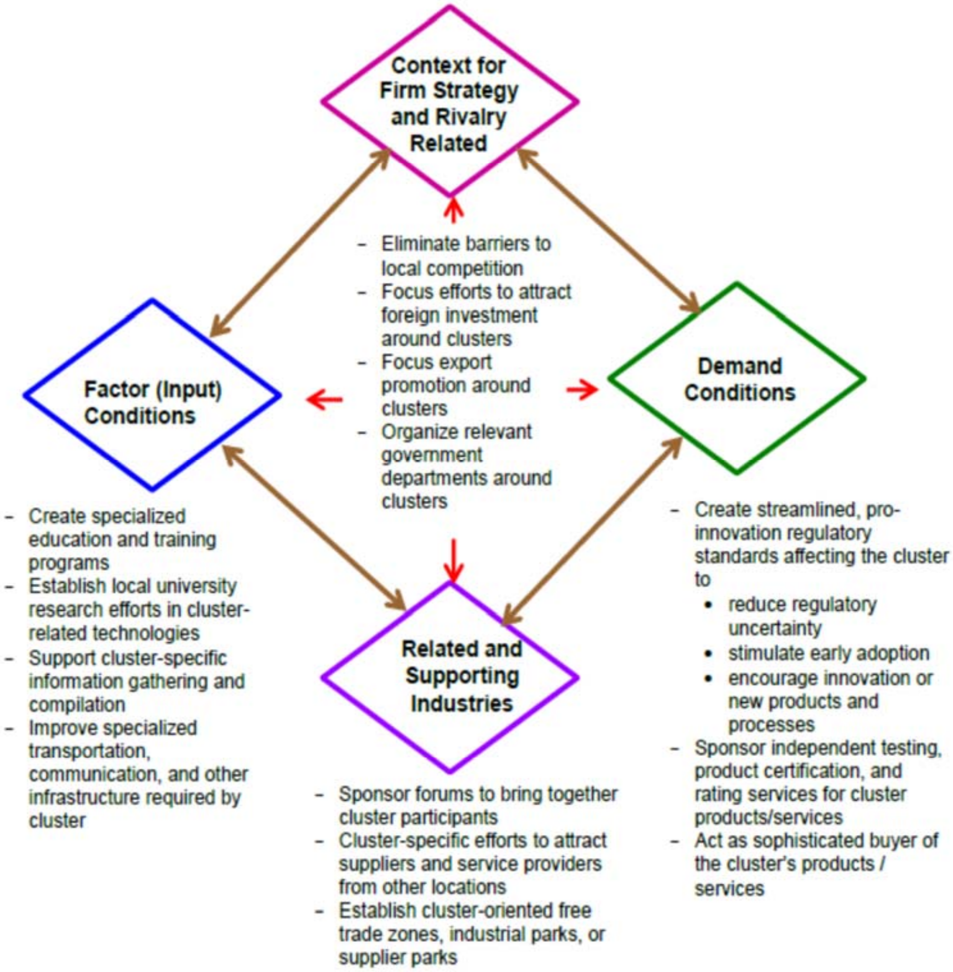

Figure 3. The role of the government in IC development (Ketels, 2003)

Table 2. New roles of industry associations for IC

Traditional Roles	New Roles
- Lobby government (Trade and regulations) - Convene meetings for networking	- Negotiate with government (Trade and regulations) - Information collection and dissemination (E.g. regular benchmarking) - Joint marketing (E.g. trade fairs, missions) - Training (E.g. curriculum for managers, close collaboration with outside educational institutions, sponsoring of targeted scholarships) - Research (E.g. university partnerships, standard setting and testing, specialized research institutes) - Procurement (E.g. joint purchasing programs) - Environmental (E.g. demonstration projects, research sponsorship) ⬇ **Cluster activation and enabling**

(Source: Ketels, 2003)

2.2. Research framework

In reference to experience of the IC development in the world, the research focuses on key issues affecting the IC development in Vietnam: the necessity of IC development, approaches IC development, conditions for IC development, governance structures, the difficulties of SMEs participants, supporting policies of the government, and the role of related organizations.

2.3. Research Methodology

The main method used in this research is desk and qualitative research. This study carries out purposeful sampling because interviewees' characteristics are experts with experiences relating to IC development. The subject aims to develop the IC of automobile industry in the Ho Chi Minh City. Therefore, the experts are selected based on knowledge and long work experience in fields relating to the automobile and supporting industries. There are nine interviewees from automobile manufacturers (focal enterprises), enterprises related to the automobile industry, industrial associations, universities - research institutes, governmental bodies (Department - Board – Sector). The data collected from the in-depth interviews with experts are mainly qualitative (Appendix). Therefore, the study emphasizes on describing and analyzing the meaning of the data.

3. FINDINGS

(a) The necessity of IC development in Vietnam

At present, Vietnam has some IC conceived as:

- At Chu Lai Open Economic Zone, there is a complex of Truong Hai automotive manufacturing and assembly as an IC.
- North Thang Long Industrial Park concentrated 100 percent FDI from Japan. In this Industrial Park (IP), large electromechanical assembly enterprises from Japan such as Canon, Panasonic link with spare parts providers from Japan as well such as Nissei, Santomas, Yasufuku, etc. The Vietnamese enterprises can hardly join in this linkage. North Thang Long IP is considered as a successfully electromechanical IP in Ha Noi. Turnover of this IP is over VND30 trillion and a USD1 billion export per year. With this effectiveness, Hanoi strongly orientates to develop this model.
- In Hung Yen Province, there is a Pho Noi textile IP with export-orientation, international links, or participation in global value chains. This could be a model to replicate.
- In the field of handicrafts, arts and crafts, some trade villages and towns such as Bat Trang bricks, La Phu textile, Dong Ky wood, Dai Bai copper, Da Hoi steel are becoming as an IC.

Through the process of specialization and concentration of similar economic activities, Vietnam's ICs form and develop naturally, not as purposefully intervened by the government and local authorities. Particularly, the successful case like Thăng Long IP with a pioneer CANON is not the original intent of the local government, but largely because of Japanese companies' impacts.

Overall, ICs in Vietnam are at the stage of budding, and none of the clusters reveal the essential nature and meaning of a genuine IC. Instead, these so-called ICs exist mainly because of spontaneous demand of foreign companies in the local region and the inside and outside links that are still rather weak.

Therefore, all the experts (9/9) interviewed believed that the development ICs in Vietnam is now of great importance. According to experts of universities, research institutes and governmental bodies, forming ICs can help local enterprises improve their competitiveness before the wave of globalization and liberalization. At the same time, experts in the SI industry acknowledge that the enterprises expected such ICs to be able to support them in terms of supply and market expansion. The current domestic SMEs, especially supporting industries, have mainly imported raw materials and export products due to the underdeveloped domestic market and low-quality materials from local suppliers.

b) Approaches to develop IC in Vietnam

Most of the experts interviewed (7 out of 9 experts) agreed that we should combine the two approaches to build ICs. According to experts from governmental bodies, both approaches and pay more attention to the "bottom-up" approach should be implemented because most of the Vietnamese enterprises is now SMEs. Based on the need of enterprises and regions, the government develops supporting policies, and environments for linkages among SMEs and. At the same time, large enterprises need to develop linkages in the stages of design, production and consumption.

In addition, the expert from the automobile manufacturers and universities – research institutes recommend that two approaches should be combined to get variety of viewpoints, distinguish responsibilities between the government and enterprises. Thus, each party has own responsibility and better cooperation.

(c) Conditions for developing IC

There is a difference in opinions of experts between enterprises and universities - research institutes about the geographical location. The former highlighted the important role of geographical proximity in reducing costs in the business activities. While the latter argues that geographical proximity is not an important factor for IC, since in the era of information technology, distance is no longer a problem hindering communication among the enterprises. The enterprises become disadvantages in a location boundary. Therefore, the linkages of IC should be opened, and based on the supply chain.

Some experts (3/9) suggest that the business environment is a critical factor. The government need provide a suitable business environment, encourage the development of domestic enterprises, create conditions for infrastructure, implement of preferential policies, offer support services, etc. to help the enterprises participate in the ICs.

Currently, Vietnamese enterprises of SI are very weak. Several experts (4/9) point out that one of the important conditions to build an IC is market demand. An attractive market demand will attract SI enterprises to join in the IC.

(d) Governance structure of IC

Experts suggest that a large company should be chosen to become a focal company of IC. This company leader will connect the SMEs so that they can develop together. Almost experts

(8/9) suggest that focal company should be strong local or foreign company. They also imply that there should be no restriction of location for IC. The location limitation of IC should just make a concentration of businesses in which the government may offer incentives for SMEs and support them in many aspects (R&D, finance, training, logistic services). Customers and suppliers can share with any of those who want participate in supply chains at home and abroad. The building of IC also gives opportunities for new enterprises, and those enterprises that wish to invest more plants can take advantage of the distance to their customers in IC.

(e) Difficulties of SMEs to participate in the development of IC

Vietnamese SI is currently weak in many aspects. The biggest difficulties of Vietnamese SMEs are quality control and technology capability (8/9). The next difficulties are the linkages of enterprises (7/9), and business management (4/9). This is a major barrier to the national industry as well as the development of IC. It leads to SMEs of SI can hardly participate in supply chain of IC now. In addition, they also have to compete with Chinese enterprises whose products and quality are cheaper and stable respectively.

(f) Supporting policies of government for IC and SI

A despite an absence of a policy on the IC development, Vietnamese government has developed many preferential policies on SI (7/9). Unfortunately, these policies exit several inadequate and overlapping things. Thus, they have not come into reality yet to meet the needs of enterprises. According to experts of government bodies, the current financial support of the government is mainly related to the issue of tax reduction for SI enterprises, while the tax is decided by parliament, but not by the government. There is no law concerning such supports at the parliament.

In addition, these experts commented that the role of the government was blurred for FDI enterprises. The FDI enterprises in Vietnam are entitled to preferential investment policies, but the government cannot control how many products of Vietnamese SI enterprises they have to use. This leads to their only link with the "family" enterprise, and the Vietnamese enterprises are unable to participate in their supply chain. In this respect, the government can act as a third party, choosing a number of Vietnamese enterprises that can meet the requirements. The three parties consisting of the government, FDI enterprises, Vietnamese enterprises would sign the supply contract. Then, the government could create favorable conditions for investment, research and development, etc. to support Vietnamese enterprises to meet orders of FDI enterprises. Therefore, it is essential to construct an information channel where the government is the link between domestic and foreign capital enterprises to develop SIs in Vietnam.

(g) Role of related organizations

Universities and research institutions in Vietnam nowadays still carry out mainly functions in research and training, but lack practical applications. Scientific products and human resources from the universities and research institutes have not contributed much to the development of the industries (3/9). Thus, the question is whether the government should have a mechanism to promote this cooperation or not, because the roles of the universities and institutes are extremely important to IC in general and enterprises in particular in terms of improvement, research and development cooperation.

Associations and professional associations have an vital role to IC because of not only the external communication channel between the state agencies with enterprises, but also the role of linking businesses, providing information, supporting enterprises in the same industry, and gathering enterprises. However, at the moment, the association is still on formalism, not efficient for the industries. All experts (9/9), the role of today's associations is generally faint. Most of the leaders of the associations originated from state-owned companies owing a macro view, but not from enterprises. This leads to lack of understanding of businesses' real needs. On the other hand, the associations have not gathered large companies for their voices to represent the voice of the entire sector.

4. CONCLUSION

Based on the synthesis of theories and experiences in developing IC in the world, this study undertook depth interviews with nine experts to explore key issues that influence the development of IC in Vietnam. The results showed that it is extremely necessary to develop IC in Vietnam and "top-down" and "bottom-up" approaches should be combined. Next, the most important condition for the IC development is associated with the market demand and the government's supporting policies. Also, the main difficulties that domestic SMEs are faced with lie on lack of information, technology, and linkages of enterprises. The linkages among universities, research institutes, and associations with enterprises are weak and loose. Finally, there should be a focal enterprise in IC, and there should not exist a limit on location boundary, instead of expanding throughout the supply chain.

This study suggests recommendations aiming at creating favorable conditions for the development of IC in Vietnam. The government should establish sanctions for FDI enterprises so that they can cooperate with local suppliers to develop domestic SIs. Practical implementation guidelines are required following the policies on encouraging or supporting the SIs. The government should also have promotion policies as well as sanctions to increase cooperation between enterprises and universities, research institutes, and associations to facilitate the development of IC. Ho Chi Minh City authorities need to have a direction for choosing appropriately focal enterprise and location of automobile IC and then to build policies encouraging SMEs in automotive supply chain to participate in this cluster.

The limitations of the studies are that the number of experts interviewed is modest and enterprises' readiness to participate in the IC is not investigated. Therefore, this study should continue to undertake surveys on the readiness of businesses in order to establish a solid basis for the formation of IC in Vietnam in general and the automotive IC in Ho Chi Minh City in particular.

Abstract
We empirically analyze the effects of vertical mergers and acquisitions on the performance of the acquiring firms. Our primary focus is on inventory-related supply chain metrics . Accordingly, we concentrate on sectors where inventories play a significant role; i.e., manufacturing, wholesale and retail industries. By using accounting panel data from Compustat database and the data on vertical acquisitions/acquisitions from SDC Platinum database, we study how the post-acquisition inventory performance compares to that of the pre-acquisition level. We also investigate how ver- tical acquisitions impact other operating performance measures such as gross profit margin, sales efficiency and profitability.

Keywords: *vertical mergers and acquisitions, empirical analysis, inventory management, prof- itability.*

1 Introduction

Vertical merger (or acquisition) occurs when an upstream supplier and a downstream distributor merge (or one acquires the other). There are two types of vertical acquisitions: forward and backward. A forward vertical acquisition occurs when a company combines with one of its downstream distributors or retailers where its products are sold. A well-known example is Disney's acquisition of American Broadcasting Company (ABC) in 1996; Disney is a leading provider of family entertainment while ABC is a broadcasting company with news, cable, and entertainment networks. A backward vertical acquisition is where a company acquires an upstream supplier that produces some of the inputs used in the production of its products. American Technology's acquisition of HST Inc is an example. American Technology is a high-tech producer of branded components while HST is a designer and manufacturer of technologically advanced components for branded consumer products. Recent vertical transactions include Google's purchase of Motorola Mobility, and HP's acquisition of Autonomy, Britain's largest software company.

According to the existing literature, there are two major effects of vertical mergers and acquisitions. One is the cost efficiency and the other is anticompetitive market foreclosure. As on example of cost efficiency that can be gained from vertical mergers, consider the well-known double marginalization in a decentralized supply chain. Double marginalization occurs when both the upstream and downstream firms have monopoly power. The upstream producer of the input will price above marginal cost when it sells the input to the downstream firm, who will then price above marginal cost again when they sell the final product that uses the input. This means the product being market up above the marginal cost twice, which creates two deadweight losses. Vertical mergers eliminates such inefficiency by enabling the upstream firm to directly observe the joint profits. The merged firm can then induce the downstream subsidiary to reveal the correct price by rewarding the downstream subsidiary only when the optimal quantity for the reported price is consistent with the observed joint profits (Perry 1989).

Market foreclosure refers to the effect of vertical mergers on non-merged firms (Salinger 1988). A backward vertical merger can cause market foreclosure, which is the exclusion that results when non-merging downstream firms are foreclosed from the upstream input supply controlled by a vertically integrated firm. The foreclosure of rivals means that remaining suppliers will face less competition. As a result, they may be able to increase their profits by raising their input prices to the non-merging downstream firms, which benefits the vertically integrated firm. Analogous effects occur in a forward vertical merger, where upstream competitors are foreclosed from selling to the downstream division of the integrated firm.

Although many empirical studies have been conducted to examine the existence of these two effects, no research has been done on how vertical mergers affect merged firms' operating as well as inventory related performance. Does the acquiring firm's operating performance improve after a vertical acquisition? How does a vertical acquisition affect the acquiring firm's inventory related performance? These questions are unaddressed in the literature. In this paper, we empirically investigate the impact of vertical mergers on merged firms performance. Our empirical work employs an unbalanced panel of 1175 acquiring firms taken from the Compustat database for the period 1995-2008. By comparing the merging firms absolute performance with their industry benchmarks, we find that i) vertical mergers are generally associated with significant deterioration in operating and inventory related performance during the first year following mergers; ii) merged firms generally take at least two years to recover from the negative effects; iii) within the five years following the vertical merger, merged firms do no exhibit significant competitive advantage over the industry average performance.

The rest of the paper is organized as follows. We review related literature in §2, then propose our hypotheses in §3. The data sources and adopted methodology are discussed in §4. §5 report the detailed results and findings. We provide the concluding discussion and future research directions in §6.

2 Literature Review

In literature, there are many expected benefits from vertical integration, such as cost savings, market foreclosure, information sharing, etc. Although a number of researchers in economics and operations management areas have investigated analytically these effects of vertical integration, less attention has been paid to providing empirical evidence of these benefits. In this section, we shall review the literature on the related areas, including both theoretical and empirical studies.

How vertical mergers affect competition is an important issue in economics. Riordan (2008) reviews the effects of vertical integration around five major theories: single monopoly profit, eliminating markups, restoring monopoly power, raising rivals' costs, and facilitating collusion. Other commonly argued benefits of vertical integration include the reduction of risk (Buzzell 1983, Porter 1985), the integrated firms' ability to innovate and to differentiate (Porter 1985, Perry 1989) increased efficiency in the exchange of information and organizational structures (Porter 1985), and improved market positions of the integrated firm (Perry 1989). Since our interest in this paper does not concern monopoly profit, monopoly power and horizontal collusion, we will focus on the theories and evidence regarding the elimination of markups and the increase in rivals' cost.

Elimination of markups and increase in rivals' cost

Salinger (1988) summarizes three major effects of vertical mergers: i) the merging firm increases its final good output; ii) the unintegrated downstream firms lowers their demand for the intermediate good; iii) the merged firm withdraws from the intermediate good market and the increased concentration causes the intermediate good go up. He shows that which effect dominates depends on market structure and under certain conditions, a vertical merger increase the price for the final products.

More recently, the post-Chicago approach (proposed by Ordover et al. (1990) and Riordan and Salop (1995)) has emerged that has shed new light on the issue of the competitive effects of vertical mergers. This new analysis shows that vertical mergers create vertical integration efficiencies between upstream suppliers and downstream distributors. Potential efficiency benefits include improved coordination in pricing, production, and design that can reduce costs and improve product quality. They also involve more efficient input usage and promotion. Hart et al. (1990) develop a theoretical model showing how vertical integration changes the nature of competition in upstream and downstream markets and identifying conditions under which market foreclosure will be a consequence or a purpose, or both, of such integration. Chen (2001) also shows that vertical mergers will lead to both an efficiency gain and collusive behavior in horizontal competition. Whether the efficiency or the collusive effect dominates depends on the cost of switching suppliers and the degree of product differentiation. A vertical merger can raise downstream rivals' cost if and only if its own cost is reduced through the integration.

Although there are many expected benefits of vertical merger, the existing empirical literature seems to have focused mostly on issues related to transaction costs, foreclosures, and the determinants of vertical integration. The empirical literature on an important aspect of vertical merger, i.e., its effect on operating performance and inventory related supply chain performance, is surprisingly limited. Among the existing studies, McBride (1983) found that vertical integration negatively impacted post-integration prices. Gaudet and Long (1996) utilize a large panel of data to analyzes the effects of three different types of mergers. They show that mergers on average do result in significant increases in profits, but reduce the sales of the merging firms. Bhuyan (2002) finds that vertical mergers negatively impact profits, which may be due to the failure of vertical mergers to create differential advantages, such as cost savings, for the integrated firm. Azzam and Pagoulatos (1999) conclude that there are serious gaps in the vertical integration literature and the limited empirical work that has been done in this area makes generalization difficult to achieve. Therefore, the main purpose of this study is to empirically examine the effect of vertical mergers on the merged firm's performance.

Information sharing

In the supply chain management literature, however, a lot of emphasis has been put on designing an appropriate contract between upstream supplier and downstream retailer to achieve a channel coordination (see Cachon (2003) for a detailed review). Although the coordinated firms still operate independently, the effects of such contracts and vertical integration can be similar[1].

Double marginalization and information asymmetry are two of the major causes of supply chain inefficiency (Tsay et al. 1999, and Ozer and Wei 2006). Without vertical integration or cooperation, these factors can distort firms' incentives such that supply chain members are primarily concerned with optimizing their own objectives, instead of achieving the optimal supply chain performance (Cachon 2003). The classic supply chain management theory suggests that the vertical integration of successive monopolies eliminates double marginalization and results in a lower price of the final good. By this argument, vertical integration both raises profits and benefits consumers (Spengler 1950).

Lee et al. (2000) show that the order information transferred within a vertical supply chain tends to be distorted and can misguide upstream suppliers in their inventory and production decisions. Their analysis suggests that information sharing between supply chain members could provide significant inventory reduction and cost savings to the upstream manufacturer. Yu et al. (2000) also illustrate the benefit of supply chain partnership with vertical partnership. They show that the negative impact of bullwhip effect on a supply chain can be reduced or eliminated because the vertical partnership can help the supply chain members share more information to reduce uncertainties.

Although there are extensive literature in supply chain management area dealing with the supply chain coordination schemes (see Cachon (2003) for a detailed review) and the benefit or information sharing (e.g., Lee et al. (2000), Chen et al. (2000), Lee and Whang (2000), Yao et al. (2007)), to the best of our knowledge, there are few empirical studies on the vertical integration and firm's inventory performance. As the only one related to this issue, Carr and Kaynak (2007) empirically investigate the relationships among communication methods, information sharing within a firm, information sharing between firms, and supplier development support. They find that information

[1]Tan (2001) states that since most of the benefits of forward and backward vertical integration can be obtained by coordinating the logistics operations of independent firms in the supply chain. In this respect, supply chain management is synonymous with integrated logistics systems.

sharing between firms have significant impact on improving buyers product quality and financial performance. However, they did not measure inventory performance such as inventory turnover for supply chain members.

3 Hypothesis Development

In this section, we postulate our hypotheses regarding the impact of vertical acquisitions on operating and inventory performance, drawing on results from extant theoretical and empirical literature. In the interest of space, we focus on the hypotheses related to the performance of the acquiring firms compared to their rivals that have similar size in this context. In total, there are seven hypotheses - three of them dealing with operating performance and the other four dealing with inventory-related supply chain performance measures. We start with the former set.

3.1 Operating performance

A well-developed body of classical economic literature describes the motivations for vertical integrations. One of such motivations is the cost savings (see Spengler (1950), Salinger (1988), and Williamson (1971)). For example, Williamson (1971) suggests that vertical integration may reduce the cost of negotiation between the upstream and downstream firms. Such an effect could also improve the coordination between supply chain players and reduce the effect of double marginalization, so as to improve the profit margin for the vertically integrated firm. On the other hand, according to the vertical foreclosure theory,[2] the foreclosure of rivals from the merged suppliers means that remaining suppliers will face less competition. As a result, they may be able to increase their profits by raising their input prices to the unintegrated downstream firms. Using a Cournot model, Salinger (1988) shows that a vertical merger will reduce the competition in the unintegrated segment of the input market, causing the price of the input to unintegrated firms in the downstream market to rise. He also shows that when no market foreclosure occurs, a vertical mergers causes the price of the final good to decrease.

Since the vertically integrated firms benefit from the cost savings and market foreclosure, their market power increases. Under a typical downward sloping demand curve, the merging firms take

[2]See Krattenmaker and Salop (1986) for a general discussion of potential anticompetitive consequences of vertical mergers.

advantage of their increase in market power by raising price, and both their output and sales will fall. Gugler et al. (2003) show that a vertical merger can increase the degree of vertical contact between the merging firms and their rivals. High vertical contact raises the costs of cutting price in any given market and thus can facilitate more cooperative behavior thereby effectively increasing the merging firm's market power. A vertical merger can also increase market power by raising entry barriers and thus effectively lowering the merging firm's elasticity of demand. Krattenmaker and Salop (1986) point out that by embedding a collusive agreement in a vertical contract that raises input prices, the merged firms can restrain sales to rivals. Salinger (1988) also states that a vertical merger may give an intermediate good producer an incentive to restrict its sales of the intermediate good.

In terms of one of the major motivations of all kinds of M&As - profitability. The market foreclosure theory suggests that the vertical integrated firms may be able to increase their profits by raising their input prices to the unintegrated downstream firms. For example, Ordover et al. (1990) show that these higher prices benefit the vertically integrated firm. If rivals' costs of inputs are increased, they will be forced to reduce their production and raise the prices they charge in the downstream market. This reduction in competition allows the downstream division of the integrated firm to increase its market share and its price. Thus the profits of the vertically integrated firm can rise, even if there are no production efficiency benefits flowing from the vertical integration. D'Aveni and Ravenscraft (1994) also show that vertical integration can increase profits through higher prices by creating barriers to entry, and the integrated firms exhibit higher profitability than non-integrated competitors in the same industry.

Based on the aforementioned theories, we postulate the following hypotheses to examine the effect of vertical mergers on merging firms' operating performance.

Hypothesis 1 *The gross profit margins for merging firms will be positively correlated with vertical mergers.*

Hypothesis 2 *The sales efficiency for merging firms is negatively correlated with vertical mergers.*

Hypothesis 3 *The profitability for merging firms is positively correlated with vertical mergers.*

3.2 Inventory-related performance

As the focus in this paper, we use four different metrics to measure the inventory performance of firms: inventory (INV) which measures the total inventory level of a firms; inventory period (IP) which measures how quickly a firm turns over its inventory; inventory responsiveness (IR), which measures how rapidly a firm adjusts its level of inventory in response to changes in the sales environment; and, gross margin returns on inventory (GMROI), which measures how much a firm earns on every dollar spent on inventory. The last three measures capture different aspects of firm's inventory performance, and hence are complementary in nature. Broadly speaking, IP is a measure of efficiency, GMROI is a productivity/profitability measure, while IR is more related to elasticity.

Inventory and inventory period

In terms of the supply chain inventory management, the major benefits of vertical merger include the information sharing within the integrated firms and the reduction of transaction cost. Lee et al. (2000) point out that sharing sales information can be viewed as a major strategy to counter the bullwhip effect. The bullwhip effect is essentially due to the phenomenon of demand distortion, which creates problems for suppliers, such as grossly inaccurate demand forecasts, low capacity utilization, excessive inventory, and poor customer service. With the integrated supply chain, the merged firms can improve their inventory performance by sharing information and reducing the bullwhip effect, which can lower the total inventory level. Therefore, it is natural to expect the inventory level for the combined firms reduce after vertical mergers.

Hypothesis 4 *The total inventory for merged firms is negatively correlated with vertical mergers.*

On the other hand, D'Aveni and Ravenscraft (1994) shows that vertical integration also results in lower transaction-related costs, but higher production costs. While Lin et al. (2002) find that the more detailed information shared between firms, the lower the total cost, the higher the order fulfillment rate, and the shorter the order cycle time. Combining the effect of vertical mergers on costs and inventory, we postulate the following regarding the merging firms' inventory period.

Hypothesis 5 *The inventory period for merged firms is negatively correlated with vertical mergers.*

Inventory responsiveness

Rumyantsev and Netessine (2007) propose inventory responsiveness metric to link a firm's inventory performance and operating performance. Specifically, they define inventory responsiveness as the difference between the percentage change in inventory level and the percentage change in sales. Hence, if the inventory for a firm is growing at a faster rate than sales, then its inventory responsiveness would be positive, and if it is growing at a slower rate, the value of inventory responsiveness would be negative. Obviously, if they grow at the same rate, then the value would be exactly equal to zero. In essence, inventory responsiveness is a measure of how well the firm adapts its inventory practices in face of changes in demand (sales). Using financial panel data from Compustat, Rumyantsev and Netessine (2007) establish that a faster inventory growth and a faster inventory decline relative to sales are both negatively associated with firm's profitability.

In our context, for vertically merged firms, we expect inventory period to decrease (Hypothesis 5) while gross profit margin to increase (Hypothesis 1). From the definition of these two metrics and coupling with the fact that we expect sales to reduce due to mergers (see Hypothesis 2), inventory should reduce at a faster rate than sales for merging firms, leading to a negative inventory responsiveness. On the basis of above, we postulate:

Hypothesis 6 *Vertical acquisitions result in a negative inventory responsiveness for merged firms.*

Gross margin returns on inventory

Gross margin return on inventory (GMROI) can be used to analyze a firm's ability to turn inventory into cash above the cost of the inventory. This particular metric is calculated as the ratio of the gross margin earned by a firm to its average inventory cost. This is a useful measure as it helps managers to see whether a sufficient amount is being earned compared to the investments in inventory assets. A ratio higher than 1 indicates a positive return on inventory investment, while a ratio below 1 means the firm is selling the product for less than what it costs the firm to acquire it. This ratio can also be expressed as the gross profit margin multiplied by sales-to-inventory ratio. Note that sales-to-inventory ratio is itself related to both the inventory period and gross profit margin.[3] Since we expect gross profit margin to increase (Hypothesis 1) and inventory period to decrease (Hypothesis

[3]Inventory-to-sales ratio is the multiplication of inventory period with COGS-to-sales ratio (i.e., one minus gross profit margin). Sales-to-inventory ratio is the reciprocal of inventory-to-sales ratio.

5), we should observe GMROI for merging firms to increase after mergers. That is:

Hypothesis 7 *The gross margin return on inventory for merged firms is positively correlated with vertical mergers.*

4 Data and Methodology Description

In this section, we discuss the data and methodology we use for establishing the effects of vertical M&As. Our sample is drawn from the population of M&As that took place between January 1, 1997 and December 31, 2006 and is included in the Securities Data Corporation (SDC) Mergers & Acquisitions database. Since we are interested in companies with more inventory related activities, we look for mergers with primary SIC codes in the following ranges: 2000-3999 (manufacturing), 5000-5199 (wholesale trade) and 5200-5999 (retail trade).[4] Moreover, we require all deals in our sample to meet the following criteria: (i) both target and acquirer are U.S. domestic, publicly traded firms, (ii) the announced merger was eventually completed, (iii) the target and acquirer have different primary four-digit SIC code, and (iv) the acquirer did not previously own a majority share of target firm and obtained more than fifty percent of the target's stock through the transaction. The first criteria is to ensure that we have access to their financial data in the Compustat database; the second one is to filter out those merger announcements that did not get approval from authorities; the third one is to exclude other horizontal M&As; and the last requirement is to ensure that transactions have a significant impact on the relationship between two merged firms. Note that throughout this paper we assume the merger date to be the date when the merger was completed (i.e., when there was a change of control of the acquirer to the target) and not when it was announced.[5]

The requirement of target and acquirer having different primary four-digit SIC code does not guarantee the vertical relationship between these two firms. To identify those vertical link between two merged firms, we use the benchmark Make and Use tables obtained from the Bureau of Economic Analysis (BEA) at the U.S. Department of Commerce to create the Input-Output table. The benchmark IO accounts are compiled once every five years and primarily based on the census data

[4] Standard Industry Classification (SIC) is an extensive hierarchical structure of codes developed by the U.S. Department of Commerce to categorize companies based on their industries.

[5] In contrast, most papers in finance (e.g., Shahrur 2005), where the objective is mainly to understand the reaction of the stock market, assume the merger date to be the date when it was announced.

collected by the Bureau of Census. In this paper, we use the 2002 benchmark accounts to define the upstream and downstream industries that experienced horizontal mergers between 1997 and 2006. The Make table is a matrix showing that the commodities (columns) that are produced by each industry (rows) at producers' prices, and the Use table shows the inputs to industry (columns) production and the commodities (rows) that are consumed by industries, consumers and government. The detailed procedure is referred to the appendix of Allayannis and Ihrig (2001). Based on the input-output matrix, we follow the approach by McGuckin et al. (1991) and define a forward (backward) vertical merger that satisfies the input percentage to the target (acquirer) from the acquirer's (target's) industry is more than 5 percent of the total input of the target (acquirer) industry. [6]

For the financial data, we use quarterly financial data for all publicly held U.S. companies with primary SIC codes in the three ranges indicated before (i.e., manufacturing, wholesale and retail sectors) for the 13-year period 1996 - 2008. We obtain this data from Standard & Poor's Compustat database accessed through Wharton Research Data Services (WRDS). We collect them for three years longer than the merger period to ensure that we have at least one (and two) more year data available for the pre- (and post-) merger analysis.

Within the 318 SIC codes covered in our sample, there are 10138 companies whose financial data is available from Compustat, and 1175 acquirers which can be identified from the SDC database.[7] The distribution of vertical M&As covered in our sample is provided in Figure 1. Due to the way Compustat collects data, some of our sample firms have missing value in their accounting data. Therefore, the actual number of usable observations is less than the sample size. For each of the 10138 companies, we collect the quarterly data on the following financial items which are required to calculate the performance metrics of interest to us: asset (data item: ATQ), cost of goods sold (data item: COGSQ), inventories (data item: INVTQ), operating income before depreciation (data item: OIBDPQ), and net sales (data item: SALEQ).

[6]McGuckin et al. (1991) shows that the categorization between a vertical and conglomerate merger are sensitive to this cutoff. And on average, a four-digit SIC code had ten material inputs involving more than 1 percent of total input costs. We use 5 percent cutoff in this paper to filter out the cases where two merged firms are not closely related from a supply chain perspective. D'Aveni and Ravenscraft (1994) define a line of business as vertically integrated when some combination of its forward or backward transfers exceeds 10 percent of its sales or cost of sales.

[7]We use the identifier GVKEY to keep track of each company in Compustat because other firm identifiers such as the company name, CUSIP, or ticker may change over time.

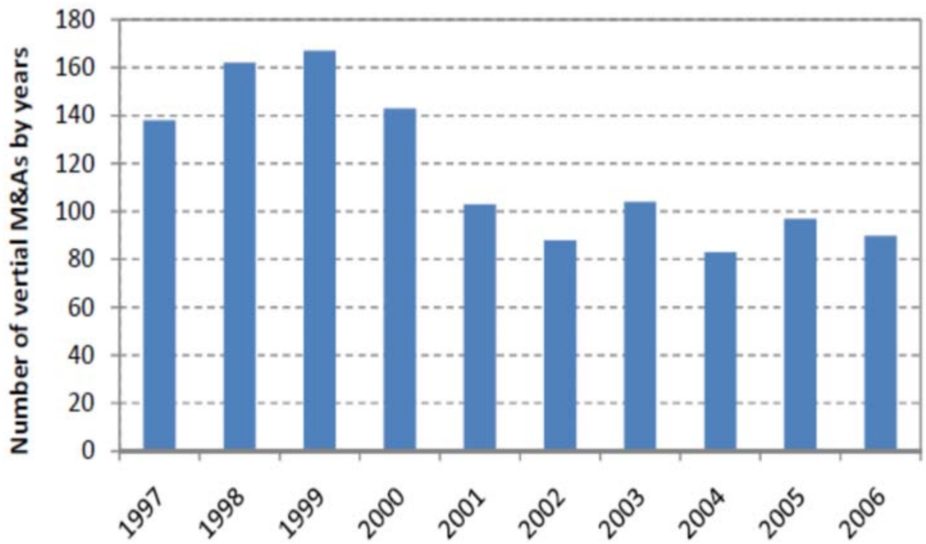

Figure 1: Distribution of 1175 vertical M&As by year

Table 1 provides the basic summary statistics for firms in our sample, based on the last fiscal quarter prior to the effective date of mergers. Several issues need to be discussed in this context. First of all, in contrast to prior research in this area, we include the financial data not only for the merging firms (targets and acquirers) but also for the non-merging ones, because later on we compare the effects of M&As on the performance of the two sets. Second, this table shows that the size of the firms in our sample varies significantly (large standard deviation and range). Moreover, the high kurtosis implies that most of the variance is due to infrequent extreme deviations, and positive skewness means that the mass of the distribution is concentrated on the left and there are relatively few high values.

Based on the above facts, we focus our attention on the change in a firm's performance instead of the level of a firm's performance, and we will mainly use Wilcoxon signed-rank test in our analysis[8]. We will also conduct the t-test and the binomial test to provide robustness checks for the results.

In order to test our hypothesis, we use basic quarterly financial data (e.g., total assets, cost of goods sold, operating income, net sales, and inventory total (INVT)) and compute the performance metrics for each firm i in quarter t as shown in Table 2. We focus our analysis on the four quarters before the merger (quarters -4 to -1) and four years following the merger (quarters 1 to 4). We

[8]Concerning the choice of an expectation model, Barber and Lyon (1996) find that test statistics using the change in a firm's performance relative to an appropriate benchmark consistently yield more powerful test statistics than do those based on the level of a firm's performance relative to the same benchmark. In the choice of statistical test, they find that nonparametric Wilcoxon test statistics are uniformly more powerful than parametric t-statistics, regardless of the operating performance measure employed.

Table 1: Descriptive Statistics for Firms in Our Sample (in million US$)

	Average	Median	St.Dev.	Max	Min	Kurtosis	Skewness
Panel A: Descriptive statistics for 1175 acquiring firms before mergers							
Total Assets	3723.31	334.88	9914.00	111550	1.395	49.96	5.84
Cost of Goods Sold	629.36	53.57	1821.53	22234	0.075	67.42	6.85
Inventory Total	473.63	54.29	1147.91	7791	0.086	17.55	3.95
Operating Income	158.79	6.84	505.21	5212	-255.5	43.45	5.76
Net Sales	997.82	90.67	2421.56	23315	0.038	26.44	4.30
Panel B: Descriptive statistics for 1175 rivals before mergers							
Total Assets	4339.41	913.31	10616.18	120058	0.008	44.27	5.57
Cost of Goods Sold	560.98	124.46	1131.25	10982.7	0.132	26.11	4.30
Inventory Total	435.42	119.64	840.55	6701	0.101	15.73	3.62
Operating Income	216.01	24.18	608.86	4036	-146.2	18.47	4.24
Net Sales	1072.15	211.40	2138.01	13982	0.011	10.95	3.17
Panel C: Descriptive statistics for all 10138 firms in sample							
Total Assets	2584.22	160.04	12105.20	479921	0.001	299.03	14.24
Cost of Goods Sold	422.36	28.11	2372.20	189081	0.001	658.82	20.03
Inventory Total	229.48	22.33	1015.30	40416	0.001	321.10	14.41
Operating Income	95.64	3.57	533.70	25324	-5810.1	383.16	16.02
Net Sales	595.73	45.43	2983.40	195805	0.001	455.62	16.95

exclude quarter 0, the quarter of the merger, from the analysis because in this quarter the two firms are consolidated for financial reporting purposes only from the merger completion date. Consistent with previous studies, we combine the target and acquiring firms' financial data before the merger to obtain the pro forma pre-merger performance of the combined firms. Then, for each sample firm, comparison of the relative change between the pre-merger and post-merger quarterly average performance provides a measure of the percentage change in absolute performance of the merging firms due to the merger. An exception is the inventory responsiveness (IR) metric, which is by definition involves a rate of change (difference between percentage changes in sales and percentage changes in inventory). For this reason, we compute the merger induced changes in IR by subtracting the *average* quarterly change in sales (pre- and post-merger) from the *average* quarterly change in inventory (pre- and post-merger).

We recognize that some of the changes in performance between pre- and post-merger could be due to macroeconomic and/or industry-specific factors. Hence, to rule out the potential industry or economy related effects, in line with previous studies (e.g., Healy et al. 1992 and Barber and Lyon 1996), we use the industry-average performance as a benchmark to evaluate the merging firms'

Table 2: Definitions of Performance Metrics

Operating Performance	Metrics
Gross profit margin	$GPM_{it} = \frac{SALEQ_{it} - COGSQ_{it}}{SALEQ_{it}}$
Sales efficiency: Sales on assets	$SOA_{it} = \frac{SALEQ_{it}}{ATQ_{it}}$
Profitability: Return on assets	$ROA_{it} = \frac{OIBDPQ_{it}}{ATQ_{it}}$
Profitability: Return on sales	$ROS_{it} = \frac{OIBDPQ_{it}}{SALEQ_{it}}$
Inventory Performance	**Metrics**
Total inventory	$INV_{it} = INVTQ_{it}$
Inventory period	$IP_{it} = \frac{INVTQ_{it}}{COGSQ_{it}}$
Inventory responsiveness	$IR_{it} = \frac{INVTQ_{it} - INVTQ_{i,t-1}}{INVTQ_{i,t-1}} - \frac{SALEQ_{it} - SALEQ_{i,t-1}}{SALEQ_{i,t-1}}$
Gross margin return on inventory	$GMROI_{it} = \frac{SALEQ_{it} - COGSQ_{it}}{INVTQ_{it}}$

Note: *ATQ* stands for total asset, *COGSQ* stands for cost of goods sold, *INVTQ* stands for total inventory, *OIBDPQ* stands for operating income before depreciation, and *SALEQ* stands for net sales.

industry-adjusted post-merger performance.[9]

Similarly to pervious studies, such as Hendricks et al. (2007), we denote P_{it} as the average quarterly performance for firm i in year t. The firm i's industry average quarterly performance in year t is PI_{it}. Then ΔAP_{it}, the industry-adjusted percentage change in performance for merging firms i in year t is

$$\Delta AP_{it} = \frac{P_{it} - P_{i,t-1}}{P_{i,t-1}} - \frac{PI_{it} - PI_{i,t-1}}{PI_{i,t-1}}.$$

To illustrate how to compute the adjusted performance, consider the following example: Suppose

[9] To check the robustness of our results, we also used the industry median performance as a benchmark to adjust the merging firm's performance. In that case, the signs of all the changes in the performance metrics of our interest are the same as the results we report, but the level of significance is weaker. We choose to focus on the industry-average adjusted performance because sometimes the industry-median performance happens to be the same as the sample firm's performance, which reduces the significance of the results.

during one year prior to the merger quarter, the average quarterly return-to-assets (ROA) ratio for the pro-forma combined firms is 0.048; and during one year subsequent to the merger quarter, the average quarterly ROA for the merged firm increases to 0.052. Therefore, there is 8.3% increase in ROA during the first year following the merger. For the same time period, we calculate the percentage change in ROA for every non-merging firms in the industry and find that the industry average ROA ratio increases by 4%. In this case, the industry-adjusted percentage change in ROA is 4.3% for the merging firm. [10]

5 Empirical Results

In this section, we report our empirical results. We start by studying the effects of M&As on the absolute performance of the merging firms. Next, we investigate how those effects compare to the effects on the industry average performance. Subsequently, we directly compare the effects on the merging firms to the effects on the performance of the matching rivals. We end this section by discussing whether (and if so, how) our results change if we take into account long-term effects of mergers (two-year post-merger rather than one).

5.1 Effects on the absolute performance

The effects of M&As on the absolute performance of the merging firms is shown under the "+1 Year Absolute" columns in Table 3. From the table we observe that the basic financial measures (e.g., Assets, COGS, Income and Sales) increase significantly after mergers.[11] As regards to operating performance, in general, the gross profit margin of the merging firms decreases significantly (by about 1%) with 54% of the firms showing deterioration. The sales efficiency also decreases significantly (by about 4%) for most of the merging firms. In terms of profitability, it seems that vertical mergers result in lower absolute profitability for the merging firms - both return on assets and return on sales measures decrease significantly (by 10% and 4% respectively).

[10] Note that, similar to Barber and Lyon (1996) and Hendricks and Singhal (2003), throughout this document, we discard extreme values by symmetrically winsorizing the data at the 1% level in each tail while calculating the ratio measures.

[11] Throughout this section, we focus on the median change in performance (as in Healy et al. (1992)) for analyzing the effects of M&As, although we also report the mean change in performance in the summary tables. The reason for this is the fact that the mean is affected by extreme values.

Table 3: Effects of vertical mergers

This table presents the merging firms' absolute and industry-adjusted performance during the period from one year before mergers to one year after mergers. Panel A reports the percentage changes in basic financial performance, Panel B reports the percentage changes in operating performance, and the percentage changes in inventory performance are reported in Panel C. We use t-test for the mean, Wilcoxon sign rank test for the median, and the binomial sign test for the percentage of negativity. The statistics are given in the row denoted "statistic" and the superscripts *, **, and *** indicate that the result is significantly different from zero at 0.10, 0.05 and 0.01 level for two-tailed tests, respectively.

More importantly, there is *no significant positive impact* on the absolute inventory performance due to vertical mergers. For example, mergers result in about 54% of the merging firms turning their inventories slower resulting in a significant 2% increase in the inventory period. This lower turn does not manifest itself in higher productivity returns from inventory investments or more responsive inventory management. Due to the significant increase in inventory (21%) and decrease in GPM, GMROI also reduces significantly. Comparing the growth in merging firms' sales and inventory, the significantly positive IR shows that the increase in inventory outweighs the increase in sales (by 3%). In summary, during the first year after vertical mergers, the merged firms experienced significant deterioration in their absolute operating and inventory related performance. This finding is consistent with the results of an Accenture survey of business executives involved in their companies' mergers or acquisitions that more than 40% of them observed problems in inventory management. (Byrne 2007).

5.2 Effects on the relative performance compared to industry average

The effects on the absolute performance discussed above do not tell the whole story since the macroeconomic factors that might affect the whole industry sector are not taken into account. To deal with this issue, in this section, we investigate the effects on the industry-adjusted performance of merging firms, where we use the effects of M&As on the industry average performance as the benchmark. We refer the readers to §4 for more details about how we calculate the adjusted performance. We proceed with the testing of the seven hypotheses about operating and inventory performances developed in §3 based on adjusted performance. As mentioned before, because of the large disparity among observations, we use the Wilcoxon signed-rank statistics to test our hypotheses and report the t-test statistics and the binomial test statistics to provide robustness checks for the results. Generally speaking, we find that the results of Wilcoxon signed-rank test and binomial test are always in good agreement, while the results of paired t-tests are not always consistent with the other tests because of the presence of extreme values. Before discussing about the effects on operating and inventory performances, we briefly discuss the effects of M&As on the basic financial performance metrics.

Basic financial performance. Under the "+1 Year Industry-adjusted" columns in Table 3, Panel A shows the percentage changes in financial data items - assets, COGS, operating income and sales - for the merging firms. The positive values of Wilcoxon sign rank z-statistic for assets, COGS, and sales indicate that compared to the average level of merging industry, merging firms experience *significantly faster growth in financial performance* after the vertical integration, all significantly different from zero at 1% level. More than 60% of the merged firm experience a significant increase in sales. The only financial performance metric that does not experience a significant change after mergers is the percentage change in operating income before depreciation.

Operating performance. The percentage changes in operating performance metrics are shown in Panel B of Table 3. Looking at the percentage changes in industry-adjusted profit margin, the statistics show that the merging firms' adjusted profit margin is not significantly different from the industry benchmark. This result does not support our first hypothesis that vertical mergers generate market power to the merged firms. However, there are strong indications that *the sales efficiency of the merging firms actually decreases.* Specifically, the industry-adjusted median value of percentage change in Sales on Assets (SOA) metric for merging firms reduces by 13% (significantly different from zero at 1% level). The binomial z-statistics also generate similar results with over 73% of merging firms experiencing a decrease of industry-adjusted SOA within four quarters after the transactions. So, there is strong support for our second hypothesis that the sales efficiency for the merging firms is negatively correlated with M&As. This is because the acquiring firms' post-merger growth in sales does not occur as fast as the growth in total assets (including inventories).

Lastly, we come to the most important operating performance measure - profitability. In the literature, profitability is usually measured by return on assets, i.e., ROA and/or by return on sales, i.e., ROS (Griffin and Mahon 1997; Dehning et al. 2007). Although the industry-adjusted performance looks better than the merging firms' absolute performance, unfortunately, the evidence shows that for both measures, vertical M&As deteriorate the profitability of the merging firms. Specifically, we note that there are negative changes in industry-adjusted ROA and ROS of merging firms (-4% and -2% respectively), which are significant at 1% level. This result is mainly driven by the fact that merged firms failed to achieve a significant improvement in operating income compared to the industry benchmark, although they are still able to increase the absolute operating income.

In summary, our empirical evidence shows that during the first year after vertical mergers, there is no any improvement in merging firms' operating performance, which is characterized by lower sales efficiency and lower profitability.

Inventory performance. The merger effects on industry-adjusted inventory performance is illustrated under the "+1 Year Industry-Adjusted" columns in Panel C of Table 3. In this context, first note that there is a significant increase in the growth of inventory held by merging firms, comparing to the industry benchmark. The median of post-merger inventory for merging firms increased 14% more than the change in the industry average level and around 37% of the merging firms' inventory growth is faster than the industry average level. This suggests that *the merging firms' inventory growth is significantly faster than their industry average level*; however, total inventory is an aggregate measure, which does not take into account the size of the firm. A better measure of inventory efficiency is inventory period (= average inventory / COGS) with a lower value of inventory period representing more efficient firms and vice versa. *From inventory efficiency perspective, merging firms are also worse than the industry average.* Due to the significant increase in industry level, merging firms' inventory periods also become longer after mergers. 55% of the merging firms' post-merger inventory periods performance is worse than the industry benchmark, and the median increase of industry-adjusted inventory period is 3%.

While the above evidence suggests that vertical mergers do not improve inventory efficiency (compared to the industry average), we also need to understand how they affect two other relevant inventory management measures: inventory responsiveness (IR) and gross margin return on inventory (GMROI). In terms of inventory responsiveness, we find that *there is significantly positive impact on the inventory elasticity metric due to M&As*, which means the industry adjusted inventory growth is faster than the industry adjusted sales growth. This fact partly explains the reduction in merging firms' sales efficiency. Moreover, we find that inventory investments are not be providing much returns to the merging firms, compared to the industry average. Rather, the median change in GMROI decreases by 5% for merging firms, with around 54% of them experiencing a significant decline. The underlying reason for this results is that the industry adjusted inventory increases faster than profit margin.

In summary, inventory-related operations for merging firms deteriorate after vertical mergers since their inventory efficiency and inventory productivity reduce. In other words, after vertical mergers, merging firms hold inventory for a longer period, and for each dollar spent on inventory, fewer profit dollars is generated in the first year after mergers than in the year prior to the merger quarter. All of these evidence suggests that vertical mergers do not benefit firms in inventory management at least in a short term.

5.3 Long-term effects of mergers

There are two main reasons to extend our analysis beyond the first year post merger: i) to assess the robustness of the short-term effects of mergers; and ii) to measure the potential bias due to the accounting treatment. In mergers where the purchase accounting method is used to account for the business combination, all the assets of the target firm have to be marked to market before being combined with the acquirer's book assets, and the difference between the purchase price and the revised book value of target firm's equity is recorded as goodwill in the acquirer's book. This accounting treatment might result in increases in the values of target total assets. Thus, results for this year are therefore not comparable across firms or for industry comparisons Healy et al. (1992). To mitigate the effects of such accounting adjustment, it is worthwhile to investigate how our results of the previous section are affected if we consider the long term effects of M&As. Specifically, rather than one year post-merger, in this section we calculate the percentage changes in performance metrics from one year to five years after the transaction. These results are exhibited in Figure 2 for the merging firms for two levels of analysis - unadjusted and industry-average-adjusted.

Based on comparison of the results in this table to those in Figure 2, we can see that, broadly speaking, most of previous performance metrics improves over time, in both absolute and relative measures. In terms of operating performance, merging firms' profit margins gradually improve and catch up with the industry average level. The adjusted changes in sales efficiency and profitability also became insignificant since the second year after mergers. As for the absolute performance, we observe an evident increase in merging firms' sale efficiency since the third year after mergers.

Regarding the inventory related performance measures, the first thing we noticed is that merging firms' inventory growth is significantly slower than the industry average benchmark since the second year after mergers, which implies a potential improvement in the inventory management of vertically integrated firms. The evidence from other performance measure verified such an improvement. The adjusted inventory period (IP) is reduced from the second year and maintains the same level as the industry average level. The adjusted inventory responsiveness (IR) and inventory productivity (GMROI) are also insignificantly different from the industry level since the second year after mergers. The absolute measures even showed some improvement in these measures.

Overall, looking at the long-term changes in merged firms' performance, we find that although mergers deteriorate firms' operating and inventory related performance immediately after the vertical integration, the negative effects diminish over time. Generally speaking, it takes about at least two years for the merged firms to recover from the merger and match the industry average performance. Interestingly, even after five years following vertical mergers, there is still no significant evidence showing that vertical mergers create a competitive advantage over industry average benchmarks.

Figure 2: Long-term effects of vertical mergers

This figure presents the merging firms' absolute and industry-adjusted performance during the period from one year to five years after mergers. Solid bars represent the absolute performance, while striped ones represent the industry-adjusted performance. The pink, yellow, and green color indicate that the result is significantly different from zero at 0.01, 0.05 and 0.10 level for two-tailed tests, respectively.

6 Summary and managerial implications

In this paper, we conduct a cross-industry empirical study of vertical mergers and acquisitions that took place between 1997 and 2006 in manufacturing, wholesale and retail sectors. Our primary focus is on inventory-related supply chain metrics, while we also report to the effects on operating performance and financial performance. The comparison between merging firms' absolute performance and industry average benchmark provides a detailed evidence on the impact of vertical M&As. To investigate the consistency of the effects over time, we extend our analysis up to five years following the transactions.

In general, we find that immediately following the vertical mergers, merging firms' operating and inventory performance deteriorate significantly. Merging firms suffer from a significant reduction in their gross profit margin and sales efficiency. The profitability is also lower than the pre-merger level. Regarding the performance in inventory related measures, the significant buildup in merging firms' inventory levels increases their inventory period while reduces the inventory productivity. The growth in inventory is much faster than the growth in sales. All these evidences suggest that merged firms experience significantly negative effect subsequent to the vertical M&As.

Looking at the long term performance of merging firms, we find that over the five years following the vertical transaction, merging firms continued to recover from the negative consequences of mergers. Generally speaking, it takes at least two years for merged firm to catch up with the industry average performance. However, there is no significant evidence showing that merged firms exhibit superior performance over the industry benchmark, even after considerable time, which suggests that vertical mergers do not provide significant competitive advantages to the merging firms.

Abstract

This study employed the Enders and Siklos (2001) asymmetric threshold co-integration frameworks, including the M-TAR model and the logistic smooth transition co-integration model to investigate whether the contagion effects had existed in international stock markets by using the changes in the asymmetric long-run equilibrium relationships between the U.S. S&P 500 index and eighteen stock markets in Asia, Europe, and America around the Subprime Mortgage Crisis between 2007 and 2010. The main empirical findings demonstrated that with the application of Engle and Granger (1987) symmetric co-integration test, the Subprime Mortgage Crisis did not reinforce the co-movement trends between the S&P 500 index and these stock markets. However, with the application of the asymmetric co-integration frameworks, there was significantly increase in these co-integration relationships between them after Lehman Brothers filed the bankruptcy on September 15, 2008, and the transition speeds between these two regimes also substantially increased in the logistic smooth transition co-integration model. Both the M-TAR model and the logistic smooth transition co-integration model showed that there existed a contagion effect between them in the aftermath of Lehman Brothers' bankruptcy. Only the China market was not transmitted by the U.S. market during this crisis; there was only an interdependence effect between the U.S. market and China market. Furthermore, the result showed that the event of the Subprime Mortgage Crisis determined the degrees of contagion effects depending on the financial linkage to the U.S. markets, which further demonstrated the differences in the causes and influence between the Subprime Mortgage Crisis and other financial crises in emerging markets.

Keywords: *Threshold Co-integration Model; Logistic Smooth Transition Co-integration Model; Contagion effect; Stock Market; Subprime Mortgage Crisis.*

1. Introduction

In early March 2007, there was a credit crisis in New Century Financial Corp., the second largest mortgage company in the U.S. It ignited the Subprime Mortgage Crisis, which disordered the financial markets in the U.S. and Western Europe (Longstaff, 2010). Fed passed the bailout plan for investment banks and institutions and has poured more than 1000 billion dollars into the financial markets to purchase the non-performing loans to rescue the liquidity of the U.S. financial markets in Quantitative Easing (QE);[1] the European Central Bank (ECB) and the Bank of Japan have also adopted similar policies recently. The Subprime Mortgage Crisis also hit the real output of the U.S. and global economy. Scholars thought the chain reactions incurred by the Subprime Mortgage Crisis have never been seen since the Great Depression.

Past literature about the contagion phenomenon due to financial crises by Lee and Kim (1993), Forbes and Rigobon (2002), Caramazza *et al*. (2004), Dungey *et al*. (2006), Lucey and Voronkova (2008), Gilmore *et al*. (2008), Arouria *et al*. (2009) about the contagion effect or the transmission effect was based on the backgrounds of several financial crises since the late 1980s, including those in the U.S. (1987), Mexico (1994), Thailand (1997), Russian (1998), and Argentina (1999). Recent literature, such as that by Sikka *et al*. (2009), Swan (2009), Longstaff (2010), Claessens *et al*. (2010), Abad *et al*. (2010), Sobreira (2011), Iyer and Peydro (2011), Samarakoon (2011), Afonso *et al*. (2012), Frankel and Saravelos (2012) and Dumontaux and Pop (2013) about the contagion effect was based on the backgrounds of the Subprime Mortgage Crisis and the EMU Sovereign-Debt Crisis.

Although the collapse of the New York stock market in 1987 triggered a global

---

[1] The QE was divided into QE I (2008), QE II (2010), QE III (2012) and QE IV (2013) from 2008 to 2014.

stock market crash, the background of the macroeconomic and technological applications was a lot different from that of the current one in terms of globalization and liberalization of the trade environment and the rapid development of capital markets in emerging countries. Freer capital flow among international security markets, electronic trading systems and the linkage of the Internet in stock markets as well as highly developed derivatives have all accelerated the speed of information transmission and increased the links of the international security markets, and these factors have brought about significant differences between the Subprime Mortgage Crisis and the U.S. stock market collapse in 1987. Other financial crises in Mexico, Thailand, Russia and Argentina were only regional crises from emerging markets; therefore, the scope of their influence was only limited to their neighboring countries where the crises occurred, and these crises did not spread globally; apparently, the impact of the Subprime Mortgage Crisis was greater than the above events. The loose financial regulatory systems, high financial deficits and government debts, insufficient foreign exchange, and unstable exchange rates in these emerging countries all contributed to the consequences of the financial crises in these countries.

However, the excessively issued derivatives by banks and the major negligence in the financial regulatory systems in the U.S. and Western European countries caused the Subprime Mortgage Crisis in the U.S. between 2007 and 2010, while nearly no government or research institution had provided early warnings for the imminent Subprime Crisis except very few economists. The recent Subprime Mortgage Crisis, which seems to have had a perceived structural change to the influences of the U.S. stock market, has had a great effect upon the major financial markets of the whole world. Therefore, we used this crisis as the breaking point to investigate the influence of the U.S. stock market on the Asian, European, and American stock markets.

Because past research about the contagion effect due to financial crises mostly emphasized the crises from emerging markets or developing countries, the scope of their influence was limited. The Subprime Mortgage Crisis, which has caused a global financial crisis, was a rare incidence in the past one hundred years; nevertheless, its impact can still be seen at present. How were the relationships between the U.S. stock market and global stock markets affected when an impact of a significant risk event occurred, e.g. the Subprime Mortgage Crisis in the U.S. financial market, due to the stronger links of the international financial markets? Was the impact more significant during the period of "the Subprime Mortgage Crisis" than during the period of "tranquil times"? Was the relatedness changed by the negative impact of the Subprime Mortgage Crisis? This study attempts to clarify the relationship changes between the U.S. stock market and international stock markets during tranquil times and during crisis times. On the one hand, we want to offer our opinions to investors about investing in international security markets; on the other hand, we also hope to provide references to government departments on policy-making for financial oversight, which was the first research motivation of our study.

Past literature about the contagion effect often employed the co-integration method to examine whether a co-integration relationship around a crisis had changed, and whether the contagion effect had existed. Two points will be considered in this study; first, the assumption of "symmetric adjustments" in the traditional co-integration model ignored that the adjustment speeds were different when the stock market was in an upward status or in a downward status. Therefore, to seek a better method to confer the interaction among international stock markets has become the main topic in this article. We employed the Enders and Siklos (2001) asymmetric threshold co-integration test to compare the changes in the asymmetric co-integration relationship between the U.S. stock market and the other stock markets around the Subprime Mortgage Crisis; we wanted to investigate the regime-switching behavior in these co-integration relationships, which was the second research motivation of our study.

However, the Enders and Siklos (2001) threshold co-integration model is not accurately and fully specified when the transition of the transitional variables or threshold variables is a jump transition process. The problems, such as whether the transition of the transitional variables is smooth between two regimes or whether there is heteroscedasticity in the information transmission in international stock markets, are seldom considered in the Enders-Siklos threshold co-integration method.

The second point was to investigate how the asymmetric adjustment and the smooth transition phenomenon influenced the contagion effect. We applied the logistic smooth transition regressive (LSTR) method proposed by Granger and Teräsvirta (1993) and Teräsvirta (1994), which was the expansion of the Enders-Siklos threshold co-integration model, which was the logistic smooth transition co-integration model, to compare the contagion effect from the U.S. stock market to the Asian, European, and American stock markets pre- and during the Subprime Mortgage Crisis.

The correlation analyses of the stock index return and the volatility of the stock index return, Engle and Granger (1987) symmetric co-integration tests, Enders and Siklos (2001) threshold co-integration model, and the logistic smooth transition co-integration model were employed to investigate the contagion or transmission effect from the U.S. stock market to global stock markets in this study. Furthermore, we employed the KSS's exponential smooth transition autoregressive (ESTAR) unit root test by Kapetanios *et al.* (2003) to examine the phenomenon of non-linear stationary in the data of all the stock markets in this study before we investigated the asymmetric transmission effect.

The structure of this article is arranged as follows: Previous literature will be discussed in Section 2, the main methodologies in Section 3, the data and empirical results in Section 4, and the conclusions in Section 5. The flow charts of this dissertation follow the conclusions.

2. Literature Review

World Bank has given contagion three definitions, namely, a broad definition, a restrictive definition, and a very restrictive definition. The broad definition means that contagion is the cross-country transmission of shocks or the general cross-country spillover effects; contagion does not need to be related to crises. The restrictive definition means that contagion is the transmission of shocks to other countries or the cross-country correlation, beyond any fundamental link among the countries and beyond common shocks. This definition is usually referred to as excess co-movement, commonly explained by herding behavior. The very restrictive definition means that contagion occurs when cross-country correlations increase during "crisis times" relative to correlations during "tranquil times".

In academic literature, a crisis contagion theory explained that if there was co-movement or a common trend between different markets, then a shock in one market would transmit to another market. Dornbusch *et al.* (2000) defined contagion as a significant increase in cross market linkages after a shock to an individual country or market, as measured by the degree to which asset prices or financial flows moved together across markets relative to this co-movement in tranquil times. Forbes and Rigobon (2001) divided how the shocks were propagated into two groups of theories: crisis-contingent and non-crisis-contingent theories.

Crisis-contingent theories are those that explain why transmission mechanisms change during a crisis, and therefore, why cross-market linkages increase after a shock. Non-crisis-contingent theories assume that transmission mechanisms are the same during a crisis or at more stable periods, and therefore, cross-market linkages do not increase after a shock. Kaminsky *et al*. (2003) redefined a contagion effect, which was a strong "immediate effect" from a market to other markets after a filed crisis event, by using several previous financial crises as references; they also pointed out that one of the main crisis transmission mechanisms was international trade. We adopted the very restrictive definition by World Bank in this study.

In empirical research, Dornbusch *et al.* (2000) and Forbes and Rigobon (2001, 2002) pointed out that four different approaches had been utilized to measure how shocks were transmitted internationally: cross-market correlation coefficients, ARCH or GARCH frameworks, co-integration techniques, and direct estimation of specific transmission mechanisms by using the Probit model.

Many researchers considered significant increases of correlation or co-movement of the stock markets were the indicators of a contagion effect. King and Wadhwani (1990) and Lee and Kim (1993) used the correlation approach and found that international stock markets had become more interrelated after the U.S. stock market collapse in October 1987. Cha and Oh (2000) showed evidence that the links between the developed markets and the Asian emerging markets began to increase after the 1987 U.S. stock market collapse and the 1997 Asian Financial Crisis. The strengthening co-movement among international stock markets continued for a longer period after the collapse.

Forbes and Rigobon (2002) argued that tests for contagion based on cross-market correlation coefficients were problematic due to the bias introduced by changing volatility in market returns (heteroskedasticity). They showed that correlation coefficients were conditional on market volatility. Under the assumption of no omitted variables or endogeneity, it is possible to adjust this bias. By using this adjustment, there was virtually no increase in unconditional correlation coefficients (i.e., no contagion) during the 1997 Asian Financial Crisis, 1994 Mexican devaluation, and 1987 U.S. stock market collapse. There was a high level of market co-movement, which they called interdependence, in all periods. Caporale *et al.* (2005) modeled the conditional variance by the application of both heteroskedasticity and endogeneity biases and invented a common shock to deal with the omitted variable problem. They found the existence of contagion within the stock markets in Hong Kong, Japan, South Korea, Singapore, Taiwan, and Malaysia during the 1997 Asian Financial Crisis.

Hamao *et al.* (1990) utilized the GARCH model and indicated that the volatility spillovers of the stock indices from New York to Tokyo, London to Tokyo, and New York to London after the 1987 U.S. stock market collapse were observed. Eun and Shim (1989) used the VAR model and found that a substantial amount of multi-lateral interaction existed among the international stock markets. Innovations in the U.S. were rapidly transmitted to other markets in a clearly recognizable fashion, whereas no single foreign market could significantly impact the movement of the U.S. stock market.

Arshanapalli and Doukas (1993) reported that co-integration relationships did not exist in the France, Germany, and the U.K. stock markets and the U.S. Dow Jones index before the 1987 U.S. stock market collapse; however, there were co-integration relationships between them after the U.S. stock market collapse. Sheng and Tu (2000) found that co-integration did not exist in the eleven Asian stock markets and U.S. stock markets before the 1997 Asian Financial Crisis, but it did during the financial crisis, which demonstrated a contagion effect. Bekaert *et al*. (2005) also reported that co-integration relationships did exist among the Asian stock markets during the period of the 1997 Asian Financial Crisis, which demonstrated a contagion effect.

In recent years, many scholars have researched on the Subprime Mortgage Crisis and EMU Sovereign-Debt Crisis. Gorton (2008) was thorough in his work of the derivatives about the subprime mortgage loan, e.g. Mortgage Backed Securities (MBS), Collateralized Debt Obligations, (CDOs) and Credit Default Swap (CDS), as well as their developing processes, issue modes and structures. Longstaff (2010) discussed the contagion effect from the CDOs to the security markets in the U.S. between 2006 and 2008; the ABX index of CDOs was employed to examine whether the contagion effect existed in the mortgage bond market in this study, and it was found that the contagion effect spread first from the lower credit rating CDOs to the higher credit rating CDOs in the CDOs market and then from the CDOs market to the markets of treasury bills and stock. Hui and Chung (2011) discussed the transmission effect from the CDS market to other financial markets in Eurozone during the period of the EMU Sovereign-Debt Crisis, and they found that the information flow in the CDS, futures, and options markets was the main cause which resulted in the spread of the crisis.

If co-integration exists between international stock markets, there will be a common trend. However, the problems of "non-linear" or "asymmetric" characteristics are not considered in the traditional co-integration model. Li and Lam (1995), Koutmos (1998), and Chiang (2001) pointed out that co-integration between stock markets was asymmetric; Wang and Lin (2005), Shen *et al*. (2007), and Chang (2008, 2010) further employed the asymmetric co-integration test for their empirical studies. On the other hand, the threshold co-integration model is not accurately and fully specified when the transition of the threshold variables is a jump transition. The problems of whether the transition of the transitional variables is smooth between two regimes or that there is heteroscedasticity in the information transmission in international stock markets are seldom considered in the threshold co-integration method.

To investigate how the asymmetric adjustment and the smooth transition phenomenon influenced the contagion or transmission effect, we applied the threshold co-integration method and the logistic smooth transition co-integration model to compare the contagion effect from the U.S. stock markets to the Asian, European, and American stock markets pre- and during the Subprime Crisis; therefore, asymmetric adjustments and smooth transition could exist in an upward status (positive impact) or a downward status (negative impact). How did the two phenomena influence contagion effects of the stock markets? Did different correlations, co-movement, interdependence, or contagion effects exist in bull markets or bear markets? These issues were seldom discussed in previous literature; therefore, we decided to explore these problems by the threshold co-integration model and the logistic smooth transition co-integration model.

What is the impact of the U.S. stock market collapse on the global stock markets during the Subprime Mortgage Crisis? Is co-integration strengthened during the financial disaster? The issue of the contagion effect in some countries in Asia, Europe and America, which we have selected for this paper, is carefully examined.

3. Methodologies

3.1 The M-TAR Model

In order to examine the "asymmetric transmission effect" from the U.S. to seven major Asian, seven major European, and four major American stock markets during the period of the Subprime Mortgage Crisis, we employed the Enders and Siklos (2001) M-TAR model of asymmetric threshold co-integration. Conventional tests for the unit root and co-integration, whether proposed by Engle and Granger (1987) or Johansen (1988. 1990, 1994), are misspecified when the adjustment process of the one-period lagged error term is asymmetric. The Enders and Siklos (2001) technique extended the Engle and Granger (1987) framework to test non-linear co-integration (also see Enders and Granger, 1998). In our analysis of the transmission effect from the U.S. stock market to Asian, European and American stock markets around the Subprime Mortgage Crisis, we employed the Enders and Siklos (2001) test for threshold co-integration. First, the long-term equilibrium relationship is as follows.

$$Y_{i,t} = \eta_0 + \eta_1 X_{t^*} + \varepsilon_{i,t} \qquad i = 1, 2 \ldots\ldots\ldots, 18 \tag{1}$$

where $Y_{i,t}$ was the logarithm of the Asian, European and American stock indices for country i on period t and $i = 1, \ldots\ldots, 18$ represents the eighteen countries in our study, respectively. X_{t^*} implies the logarithm of the U.S. stock index, while t^* represents period $t-1$ in the U.S. market, which stands for the U.S. market versus the Asian and European markets, but period t in the U.S. market, which stands for the U.S. market versus the American markets, when the time lag of the trading day had to be considered. (Eun and Shim, 1989; Liu *et al*., 1998). $\varepsilon_{i,t}$ measures the estimated residuals. Enders and Siklos (2001) modified ε_t to allow for two types of asymmetric error corrections based on a co-integrating relationship as depicted in (1).

$$\Delta\varepsilon_t = M_t \rho_1 \varepsilon_{t-1} + (1 - M_t)\rho_2 \varepsilon_{t-1} + \sum_{i=1}^{p-1} \beta_i \Delta\varepsilon_{t-i} + \zeta_t \tag{2}$$

$$M_t = \begin{cases} 1 & \text{if } \Delta\varepsilon_{t-1} \geq r \\ 0 & \text{if } \Delta\varepsilon_{t-1} < r \end{cases} \tag{3}$$

where M_t is the Heaviside indicator function, r denotes the unknown threshold value,[2] and ζ_t is the residual of the white-noise disturbance. (2) and (3) represent

[2] The threshold value is endogenously determined by using the Chan's (1993) grid search method to find the consistent estimate of the threshold. This method arranges the values, $\{\Delta\varepsilon_t\}$, in an

the M-TAR model.[3]

In the M-TAR model, the adjustment is modeled by $\rho_1\varepsilon_{t-1}$ that $M_t = 1$ when the threshold variable, as the lagged different error term ($\Delta\varepsilon_{t-1}$) is above the threshold value r and by $\rho_2\varepsilon_{t-1}$ that $M_t = 0$ when $\Delta\varepsilon_{t-1}$ is below the threshold value. The no co-integration hypothesis ($H_0 : \rho_1 = \rho_2 = 0$) was tested using specifically derived critical values provided by Enders and Siklos (2001). If the null of no co-integration was rejected, the null of symmetric ($H_0 : \rho_1 = \rho_2$) can be tested using a standard F-test.

3.2 The Logistic Smooth Transition Co-integration Model

When we examined the "asymmetric contagion effect" from the U.S. stock market to Asian, European, and American stock markets during the period of the Subprime Mortgage Crisis, we also had to consider the problem of whether the transition process of the threshold variable was a smooth transition between two regimes. Therefore, we applied the Granger and Teräsvirta (1993) and Teräsvirta (1994) logistic smooth transition regression (LSTR) technique to further extend the Enders and Siklos (2001) M-TAR framework, which is called the logistic smooth transition co-integration model. And, the long-term equilibrium relationships between the U.S. stock market and the eighteen stock markets were measured by $\varepsilon_{i,t}$, which was estimated via OLS (1)..

---

ascending order and excludes the smallest and largest 15 percent, and the consistent estimate of the threshold is the parameter that yields the smallest residual of sum squares (RSS) over the remaining 70 percent.

[3] Enders and Granger (1998) pointed out the M-TAR model was especially valuable when adjustment was asymmetric such that the series exhibited more "momentum" in one direction than the other.

Next, we employed the foregoing model to test non-linear co-integration or asymmetric co-integration with a logistic smooth transition process between our samples, which is generalized from the Enders-Siklos M-TAR framework as:

$$\Delta\varepsilon_t = \rho_1\varepsilon_{t-1} + (\rho_2\varepsilon_{t-1})q(\Delta\varepsilon_{t-1};\gamma,r) + \sum_{i=1}^{p-1}\beta_i\Delta\varepsilon_{t-i} + \omega_t \tag{4}$$

With

$$q(\Delta\varepsilon_{t-1};\gamma,r) = \left(1+\exp(-\gamma(\Delta\varepsilon_{t-1}-r))\right)^{-1}, \qquad \gamma \ge 0 \tag{5}$$

where $q(\Delta\varepsilon_{t-1};\gamma,r)$ is the logistic smooth transition function, $\Delta\varepsilon_{t-1}$ is the threshold variable or transition variable, r is the threshold value or location parameter and ω_t is the residual of the white-noise disturbance ($\omega_t \sim$ iid (0, σ^2)), and γ is the smooth parameter or slope parameter in $q(\Delta\varepsilon_{t-1};\gamma,r)$, which is employed to measure the transition speed between two difference regimes.

Note that in this case of our study, $\Delta\varepsilon_{t-1}$ is the lagged different error term. Clearly, if $\gamma \approx \infty$, ρ_i in the state dependent (4) changes monotonically with the independent variable $\Delta\varepsilon_{t-1}$ as (5) in (4) is a smooth continuous increasing function of $\Delta\varepsilon_{t-1}$ and takes a value between 0 and 1, depending on the magnitude of $\Delta\varepsilon_{t-1}$. When $\Delta\varepsilon_{t-1} = r$, the value of the transition function ($q(\Delta\varepsilon_{t-1};\gamma,r)$) equals to 0.5, and the current regime is half way between the two extreme upper and lower regimes. When $\Delta\varepsilon_{t-1}$ is large and positive ($\Delta\varepsilon_{t-1} > r$), the value of the transition function equals to 1, $\Delta\varepsilon_t$ is effectively generated by the linear model

$\Delta\varepsilon_t = (\rho_1 + \rho_2)\varepsilon_{t-1} + \sum_{i=1}^{p-1}\beta_i \Delta\varepsilon_{t-i} + \omega_t$, while when $\Delta\varepsilon_{t-1}$ is large and negative ($\Delta\varepsilon_{t-1} < r$), the value of the transition function $q(\Delta\varepsilon_{t-1};\gamma,r)$ approaches 0, $\Delta\varepsilon_t$ is virtually generated by $\Delta\varepsilon_t = \rho_1\varepsilon_{t-1} + \sum_{i=1}^{p-1}\beta_i \Delta\varepsilon_{t-i} + \omega_t$. The intermediate value of $\Delta\varepsilon_{t-1}$ provides a mixture of the two extreme regimes. Note that the M-TAR model manifests a special case since when smoothness parameter γ approaches infinity in (5), $q(\Delta\varepsilon_{t-1};\gamma,r)$ becomes a Heaviside indicator function with $q(\Delta\varepsilon_{t-1};\gamma,r)$ = 1 for all values of $\Delta\varepsilon_{t-1}$ greater than r and $q(\Delta\varepsilon_{t-1};\gamma,r)$ = 0 otherwise, and (4) becomes the M-TAR model. And, if $\gamma \approx 0$, the value of the transition function equals to 0.5 regardless of whether $\Delta\varepsilon_{t-1} - r$ is positive, negative, or 0.

In the logistic smooth transition Enders-Siklos co-integration framework (4 and 5), we can still employ the Enders and Siklos (2001) co-integration test to examine the co-integration relationship; therefore, the no co-integration hypothesis ($H_0 : \rho_1 = \rho_2 = 0$) was tested using specifically derived critical values provided by Enders and Siklos (2001).

When γ approaches zero, (4) becomes the linear AR(p) model, implying that the AR model is nested in the logistic smooth transition Enders-Siklos co-integration model. Therefore, our first step in specifying the model is to test for linearity against the logistic smooth transition Enders-Siklos co-integration model form. If the null of linearity can not be rejected, we shall conclude that the AR model adequately represents the data generating process. However, if linearity is rejected, we will go on to estimate the highly non-linear logistic smooth transition Enders-Siklos co-integration model form using the non-linear least squares (NLLS) approach. From (4) and (5), it can be seen that testing $H_0 : \gamma = 0$ is a non-standard testing problem, since (4) is identified only under the alternative $H_1 : \gamma \neq 0$. Thus, standard t- and F-testing methods are not appropriate steps to arrive at a model choice. Therefore, this study follows Luukkonen *et al*. (1988) to compute a first- and third-order Taylor series approximation to the $\left(1+\exp(-\gamma(\Delta\varepsilon_{t-1}-r))\right)^{-1}$ under the null of $\gamma = 0$ .in (4)

When a third-order Taylor series approximation is used, the expanded and re-parameterized equation is:

$$\begin{aligned}\Delta\varepsilon_t = \alpha + \beta_1\varepsilon'_{t-1} + \beta_2(\Delta\varepsilon_{t-1}) + \beta_3(\Delta\varepsilon_{t-1})^2 + \beta_4(\Delta\varepsilon_{t-1})^3 \\ + \beta_5\varepsilon'_{t-1}(\Delta\varepsilon_{t-1}) + \beta_6\varepsilon'_{t-1}(\Delta\varepsilon_{t-1})^2 + \beta_7\varepsilon'_{t-1}(\Delta\varepsilon_{t-1})^3 + \omega_t\end{aligned} \tag{6}$$

The possible way to identify the appropriate model, the linear co-integration model, and the logistic smooth transition co-integration model is through a sequence of test parameter values from (6), (Woodward and Marisetty, 2005). Thus, we believe that the linearity test is identical to testing the joint restriction that all non-linear terms are zero in the null hypothesis, which is as follows:

$$H_0 : \beta_i = 0 \qquad i = 2, ...7 \tag{7}$$

In (7), if the H_0 is not rejected, we will select the linear co-integration model. If H_0 is rejected, we will select the logistic smooth transition co-integration model.

4. Data and Empirical Results

4.1 Data Description

This study was conducted by using the U.S., Asian, European, and American stock markets. The Standard & Poor's 500 (S&P 500) index in the U.S., seven major Asian stock markets including Taiwan, Hong Kong, Singapore, Japan, Korea, India, and China, seven major European and four major American stock markets, including the U.K., Germany, France, Netherlands, Belgium, Norway, Sweden, Canada, Mexico, Argentina, and Brazil, were researched in this part of our study, and all observations were taken logarithms.[4] The trade stocks in the S&P 500 index included the top 500 enterprises in NYSE and AMEX.[5] The reason why the S&P 500 index was chosen was because the total market value of the S&P 500 index dominated over 80% of the total value of NYSE. In addition, after taking factors such as liquidity and industrial representation into consideration, we believed that this index could reflect the conditions of the capital markets, the security markets, and the economy of the U.S more validly than the Dow Jones index.

The entire sample period was from September 1, 2005 to March 31, 2010 for a total of 820 daily observations which were obtained for each variable.[6] Trading days and closing days were different in various stock markets; therefore, if one market did not have any transaction on a particular day, we would delete the data in other markets on the same day. We only kept the data of synchronized trading days in all stock markets. Hamao *et al.* (1990) pointed out that discarding the data of non-synchronized trading days would not affect the accuracy of the empirical results.

Since there is still no consensus on the start date for the Subprime Mortgage

[4] The sample of the stock index in China is Shanghai Stock Exchange Composite index (SSE Composite index). Furthermore, there are restricted fluctuation ranges in the stock markets of Taiwan, Korea, and China, which are 7% for Taiwan, 15 % for Korea, and 10% for China, respectively. But there are no such restrictions in the U.S., the U.K., Germany, Hong Kong and Singapore stock markets. In past literature, many scholars questioned whether the restrictions would affect researchers' evaluation results. In our study, there were 17 days on which the TSEC Weighted Index exceeded the 7% limit, 18 days on which the KOSPI Composite Index exceeded the 15% limit, and 11 days on which the SSE Composite Index exceeded the 10% limit in our research period, all of which accounted for less than 3% of the entire samples. Shen and Wang (1998) pointed out that when the samples with restricted ranges were less than 5% of the entire samples, their impact on the evaluation results could be considered insignificant. Furthermore, due to the fact that the restricted fluctuation ranges were aimed at individual stocks, the probability of the stock prices of those individual stocks rose and fell at the same time was very low on a trading day. Since the stock indices were adopted in this study, the influence from the restricted fluctuation ranges to our empirical results would not be significant.

[5] NYSE and AMEX are the abbreviations of the New York Stock Exchange and the American Stock Exchange, respectively.

[6] In order to ensure the robust in the empirical results and avoid bias and non-consistency in the empirical results due to the sample numbers with huge differences around the Subprime Crises and the influence of the interference from the EMU Sovereign-Debt Crisis, the entire sample period was set from September 1, 2005 to March 31, 2010 in our study.

Crisis, it is not easy to determine an exact date. In general, scholars (Gorton, 2008; Sikka *et al*. 2009; Claessens *et al*. 2010; Longstaff, 2010) and the financial industry considered the outburst of the financial crisis of the New Century Financial Corp. as the beginning of the crisis. However, the event of Lehman Brothers' filing for bankruptcy on September 15, 2008 aggravated the Subprime Mortgage Crisis (Swan, 2009; Longstaff, 2010; Sobreira, 2011; Afonso *et al*. 2012; Frankel and Saravelos, 2012; Dumontaux and Pop, 2013). The negative effects of the Subprime Mortgage Crisis on the U.S. and global stock markets were different between the two periods, namely, between 2007 and 2008 and between 2009 and 2010. Longstaff (2010) pointed out that the Subprime Mortgage Crisis could be divided into two sections in the timeline, the first section being earlier 2007, and the reason was that the institutional investors, e.g. Bear Stearns and Merrill Lynch, suffered huge losses due to their investment in subprime debts or derivatives. The second section began at the end of 2008, and the reason was that the global financial system continued to deflate currency due to eliminations of the huge debts about subprime mortgage by institutions, enterprises, and governments. Therefore, in order to assure the consistency in our study, we used the date on which the trading of stocks of New Century Financial Corp. was terminated in NYSE, i.e. March 13, 2007, as the first cutting point, and the data on which Lehman Brothers filed their bankruptcy, i.e. September 15, 2008, as the second cutting point. Thus, the period of "the pre-Subprime Mortgage Crisis" was defined as the period from September 1, 2005 to March 13, 2007, and the first section of the period of "during the Subprime Mortgage Crisis" was defined as the period from March 14, 2007 to September 15, 2008, and the second section of the period of "during the Subprime Mortgage Crisis" was defined as the period from September 16, 2008 to March 31, 2010. We, therefore, compared the estimated results of the different periods. The return of stock price indices, which were the logarithms of after the first difference, was employed in our study. The stock price index return is as follows:

$$\Delta LIP_{i,t} = (\ln IP_{i,t} - \ln IP_{i,t-1}) \times 100$$

Where $LIP_{i,t} = \ln IP_{i,t}$, $IP_{i,t}$ was the 19 stock markets in this study.

Table 1 represents the summary statistics for all the returns in our study, and Figures 1 and 2 show that the time trends of logarithms of the stock indices and the stock index returns in 19 stock markets, respectively. In Figure 1, there were downward trends in 19 stock indices, and in Figure 2, there was substantially increase in the variation of returns in the 19 stock markets during the period between the second half of 2007 and the first half of 2009. The results of the three unit root tests, Augmented Dickey and Fuller (ADF; 1984), Phillips and Perron (PP; 1988) and Kwiatkowski, Phillips, Schmidt, and Shin (KPSS; 1992), were summarized in Table 2, which shows that the null hypothesis of non-stationarity can not be rejected for any levels of these series. After the first difference, the null is rejected at the 1% significance level for all the series. Therefore, we concluded that all the variables were the $I(1)$ type series at the 1% significance level. Table 3 represents the results of the KSS's (2003) ESTAR unit root test, which showed that variables of all stock indices in this study were non-linear $I(1)$ series at the 1% significance level.

Because the correlation analysis of volatility of the stock index return was employed to investigate the contagion or transmission effect in this study, we used the ARMA(p,q)-GARCH(1,1) model to fit the conditional variance, i.e. the volatility of return; therefore, we first applied the ARCH-LM test to investigate the heteroscedasticity of the conditional variance in returns. Table 4 represents the results of the ARCH-LM test for the volatility of returns in the period of the pre-Subprime Mortgage Crisis 〈Table 4-(1)〉, the first section (section I) of the period of during the Subprime Mortgage Crisis〈Table 4-(2)〉, and the second section (section II) of the period of during the Subprime Mortgage Crisis〈Table 4-(3)〉for all the returns in our study. In Table 4, when the residuals of the ARMA(p,q) model by the ARCH-LM test were examined, the null hypothesis of no GARCH effect was rejected at the 10% significance level in the three periods. Therefore, the use of GARCH(1,1) modeling to extract the values of the return volatility was appropriate.

Tables 5 and 6 represent the results of the non-conditional correlation coefficients of returns and the volatilities of returns, and the t statistics of them between the U.S. and Asian, European, and American stock markets in the three periods around the Subprime Mortgage Crisis, respectively, and Figure 3 shows the volatility of returns in the 19 stock markets.[7] In Figure 3, there was also substantial increase in the volatilities of returns in the 19 stock markets during the period between the second half of 2007 and the first half of 2009. Especially, it reached the peak during 2008 and 2009, which showed that higher and persistent fluctuations could be observed since the eruption of the Subprime Mortgage Crisis; the phenomenon also demonstrated the negative impact of the Subprime Mortgage Crisis on the stock markets in various countries was very severe. In Tables 5 and 6, the results show that both the correlation coefficients of returns and the volatility of returns increased significantly between the U.S. and most of the Asian, European, and American markets during the Subprime Mortgage Crisis, especially in section II after Lehman Brothers filed the bankruptcy on September 15, 2008, except the China stock market, The results in Table 6 also represented that there were volatility spillovers between the U.S. stock market and the above-mentioned stock markets, and the results in Tables 5 and 6 supported the crisis-contagion theory by Dornbusch *et al.* (2000) and Forbes

[7] Both Tables 5 and 6 in our study, the t statistics of correlation coefficients of returns and the volatility of returns between various periods were calculated by Fisher's Z transformation.

and Rigobon (2001).

4.2 The Empirical Results

In this part, we employed the Engle and Granger (1987) co-integration test to examine the symmetric long-run equilibrium relationships, i.e. co-integration relationships, and the Enders and Siklos (2001) M-TAR model and the logistic smooth transition co-integration model, respectively, to investigate the changes in the asymmetric co-integration relationships between the U.S. S&P 500 index and eighteen stock markets in Asia, Europe, and America around the Subprime Mortgage Crisis between 2007 and 2010.

Table 7 represents the results of the Engle-Granger co-integration relationships between the U.S. and the eighteen stock markets in the three periods around the Subprime Mortgage Crisis. The null hypothesis of no co-integration was also shown in Table 7. In Table 7-(1), the results of the Engle-Granger ADF statistics show that there were co-integration relationships between the S&P 500 index and the U.K. and Germany stock markets at the 5 % significance level in the period of the pre-Subprime Mortgage Crisis. In Table 7-(2), the results show that there was a co-integration relationship between the U.S. stock market and Mexico stock market at the 5% significance level in the section I of the period of during the Subprime Mortgage Crisis. In Table 7-(3), the results show that there was only a co-integration relationship between the U.S. stock market and Germany stock market at the 1% significance level in section II of the period of during the Subprime Mortgage Crisis. The results in Table 7 show that there was only significant increase in the co-integration relationship between the S&P 500 index and Germany DAX index around the Subprime Mortgage Crisis; this result was not consistent with the results of the correlation analyses of returns and the volatility of returns in Tables 5 and 6, and it did not support the crisis-contagion theory by Dornbusch *et al.* (2000) and Forbes and Rigobon (2001).

Enders and Granger (1998) and Enders and Siklos (2001) proposed two models for the threshold co-integration test, namely, the TAR model and the M-TAR model. This study adopted the M-TAR model. Enders and Granger (1998) believed that when asymmetrical adjustments occurred in the data series, the determination of the Heaviside indicator function might also be decided by the first difference value of error correction term on period $t-1$ ($\Delta\varepsilon_{t-1}$). Boucher (2007) indicated that the speed of convergence of parameter estimation by using the M-TAR model would be faster than that of the TAR model. Table 8 represents the results of our estimation of the threshold co-integration relationships between the U.S. stock market and the eighteen stock markets in the three periods around the Subprime Mortgage Crisis. The null hypothesis of no co-integration (F_C) and symmetric adjustment (F_A) was also shown in Table 8. In Table 8-(1), both F_C and F_A demonstrated the relationships of asymmetric co-integration between the U.S. stock market and the India, France, Norway, Canada, and Mexico stock markets in the period of pre-Subprime Mortgage Crisis. In Table 8-(2), the F_C statistics rejected the null hypothesis at the 1% significant level, and the F_A statistics rejected the null at the 10% level in section I of during the Subprime Mortgage Crisis except the China stock market. Both F_C and F_A demonstrated the asymmetric co-integration relationships between the U.S. stock market and most of the eighteen stock markets in section I of during the Subprime Mortgage Crisis except the China stock market. In

Table 8-(3), both F_C and F_A demonstrated the asymmetric co-integration relationships between the U.S. market, and most of the all stock markets except the China stock market in section II of the period of during the Subprime Crisis.

Finally, we investigated how the asymmetric adjustment and the smooth transition phenomenon influenced the transmission or contagion effect by applying the logistic smooth transition co-integration model to compare the transmission or contagion effect from the U.S. stock market to the eighteen stock markets in the three periods of pre- and during the Subprime Mortgage Crisis.

Table 9 represents the results of the Enders-Siklos M-TAR co-integration test in logistic smooth transition framework and linearity test for the co-integration relationships between the U.S. stock market and the eighteen stock markets in the three periods around the Subprime Mortgage Crisis. The null hypothesis of no co-integration ($F_C : \rho_1 = \rho_2 = 0$) and linearity model ($F_L : \beta_2 = ... = \beta_7 = 0$) were shown in Table 9. In Table 9-(1), both F_C and F_L demonstrated the relationships of logistic smooth transition co-integration between the U.S. stock market and the Hong Kong, India, Germany, France, Canada, and Mexico stock markets in the period of pre- Subprime Mortgage Crisis. In Table 9-(2), both F_C and F_L demonstrated the logistic smooth transition co-integration relationships between the U.S. stock market and most of the all stock markets in section I of during the Subprime Mortgage Crisis except the China stock market. In Table 9-(3), both F_C and F_L demonstrated the logistic smooth transition co-integration relationships between the U.S. market and most of the all stock markets in our study except the China stock market in section II of during the Subprime Mortgage Crisis.

By further comparing the F_C statistics in Table 8 and Table 9, we found that the co-integration relationships had significantly increased after the shock of the Subprime Mortgage Crisis between the U.S. market and most of the Asian, European, and American stock markets except the China and Brazil stock markets from Tables 8, and except the China stock market from Tables 9. Both Table 8 and Table 9, the results showed that there were "contagion" or "transmission" effects between the U.S. market and most of the Asian, European, and American stock markets after the Subprime Mortgage Crisis, especially in section II of the Subprime Crisis which after Lehman Brothers filed the bankruptcy on September 15, 2008. However, there was only an "interdependence effect" between the U.S. market and the China and Brazil stock markets from Table 8, and between the U.S. market and the China stock market from Table 9. Forbes and Rigobon (2001) defined the contagion of the international stock markets as a significant increase in cross market linkages or co-movement between one market and others after a shock or during a crisis, and our results supported the "contagion effect" between the U.S. stock market and some of the stock markets in the surveyed countries in our study.

By further comparing the F_A statistics in Tables 8-(1), 8-(2) and 8-(3), we found that the asymmetry in the co-integration relationships had also significantly increased after the crisis between the U.S. stock market and most of the eighteen stock markets except the China stock market. The result showed that the Subprime Mortgage Crisis induced quick transmission of massive negative information among many stock markets. These lead to higher risk aversion for international investors.

From the results of F_L statistics in Table 9, we also found similar results in Table 8, which the co-integration relationships were asymmetric or non-linear, and the order of the ranks of the stock market co-integration relationship between the above-mentioned stock markets and the U.S. stock market were similar to that in

Table 8. Moreover, by further comparing the F_L statistics and the smooth parameter (γ) in Tables 9-(1), 9-(2) and 9-(3), we found that the transition speed of co-integration relationships between the difference regimes had also conspicuously increased after the crisis between the U.S. stock market and most of the Asian, European, and American stock markets except the China stock market. The result showed that the Subprime Mortgage Crisis induced quick transmission of massive negative information among many stock markets. These also led to higher risk aversion for international investors.

According to the empirical results in Tables 8 and 9, the order of the ranks of the stock market co-integration relationship between the above-mentioned stock markets and the U.S. stock market is as follows: the countries in Europe (the order of the ranks: France, the U.K, Germany, Belgium, Netherlands, Norway, and Sweden), the countries in America (the order of the ranks: Canada, Mexico, Argentina, and Brazil), and the countries in Asia (the order of the ranks: Singapore, Japan, Hong Kong, Korea, Taiwan, India, and China).

This can be explained with the fact that the financial markets in European countries are relatively advanced markets and have had more linkage with the U.S. financial and security markets, whereas the financial markets in Latin America and Asian countries are emerging markets and have less linkage with the U.S. financial markets.

The contagion effects on European markets were stronger than those on Latin American and Asian markets. In the past, most of the financial crises originated from the countries, which were considered to be emerging markets with a lot of foreign debt, weak financial institutions, and unsound financial supervisory systems. The neighboring countries were apt to be influenced because of their close geographical locations to the origin of a financial crisis. However, the Subprime Mortgage Crisis was due to the huge losses of credit derivatives in the U.S. financial and securities market. It originated from the most advanced country and no one expected this could happen. Surprisingly, the most severely influenced markets were not the neighboring Latin American and Asian markets. Therefore, the extent of financial linkage with the U.S. market might be the explanatory factor of strength of the contagion effect. Because many financial institutions and investors held a lot of subprime mortgage securities in the countries in Western Europe, it was reasonable that the contagion effects were more significant in the European markets than in the Latin American and Asian markets. In short, the origin and impact of the Subprime Mortgage Crisis were different from those of the financial crises in emerging markets.

5. Conclusions

The crisis contagion theory states that exogenous shocks are transmitted to many countries through transmission mechanisms. This effect leads to co-movement of stock markets. Dornbusch *et al.* (2000) and Forbes and Rigobon (2001) pointed out that contagion effects existed when negative impacts occurred during the crisis.

Co-integration relationships between stock markets represent market co-movement or common trends, and the co-integration analysis is widely used to investigate whether or not the long-term equilibrium relationship between stock markets is changed when a financial crisis happens. If the equilibrium relationship changes, the contagion effect occurs. However, the traditional symmetric co-integration analysis ignores the characteristics of asymmetric adjustment in stock markets (Li and Lam, 1995; Koutmos, 1998; Sarantis, 2001; Chiang, 2001). Therefore, we employed the Enders and Siklos (2001) threshold co-integration framework, including the M-TAR model and the logistic smooth transition regressive

(LSTR) method proposed by Granger and Teräsvirta (1993) and Teräsvirta (1994), which was the expansion of the M-TAR model, which allowed asymmetric adjustments and smooth transitions, when analyzing stock market relationships. We tested the asymmetric long-term equilibrium relationship between the U.S. stock market and eighteen stock markets in Asia, Europe, and America around the Subprime Mortgage Crisis.

In this study, we anticipated contagion effects among international stock markets would lead to co-integration between the U.S. and Asian, European, and American stock markets. However, the results of the Engle and Granger (1987) co-integration test did not indicate co-integration relationships between the U.S. and these stock markets. These results were not consistent with the correlation analyses of returns and the volatility of returns, for the correlation coefficients of returns and the volatilities of returns both increased. In addition, these results were different from previous empirical studies, and our assumption could not be verified by traditional co-integration methods. Furthermore, the test results of the Enders-Siklos threshold co-integration model and the logistic smooth transition co-integration model did indicate that co-integration relationship increased. Therefore, the models of threshold co-integration and logistic smooth transition co-integration are the better methods to analyze dynamic stock market relationships.

There are several major findings in this study. First of all, the empirical results supported previous research. We found that the Enders-Siklos threshold co-integration relationships between the U.S. S&P 500 index and most of the stock markets in Asia, Europe, and America increased significantly except the China market and Brazil market, and, the logistic smooth transition co-integration relationships between the U.S. stock market and most of the all stock markets in our study increased significantly except the China market, especially after Lehman Brothers filed for bankruptcy, however, in both models ,the co-integration relationship did not exist between the U.S. market and China market around the Subprime Mortgage Crisis.

The information demonstrated that the Subprime Mortgage Crisis in the U.S. had a contagion effect on international stock markets. When the adjustments of asymmetric and logistic smooth transition in stock markets were compared, the influence of good news and bad news in the U.S. market was significantly enhanced during the crisis (threshold co-integration and logistic smooth transition co-integration). Furthermore, the smooth parameter also significantly increased after the shock of the crisis, the results of which showed evidence that the heteroscedasticity of information transmission in international stock markets increased significantly during the period of the Subprime Mortgage Crisis. It was more likely that the transmission of massive negative information resulted in higher risk aversion for international investors.

The second finding differed from previous literature. Previous works on financial crises revealed that most crises originated from emerging markets. (Aggarwal *et al.*, 1999; Collins and Biekpe, 2003; Dungey *et al.*, 2006) The neighboring countries were easily affected because of their close geographical locations to the origin of the financial crisis: nevertheless, the Subprime Mortgage Crisis was not from an emerging market. In addition, the contagion effect of the stock markets in European countries was more significant than that in Asian and Latin American countries. It was contrary to our assumption that Asian and Latin American countries would be affected more severely. The possible explanation was that the degree of financial linkage with the U.S. market contributed to the strength of the contagion effect. Since the relatively advanced stock markets in Europe were globalized and deregulated markets, they were affected notably. While the stock markets in Asia and Latin America were less globalized and less deregulated, they were affected moderately. Unlike a financial crisis of an emerging market, the Subprime Mortgage Crisis caused quite different contagion effects which were explored in this research.

Finally, the Subprime Mortgage Crisis had weakened international portfolio diversification; therefore, international investors could not diversify their risks by investing in the Asian, European and American stock markets during the crisis. It is likely that if a world financial center is in trouble, global investors will be unavoidably influenced.

Notes: 1. The volatility of returns is measured by the conditional variance of returns from the ARMA(p,q)-GARCH(1,1) model, the lag-lengths of the ARMA(p,q) model selected by minimizing AIC.

2. *, ** and *** denote significance at 10%, 5% and 1% significance levels, respectively; the numbers in the parentheses are the p-value.

Abstract

This paper presents a parsimonious and theoretically-sound basis for extracting forward-looking measures of both equity and commodity betas, and the risk-premium on crude-oil futures contracts.

Defining forward-looking betas as perturbations of historical estimates, we use the market prices of equity, index and commodity options under a single-factor market model to estimate the appropriate forward-looking perturbation to apply to the historical beta. This permits us to compute forward-looking term structures of equity and commodity betas.

In the commodity arena, we use both one- and two-factor models to obtain estimates of a forward-looking measure of the correlation between crude-oil and the S&P 500. Combining these with forward-looking (i.e., implied) volatilities on commodities and stock-market indices, we utilize these forward-looking betas and correlations to provide an ex-ante estimate of the expected future crude-oil spot price through the use of an equity ex-ante risk premium and the conditional CAPM.

Keywords: *Implied volatilities, implied correlations and implied market betas; Expected spot price of oil.*

1 Introduction

The search for forward-looking indicators is a natural one in finance, as one of the primary roles of the discipline is to utilize market information to discern participants' views and expectations. This paper attempts to apply that principle to two distinct issues in financial economics:

1. The analysis of implied volatility, implied correlation and implied betas, and their impact on investment analysis and practice. Equity implied volatility dates back to Latané and Rendleman (1976).[1] Implied correlations have been more challenging, typically requiring the simultaneous pricing of individual *and* (relatively illiquid) spread options so as to permit isolation of the two vols and the implied correlation using the Margrabe (1978) formula.

   Implied equity betas are even more recent, and with several requiring alternative modifications on the "hybrid"-model use of option and historical data. Thus, French, Groth and Kolari (1983) use option-implied volatility with historical correlations. Siegel (1995) uses a hypothetical Margrabe-style exchange option to price "implicit betas." Assuming the skewnewss of the idiosyncratic shock is zero, Chang, Christoffersen, Jacobs and Vainberg (2012) use option-implied volatility and skewness measures from out-of-the-money equity and index options to derive forward-looking betas. In turn, Buss and Vilkov (2012) use forward-looking information from option prices to estimate option-implied correlations, construct option-implied predictors of factor betas and find a monotonically increasing risk-return relation. Finally, Broadie, Chernov and Johannes (2007) use an affine jump-diffusion model to estimate risk premia using S&P futures options.

   In contrast, our approach is a distinctly different hybrid: We use historical betas as well as historical idiosyncratic variances as inputs in order to obtain the *perturbations* or *adjustment factors* (to these historical measures) implied by observed equity and index option prices. By using at-the-money (ATM)

[1] Some of the earlier literature referred to this volatility with the adjective "implicit."

options, our approach does not require computation of skewness, an issue that can be especially problematic in longer-dated options where the vol skew is known to "flatten out." Moreover, by utilizing the entire term structure of volatilities (for the stock and the S&P), we are able to compute a term structure of betas and idiosyncratic variances out to the most-distant option expiration date. In light of the behavior of idiosyncratic variance during a financial crisis, the term structure of idiosyncratic variances is one way of quantifying the duration of such a crisis.

2. As is well-known, there is significant debate on the question of whether forward prices in energy markets are biased or unbiased predictors of future expected prices. The empirical work dating back to Houthakker (1957), Chang (1985), Fama (1987) and Bessembinder (1992) showed that in financial and *mature* commodity futures markets, risk premia in general satisfy the integrated-market model, which predicts risk premia are proportional to the covariance of the futures return with the return on the pricing kernel which we take to be the market portfolio. In a different approach, Kolos and Ronn (2008) estimate the risk premium by computing the ratio of expected return to standard deviation whilst explicitly accounting for the Samuelson effect (aka the "term structure of volatility") in commodity futures contracts.

   Having obtained a forward-looking measure of beta or correlation, there exists an appealing application to the commodity case, specifically, to that most-liquid commodity market of crude-oil futures. Assume the observability of an *ex-ante* risk-premium on the S&P 500 Index,[2] the implied vol of that index and the implied vol of a crude-oil futures contract. Then under a conditional-CAPM, the only remaining requisite input is the beta (or the correlation) of the oil-futures contract with the S&P 500 Index.

   Analogous to the equity analysis presented above, we first proceed with a one-factor model, which permits us to extract the beta between oil prices and the S&P 500. Under a conditional-CAPM, the S&P-500 beta of crude-oil futures

[2] To obtain such an *ex-ante* estimate, we will utilize the procedure specified in Doran, Ronn and Goldberg (2009) and described more fully below.

contract, in conjunction with the implied vols on the stock index and the crude-oil futures contract, provides an estimate of the forward-looking risk premium on oil.

As will be demonstrated empirically below, the practical contribution of this section is to permit investors to distinguish clearly between *demand*-side and *supply*-side shocks to the expected price of oil. A demand-side shock is defined as one arising from a change in the economy's demand for oil products, usually associated with either growth or recessionary conditions; the attendant correlation between oil prices and the S&P is positive. In contrast, supply-side shocks are attributable to constraints on oil supplies reaching consumer markets, due to either hurricanes in the Gulf of Mexico, geopolitical crises in the Middle East or spiking oil prices outpacing economic growth; in this case the correlation between oil prices and the S&P 500 is negative.

A negative correlation will be shown to imply an upward-bias of the futures price relative to its expected-spot price (under the physical measure) counterpart.[3] The approach proffered here thus provides a quantitative measure for this risk premium. Moreover, the procedure detailed below provides a *forward-looking* correlation, and as such is superior to the historical correlation, between crude-oil futures and the S&P.

The paper now proceeds as follows. Considering the format of standard equity options, Section 2 demonstrates the empirical methodology by presenting the one-factor model for standard equity options, its corresponding econometric specification and empirical results. Section 3 extends the one-factor model to its commodity

[3] With the advent of a perceived supply-side crisis, the lay press typically includes numerous references to an oil-price surcharge. For example,

> "The possibility that there might be a disruption in oil supply at some time in 2012 as Iran retaliates has, I think, permanently embedded a \$10 to \$20 premium in the price of oil,"

according to the chief global economist at the Economic Outlook Group cited in the 12/28/11 issue of the *New York Times*.

To be fair, such references are typically made with respect to *spot prices*, but the theory suggests they be reflected in the prices of futures contracts.

analogue, producing the critical betas and correlations between oil markets and the S&P 500 pricing kernel. As a robustness check to the one-factor model, Section 4 extends to the *two*-factor analogue, focusing specifically on equity options and the implied correlations between crude-oil and the stock market. Finally, Section 5 uses the resulting forward-looking measures of the correlation between the one-year oil futures contract and the S&P 500 Index to obtain a forward-looking measure of the expected spot price of oil. Section 6 concludes.

2 Using Equity Options to Obtain Forward-Looking Equity Betas

2.1 The Continuous-Time Theoretical Model

The theoretical, continuous-time model requires the specification of the stochastic processes for the market portfolio, stochastic volatility and the individual-stocks' returns:

$$\frac{dM_t}{M_t} = \mu_m\, dt + \sqrt{V_{mt}}\, dz_{mt} \tag{1}$$

$$dV_{it} = k_i\left(\psi_i - V_{it}\right) dt + \xi_i \sqrt{V_{it}}\, dz_{it} \tag{2}$$

for $i = m, S$, where $\sqrt{V_{mt}}$ is the stochastic volatility of the market portfolio and $\sqrt{V_{St}}$ is the stochastic volatility of stock S.

Accordingly, the conditional-CAPM version of the asset in continuous time is:

$$\begin{aligned} \frac{dS_t}{S_t} &= r\, dt + \beta_t\left(\frac{dM_t}{M_t} - r\, dt\right) + \sqrt{V_{St}}\, dz_{St} \\ &= \left[r + \beta_t\left(\mu_m - r\right)\right] dt + \beta_t\sqrt{V_{mt}}\, dz_{mt} + \sqrt{V_{St}}\, dz_{St} \end{aligned} \tag{3}$$

and $dz_{mt}\, dz_{St} = 0$.

The variance of the market portfolio is V_{mt}, and the total variance of the return on the generic stock is:

$$\mathrm{Var}\left(\frac{dS_t}{S_t}\right) = \beta_t^2 V_{mt} + V_{St}$$

where $\beta_t^2 V_{mt}$ is systematic variance proportional to β_t, and V_{St} is the idiosyncratic variance.

To permit the stock's beta to change over time, we specify the process for the correlation coefficient ρ_{Smt} :

$$d\rho_{Smt} = \alpha_\rho \left(\varphi_\rho - \rho_{Smt}\right) dt + \sigma_\rho \, dz_{\rho t} \tag{4}$$

When we explicitly consider n stocks $j = 1, 2, \ldots, n$, we take appropriate care in subscripting the processes:

$$\begin{aligned} dV_{Stj} &= k_S \left(\psi_{Sj} - V_{Stj}\right) dt + \xi_S \sqrt{V_{Stj}} \, dz_{St} \\ d\rho_{Smtj} &= \alpha_\rho \left(\varphi_{\rho j} - \rho_{Smtj}\right) dt + \sigma_\rho \, dz_{\rho t} \end{aligned} \tag{5}$$

Note the modeling of the two equations in (5): In order to capture the greatest possible number of degrees of freedom in the empirical tests, ψ_{Sj}, $\varphi_{\rho j}$ and the initial values V_{Stj}, ρ_{Smtj} will be stock-specific, while all the other parameters will be the same across stocks.

Finally, when we apply the *risk neutral measure*, it is possible to retrieve the following risk premia:

Risk Premium	Associated with	Wiener shock affecting the
θ_m	dz_{mt}	Market portfolio
θ_{vm}	dz_{vmt}	Stochastic volatility of the market portfolio
θ_{vS}	dz_{vSt}	Stochastic volatility of the generic stock
θ_S	dz_{St}	Individual stock
θ_ρ	$dz_{\rho t}$	Correlation between the stock and the market portfolio

For example, $\theta_m \equiv \left(\mu_m - r\right) / \sqrt{V_{mt}}$.

2.2 Initial Discrete-Time Econometric Tests — Equity Options

Consider the one-factor market-model equation,

$$R_i = a_i + \beta_{i,\,\mathrm{SPX}} R_{\mathrm{SPX}} + e_i \tag{6}$$

where we assume $\mathrm{Corr}(R_{\mathrm{SPX}}, e_i) = 0$. Applying the variance operator to (6) yields

$$\Sigma_i^2 = \beta_{i,\,\mathrm{SPX}}^2 \sigma_m^2 + \sigma_i^2, \tag{7}$$

where

$\Sigma_i^2 \equiv \mathrm{Var}(R_i)$, the variance of the return on stock i

$\sigma_m^2 \equiv \mathrm{Var}(R_{\mathrm{SPX}})$, the variance of the return on the S&P 500 market index

$\sigma_i^2 \equiv \mathrm{Var}(e_i)$, the idiosyncratic variance

Eq. (7) applies to *historical* $\left\{\widehat{\Sigma}_i,\, \widehat{\beta}_{i,\mathrm{SPX}},\, \widehat{\sigma}_i\right\}$ data with $\widehat{\beta}_{i,\mathrm{SPX}} \equiv \mathrm{Cov}\left(R_i, R_{\mathrm{SPX}}\right)/\mathrm{Var}\left(R_{\mathrm{SPX}}\right)$ over some specified time interval.[4] From eq. (7), it is trivial to solve for the historical idiosyncratic risk $\widehat{\sigma}_i$:

$$\widehat{\sigma}_i^2 = \widehat{\Sigma}_i^2 - \widehat{\beta}_{i,\mathrm{SPX}}^2 \sigma_m^2. \tag{8}$$

Relationship (7) also holds *prospectively,* that is, to implied vols $\{\Sigma_i,\, \sigma_i\}$ extracted from option prices on the individual equities i and the market portfolio $m \equiv$ SPX. Now consider a specification that explicitly models the relationship between historical estimates $\left\{\widehat{\beta}_{i,\mathrm{SPX}},\, \widehat{\sigma}_i\right\}$ and forward-looking ones $\{\beta_{i,\mathrm{SPX}},\, \sigma_i\}$. In theory, the difference between historical and *ex-ante* statistics arises from two sources:

1. The information set. The historical returns, variances and covariances are due to a specific realization of uncertainty. That information set is (part of) investors' perceptions of the future, but investors may and presumably do consider other sources of information in forming expectations of the future.

2. A risk premium, aka the "market price of volatility risk." Technically, implied vols are risk-neutral expectations of future realized vols, but as is well-known, there can be a non-zero market price of volatility risk that separates the statistical from the risk-neutral expectations. While the literature is not unanimous, most researchers have found risk-neutral implied vols exceed their statistical-expectations counterparts: See Jackwerth and Rubinstein (1996), Pan (2002), Bakshi and Kapadia (2003a, 2003b), Low and Zhang (2005), Doran and Ronn (2008) and Bollerslev, Gibson and Zhou (2011). Since both the LHS and RHS of eq. (7) pertain to risk-neutral expectations, the forward-looking betas we obtain here are risk-neutral. Whether such betas are upward-

[4] Throughout this paper, variables with a "carat" $\widehat{}$ denote historical estimates.

or downward-biased predictors of forward-looking *statistical* (not risk-neutral) betas is beyond the scope of this research.

The econometric model we posit is one which utilizes *Cross-Sectional Daily Tests with a Term Structure of Betas:* In this test we employ a cross-sectional analysis at a given point in time, taking into explicit consideration the entire term structure of betas. Since equity implied vols are provided on a daily basis out to 18 mos. maturities, we can fill in the missing observations by assuming forward vols are constant between observable expiration dates.[5] Then, for each stock i and maturity m at date t, we use the relationships

$$\begin{cases} \Sigma_{imt}^2 &= \beta_{i,m,t}^2 \sigma_{\mathrm{SPX},m,t}^2 + \sigma_{i,m,t}^2 \\ \beta_{i,m} &= \widehat{\beta}_{i,\mathrm{SPX}} + \alpha_{i,1c} + \alpha_{i,1l}(m-1) + \alpha_{i,1q}(m-1)^2 \\ \sigma_{i,m} &= \widehat{\sigma}_i + \alpha_{i,4c} + \alpha_{i,4l}(m-1) + \alpha_{i,4q}(m-1)^2 \end{cases} \tag{9}$$

In this case, for each stock i on date t we have $m-6 = 12$ d.f. Although we naturally retain the i-dependence of the historical estimates $\left\{\widehat{\beta}_{i,\mathrm{SPX}}, \widehat{\sigma}_i\right\}$, to increase the number of degrees of freedom, we make the simplifying assumptions the estimated coefficients $\{\alpha_{i,1c}, \alpha_{i,1l}, \alpha_{i,1q}, \alpha_{i,4c}, \alpha_{i,4l}, \alpha_{i,4q}\}$ are all *i-independent:* This increases the number of degrees of freedom by the number of stocks $N = 8$ to $12N = 96$.

2.3 Empirical Results — Equity Options

The empirical results reported here cover the period Jan. 3, 2008 – July 31, 2012. $N = 8$ stocks are utilized. They are the stocks included in Bloomberg's BUSOILP Index: Anadarko Petroleum Corp., Apache Corp., ConocoPhillips Co., Chevron

---

[5] Using the principle variance is additive across maturities — since S&P returns are uncorrelated across time — for both individual stocks and market index, the algorithm is the following:

For the very first maturity's σ_1, we simply set that equal to the observable σ_2. For the next two maturities, $m = 4$, 5, we solve for σ_4 and σ_5 using the observable σ_3 and σ_6 :

$$(4/12)\sigma_4^2 = (3/12)\,\sigma_3^2 + \left[\sigma_6^2\,(6/12) - \sigma_3^2\,(3/12)\right]/3.$$

We repeat this for successive maturities out to 24 mos. for the S&P and 18 mos. for the individual stocks, whose actively-traded options do not extend to 24 mos.

Corp., Hess Corp., Occidental Petroleum Corp., Marathon Oil Corp. and Exxon-Mobil Corp.[6] We need specify the empirical proxies for the three sets of historical variables $\left\{\widehat{\Sigma}_{it},\, \widehat{\beta}_{i,\mathrm{SPX},t},\, \widehat{\sigma}_{it}\right\}$ as well as the nine ATM implied vols on the S&P 500 and the individual stocks i, $\{\sigma_{mt},\, \Sigma_{it}\}$:

1. The historical estimates $\left\{\widehat{\Sigma}_{it},\, \widehat{\beta}_{i,\mathrm{SPX},t},\, \widehat{\sigma}_{it}\right\}$ on each stock i are obtained from one-year rolling regressions of eq. (6) culminating on date t.
2. The nine ATM implied vols $\{\sigma_{mt},\, \Sigma_{it}\}$ are obtained from ATM options on the S&P 500 Index and the eight individual BUSOILP stocks as observed on date t.

Test #1 — Cross-Sectional Daily Tests (9):

We report the tests of these equations (9) by presenting time-series plots of

[6] The Anadarko Petroleum Corp., a member of the BUSOILP eight, owned a 25% interest in Deepwater Horizon, the oil rig operated by BP PLC in the Gulf of Mexico. As a consequence of the catastrophic sinking of that oil rig on April 20, 2010 Anadarko stock underperformed the BUSOILP index by as much as 35% by June 30, 2010, and remains some 20 percentage points below as of Aug. 2013. Moreover, its 60-day-moving window correlation with BUSOILP declined from 0.84 in April to a low 0.445 on 5/18/2010, before recovering to 0.779 on 9/2/2010.

Figure 1's α_{1l} and Figure 2's α_{4c}.[7] Finally, Figure 3 reports the simple-average historical and implied equity betas for the eight BUSOILP stocks.

[7] The available data permits alternative interesting aggregation of the data and resulting empirical tests. For example, consider:

1. A Time-Series Test: Assuming data on N stocks and their associated ATM options, we now formulate a model that aggregates information and specifies a constant stock-specific correction over an entire sample period:

$$\min_{\{a_{1i},\, a_{2i}\}} \quad \sum_{t=1}^{T}\sum_{i=1}^{N}\left(\Sigma_{it}^2 - \widehat{\beta}_{i,\text{SPX},t}^2 a_{1i}^2\sigma_{mt}^2 - \widehat{\sigma}_{it}^2 a_{2i}^2\right)^2.$$

   In words, we seek to solve for the date-t specific correction factors $\{a_{1i},\, a_{2i}\}$ which would satisfy eq. (7). In this test, while the correction factors are stock-specific, they are constant for each stock across the time period being considered.

2. A Constrained Time-Series Test: The third test is a special case of Test 2. In an effort to achieve parsimony with respect to the number of estimated parameters, we constrain the correction factors $\{a_{1i},\, a_{2i}\}$ to be i-independent, $\{a_1,\, a_2\}$:

$$\min_{\{a_1,\, a_2\}} \quad \sum_{t=1}^{T}\sum_{i=1}^{N}\left(\Sigma_{it}^2 - \widehat{\beta}_{i,\text{SPX},t}^2 a_1^2\sigma_{mt}^2 - \widehat{\sigma}_{it}^2 a_2^2\right)^2.$$

beta_imp

From Fig. 1, we note the relative sparse incidence of a significantly non-zero value to α_{1l} : Thus, there does not appear to be a frequently-occurring non-flat *term structure of* equity betas. In turn, Fig. 2 appears to indicate the forward-looking idiosyncratic vol reflects market conditions: When large market moves diminish idiosyncratic volatilities (relative to market-related moves), the market forecasts a *reversion* to more-normal conditions thereafter.

Fig. 3, in turn, demonstrates the average value for the high-beta oil equities (BUSOILP simple-average $\widehat{\beta}$ over this period: 1.18) is generally *lower than* its historical counterpart. The average difference over this period is -0.322, with a std. error of 0.011.

Finally, it is instructive to compare and contrast the oil-company equity betas reported here with those obtained by Chang, Christoffersen, Jacobs and Vainberg (CCJV) (2012) and Buss and Vilkov (2012). CCJV generally report far-lower betas (0.33 to 0.80), but that may well be due to the earlier 1996 – 2004 time period covered in their sample: As is well-known, crude-oil exhibited a far-lower correlation prior to the Great Recession. Whether the heightened correlation exhibited more recently is due to the disparate perspectives of "financialization of the energy industry" or to "integrated capital markets" remains an issue to be resolved. Buss and Vilkov (2012), in turn, report a marginally higher implied beta relative to the historical beta. One of the findings of the current paper is that the relationship between historical and implied is quite sensitive to the time period being analyzed — specifically, whether we are in "crisis" or calm mode.

3 Using *Commodity* Options to Obtain Forward-Looking *Commodity* Betas

We now apply the one-factor model directly to crude-oil futures contracts. Specifically, for varying maturities T apply a market-model to returns on crude-oil futures contracts,

$$r_T = a_T + \beta_T R_{\text{SPX}} + e_T \tag{10}$$

$$\Sigma_T^2 = \beta_T^2 \sigma_{mT}^2 + \sigma_T^2 \tag{11}$$

where

$\Sigma_T^2 \equiv \mathrm{Var}(r_T)$, the variance of the return on crude-oil futures contract of maturity T

$\beta_T \equiv \mathrm{Cov}\,(R_T,\, R_{\mathrm{SPX}})/\ \mathrm{Var}\,(R_{\mathrm{SPX}})$, market beta of oil futures contract of maturity T

$\sigma_{mT}^2 \equiv \mathrm{Var}\big(R_{\mathrm{SPX},T}\big)$, the variance of the return on the S&P 500 market index to expiration date T

$\sigma_{iT}^2 \equiv \mathrm{Var}(e_{iT})$, the idiosyncratic variance

As before, the hybrid portion of the model links the historical estimates $\{\hat{\beta}_i,\, \hat{\sigma}_i\}$ to their forward-looking analogues $\{\beta_i,\, \sigma_i\}$ via either multiplicative (12) or additive (13) *quadratic* corrections: Pooling all maturities $T \leq 2$, at any date t,

$$\begin{cases} \beta_{Tt} &= \hat{\beta}_{1t}\left[1 + a_{1ct} + a_{1lt}\,(T-1) + a_{1qt}\,(T-1)^2\right] \\ \sigma_{Tt} &= \hat{\sigma}_{1t}\left[1 + a_{2ct} + a_{2lt}\,(T-1) + a_{2qt}\,(T-1)^2\right] \end{cases} \tag{12}$$

$$\begin{cases} \beta_{Tt} &= \hat{\beta}_{1t} + \alpha_{1ct} + \alpha_{1lt}\,(T-1) + \alpha_{1qt}\,(T-1)^2 \\ \sigma_{Tt} &= \hat{\sigma}_{1t} + \alpha_{2ct} + \alpha_{2lt}\,(T-1) + \alpha_{2qt}\,(T-1)^2 \end{cases} \tag{13}$$

Test #2 — Cross-Sectional Daily Tests (13):

The results are reported in Figs. 4 and 5:

1. Fig. 4 reports the linear adjustment, α_{1lt}, for the futures contracts. Note the non-zero values of the adjustment at the high-volatility period of the Great Recession and during the Arab Spring of 2011, and their smoothened value.[8]

2. Regarding the betas of the prompt-month contract on the S&P 500 Index, these report the historical betas, the resulting additive-quadratic adjusted betas, and their smoothened analogue. The key point is that the hybrid adjusted

[8] See Gutierrez, Linhart and Pitblado (2003) for the smoothing algorithm.

betas anticipate some of the important changes which occurred in the past two crises — the crash of 2008 and the "Arab Spring" events of 2011 — when there were sharp changes in the sign of these betas.[9]

[9] Recognizing that Implied Betas are also functions, in part, of *Historicals,* the regression test uses betas for the period 05/21/2008 to 04/05/2010 (with subsequent data used to compute subsequently-realized betas):

$$\begin{array}{c}\text{Subsequently-Realized}\\ \text{Historical Betas}\end{array} = \text{const.} + a\begin{pmatrix}\text{Historical}\\ \text{Betas}\end{pmatrix} + b\begin{pmatrix}\text{Implied}\\ \text{Betas}\end{pmatrix}.$$

In the empirical results for maturities out to 24 mos., the coefficient $\hat{b}$ was statistically significant for 14 of those 24 maturities: 1 – 6, 9 – 10, 15 – 16, 18, 21, 22 and 24.

4 Using Equity Options to Obtain Forward-Looking $\mathrm{Corr}(R_{\mathrm{CL}}, R_{\mathrm{SPX}})$

4.1 The Two-Factor Model

Consider the rate of return R_i on the equity of an oil company and relate that return to two underlying assets, the stock market return R_{SPX} and the 1-yr. crude-oil futures contract R_{CL}, and an uncorrelated idiosyncratic noise term e_i :[10]

$$R_i = a_i + \beta_{i,\mathrm{SPX}} R_{\mathrm{SPX}} + \beta_{i,\mathrm{CL}} R_{\mathrm{CL}} + e_i. \tag{14}$$

Three comments regarding eq. (14) are in order:

1. Eq. (14) is not an *asset pricing* formulation. That is, we make no assumptions regarding the magnitude of a_i; our interest here is purely in the vols and correlation.

2. If we sought to understand the rates of return on oil stocks, we could debate at length the optimal *maturity* of the oil futures we should be utilizing. Presumably, this would have something to do with the company-specific rate of extraction from current and prospective oil fields. Our point here is different: We *fix* the maturity at the one-year mark, and leave all other uncorrelated effects to reside in e_i.

3. As is well-known, these oil companies also have exposure to natgas, which product they frequently extract in the same or different fields. Once again, since we are interested in crude-oil/S&P correlation and vols, by construction we leave all other uncorrelated effects to e_i.

Applying the variance operator to (14) yields

$$\Sigma_i^2 = \beta_{i,\mathrm{SPX}}^2 \sigma_m^2 + 2\beta_{i,\mathrm{SPX}} \beta_{i,\mathrm{CL}} \rho_{m,\mathrm{CL}} \sigma_m \sigma_{\mathrm{CL}} + \beta_{i,\mathrm{CL}}^2 \sigma_{\mathrm{CL}}^2 + \sigma_i^2, \tag{15}$$

---

[10] That is,

$$\begin{aligned} \mathrm{Corr}\,(R_{\mathrm{SPX}}, e_i) &= 0 \\ \mathrm{Corr}\,(R_{\mathrm{CL}}, e_i) &= 0 \end{aligned}$$

The regression formulation we utilize to extract historical parameter values does satisfy a special case of this condition, $\mathrm{Corr}\,(\beta_{i,\mathrm{SPX}} R_{\mathrm{SPX}} + \beta_{i,\mathrm{CL}} R_{\mathrm{CL}}, e_i) = 0$.

where

$$\Sigma_i^2 = \mathrm{Var}(R_i)$$
$$\sigma_m^2 = \mathrm{Var}(R_{\mathrm{SPX}})$$
$$\sigma_{\mathrm{CL}}^2 = \mathrm{Var}(R_{\mathrm{CL}})$$
$$\rho_{m,\mathrm{CL}} = \mathrm{Corr}(R_{\mathrm{SPX}},\, R_{\mathrm{CL}})$$
$$\sigma_i^2 = \mathrm{Var}(e_i)$$

4.2 Specification of the Econometric Tests for the Two-Factor Model

By analogy to the one-factor model, the additive and multiplicative corrections for the two-factor model are:[11]

$$\begin{cases} \beta_{i,\mathrm{SPX}} &= \hat{\beta}_{i,\mathrm{SPX}} + \alpha_{1c} + \alpha_{1l}\,(T-12) \\ \beta_{i,\mathrm{CL}} &= \hat{\beta}_{i,\mathrm{CL}} + \alpha_{2c} + \alpha_{2l}\,(T-12) \\ \rho_{m,\mathrm{CL}} &= \hat{\rho}_{1,\mathrm{CL}} + \alpha_{3c} + \alpha_{3l}\,(T-12) \\ \sigma_i &= \hat{\sigma}_i + \alpha_{4c} + \alpha_{4l}\,(T-12) \end{cases} \tag{16}$$

Since the correlation $\rho_{m,\mathrm{CL}}$ is not stock i-specific, it does not require a modification of the historical correlation $\hat{\rho}_{m,\mathrm{CL}}$, but can be simply computed as one of the outputs of the optimization routine (17) defined below. However, in practical implementation it was found useful to nevertheless model that as in (16) above in order to obtain more-convergent solutions.

Cross-Sectional Daily Tests of (16): Assuming data on N stocks and M maturities and their associated ATM options, in this set of tests, we formulate the additive-model (16) each day t in the sample period:[12]

[11] A natural modeling case to examine is the *affine*, which would combine additive and multiplicative as special cases. Although we did experiment with such a model, the results experienced greater convergence difficulties, as well as rendering their interpretation more problematic.

[12] The formulation of the three additive models is again analogous to their multiplicative counterparts.

$$\min_{\{\boldsymbol{\alpha}\}} \sum_{i=1}^{N} \sum_{m=1}^{M} \Big(\Sigma_i^2 - \Big[\widehat{\beta}_{i,\mathrm{SPX}} + \alpha_{1c} + \alpha_{1l}\,(M-12)\Big]^2 \sigma_m^2$$
$$+2\,\Big[\widehat{\beta}_{i,\mathrm{SPX}} + \alpha_{1c} + \alpha_{1l}\,(M-12)\Big]\Big[\widehat{\beta}_{i,\mathrm{CL}} + \alpha_{2c} + \alpha_{2l}\,(M-12)\Big]\big[\widehat{\rho}_{1,\mathrm{CL}} + \alpha_{3c} + \alpha_{3l}\,(M-12)\big]\cdot$$
$$+\,\widehat{\beta}_{i,\mathrm{CL}}^2 a_{2t}^2 \sigma_{\mathrm{CL}}^2 + \widehat{\sigma}_i^2 a_{4t}^2\Big)^2$$
$$\boldsymbol{\alpha} \equiv \{\alpha_{1ct},\, \alpha_{1lt},\, \alpha_{2ct},\, \alpha_{2lt},\, \alpha_{3ct},\, \alpha_{3lt},\, \alpha_{4ct},\, \alpha_{4lt}\}$$

4.3 Empirical Results

Test #3 — Cross-Sectional Daily Tests (17):

Figure 5 below presents the time-series of historical and implied correlations over the period 1/3/2008 – 7/31/2012. While exceeding unity is statistically impossible, such does occur in *point estimates* elsewhere in commodity finance: One example may be found in the implied correlation inferred from applying the Margrabe (1978) formula to *spread options* using implieds for the two sides of the spread. While broadly consistent with the results obtained for the single-factor case (13), there is an abundance of "noise" in the results reported here.

5 Computing Expected Crude-Oil Spot Price Based on Implied Corr(CL, SPX)

To understand the previous two figures in historical perspective, recall in the first half of 2008, oil price surged to all-time highs, peaking at \$145.54 on July 3rd. These oil-price increases contrasted with developed economies' initial slide into recession, resulting in a negative correlation between oil prices and the S&P 500 proxy for world economic activity. This confluence is more acutely reflected in the forward-looking correlations, which are more negative than their historical analogues. As previously presented in Table 1, the ability to observe the sign of the correlation coefficient, and in particular one that is forward-looking, permits us to understand whether a prevailing shock to oil prices is supply- or demand-side in nature.

Moreover, per the analytics below, that sign will also dictate whether the prevailing futures contract is an upward- or downward-biased predictor of expected crude-oil spot prices. These implications of a forward-looking negative correlation(CL, SPX) flow from an application of the CAPM: Since $\beta_{\text{CL, SPX}}$ is proportional to $\rho_{\text{CL, SPX}}$, $\text{sign}(\rho_{\text{CL, SPX}})$ will determine whether the futures contract price is a downward- or upward-biased estimate of the expected spot price of crude one year out. To see this, assume the CAPM obtains for commodities — i.e., that the CAPM is the correct pricing model as crude-oil futures prices trade in fully-integrated capital markets. In that case, we have[13]

$$
\begin{aligned}
\mu_{\text{CL},t} &= \beta_{\text{CL}}\left(\mu_{Mt} - r_t\right), \qquad (18)\\
&= \frac{\text{Cov}\left(R_{\text{CL}},\, R_M\right)}{\text{Var}\left(R_m\right)}\left(\mu_{Mt} - r_t\right)\\
&= \frac{\rho_{\text{CL},t}\sigma_{\text{CL},t}}{\sigma_{Mt}}\left(\mu_{Mt} - r_t\right) \equiv \rho_{\text{CL},t}\sigma_{\text{CL},t}\,\lambda_t \qquad (19)
\end{aligned}
$$

where

$\mu_{\text{CL},t}$ = the expected rate of change on the one-year crude-oil futures contract at date t

[13] Note that in (19) we abstain from subtracting the riskfree rate on the LHS since, for costless-to-enter futures contract, the return in a risk-neutral world is 0 (not the riskfree rate of interest).

β_{CL} = the beta for the one-year crude-oil futures contract. Formally, $\beta_{\text{CL}} = \text{Cov}(R_{\text{CL}}, R_M)/\text{Var}(R_m)$

$\rho_{\text{CL},t}$ = the current *ex-ante* correlation between $F_{\text{CL},t}$ and the Market portfolio

$\sigma_{\text{CL},t}$ = Implied vol on the one-year crude-oil futures contract

λ_t = Current date-t stock market Sharpe Ratio $\equiv \dfrac{\mu_{Mt} - r_t}{\sigma_{Mt}}$

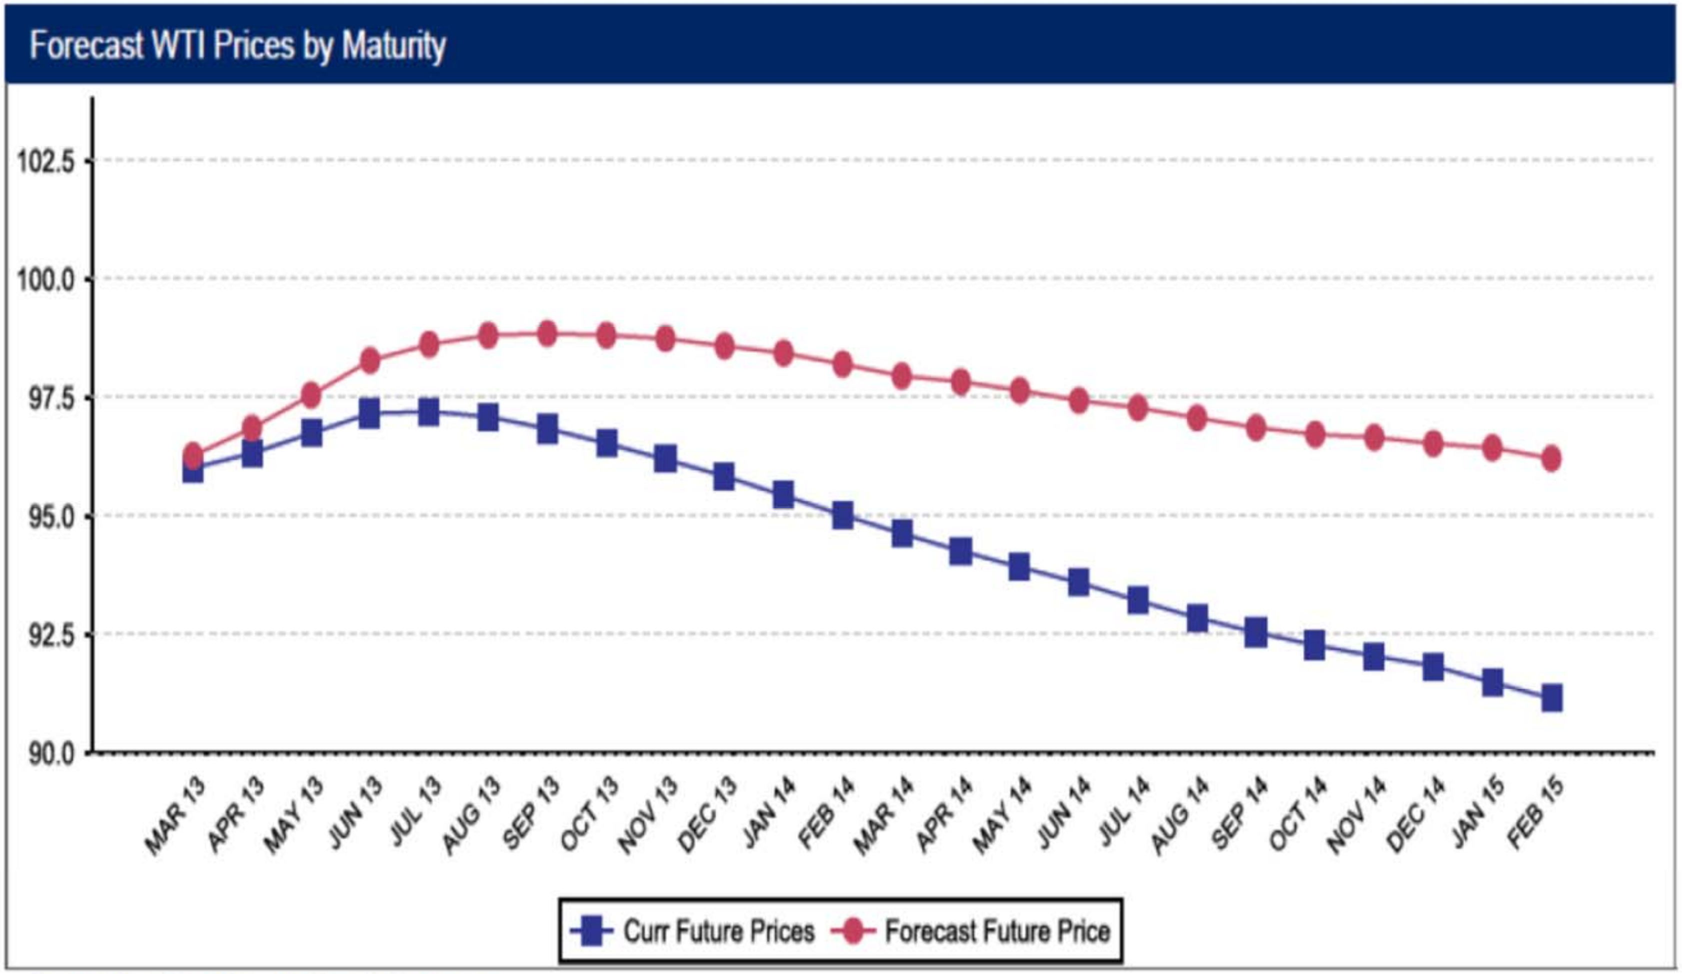
A forward-looking date-t Sharpe Ratio may be obtained using the methodology in Doran, Ronn and Goldberg (2009). The authors obtain a Sharpe Ratio λ_t given by the expression $\lambda_t \equiv 0.46 - 0.162\,\dfrac{\text{S\&P }500_t}{\text{S\&P }500_{t-5,t-6}}$. The reader is referred to the article for details regarding the estimation of the two values 0.46 and $-.162$. The ratio $\text{S\&P }500_t/\text{ S\&P }500_{t-5,t-6}$ is defined as the current value of the S&P divided by its average value over an annual period centered 5.5 yrs. ago.

We can now compute the one-year $[t,\ t+1]$ expected rate of return on the futures contract to its date-$t+1$ maturity. Recalling the terminal value of the WTI futures contract is by definition the spot price of crude, we compute the expected rate of change on the futures contract from date t to its spot price at $t+1$:

$$
\begin{aligned}
E\left(F_{\text{CL},T}\right) &\equiv F_{\text{CL},t}\exp\left\{\mu_{\text{CL},T}T\right\} \\
&= F_{\text{CL},t}\exp\left\{\frac{\rho_{\text{CL},t}\sigma_{\text{CL},t}}{\sigma_{Mt}}\left(\mu_{Mt}-r_t\right)T\right\} \\
&\equiv F_{\text{CL},t}\exp\left\{\rho_{\text{CL},t}\sigma_{\text{CL},t}\lambda_t T\right\} \\
\Longrightarrow\ \frac{1}{T}\ln\left[\frac{E\left(F_{\text{CL},T}\right)}{F_{\text{CL},t}}\right] &= \rho_{\text{CL},t}\sigma_{\text{CL},t}\lambda_t \\
\begin{array}{c}\text{Annualized Expected}\\ \text{Futures Price Change}\end{array} &\equiv \text{Corr}\left(R_{\text{CL}},\ R_M\right)\begin{pmatrix}\text{Current Futures}\\ \text{Implied Vol}\end{pmatrix}\begin{pmatrix}\text{Current Stock Market}\\ \text{Sharpe Ratio}\end{pmatrix}
\end{aligned}
\tag{20}
$$

For a one-year-ahead expected price, $T = t+1-t = 1$. In (20), the RHS contains three elements, all of which lend themselves to forward-looking measures. $\sigma_{\text{CL},t}$ is observable through the market price of its corresponding option, and as noted the literature provides alternative estimates of the prospective Sharpe Ratio λ_t. The third is $\mathrm{Corr}\left(R_{\mathrm{CL}}, R_M\right)$, the implied correlation between crude-oil futures and the S&P 500.

Using a 60-day moving-window historical correlation of crude-oil futures with the S&P in the conditional-CAPM approach described above, Figs. 6 and 7 depict the entire term structure of expected spot prices at two distinct points in time. The result of substantial interest here is this: Even though both term structures of futures prices are in *backwardation*, the term structure of expected spot prices is virtually flat.



Source: Bloomberg, Guzman Financial Engineers

6 Conclusions

The paper has documented the potential for using options on equities, commodities and a market index to infer forward-looking statistics of relevance to portfolio managers and analysts in capital budgeting:

1. Applying a single-factor model to equity, commodity and index options, we were able to use historical data parsimoniously to obtain reasonable and intuitively-appealing forward-looking equity betas.

2. Using a two-factor extension to include the return on a crude-oil futures contract, we computed a forward-looking correlation between oil and the S&P, and proceeded to obtain an expected futures price of oil using the CAPM. The empirical results were intuitively appealing in reflecting current conditions in the oil and equity markets.

3. We applied these statistical concepts to inferring a conditional-CAPM forecast of crude-oil spot prices.

The work here admits of extensions in several interesting directions. With respect to the equity analysis considered in Section 2,

1. Add additional stocks, so as to permit credible and accurate measurement of the slope and intercept coefficients

2. Confirm whether, on average, and especially during times of crises, the implied systematic variance ratio $(\beta_{im}\sigma_m/\Sigma_i)^2$ exceeds its historical counterpart $\left(\widehat{\beta}_{im}\widehat{\sigma}_m/\widehat{\Sigma}_i\right)^2$

With respect to the oil futures contracts considered in Section 3, the key extension deferred to next paper is whether the oil-price predictor here outperforms two alternative predictors of crude-oil spot prices are:

1. Practitioner's use of the crude-oil *spot price* as a predictor of future spot prices

2. The futures price as an unbiased predictor of future spot prices

Abstract

This paper investigates how the introduction of single stock futures impacts on the margin trading of the underlying stocks. This study selects twenty stocks, which are listed on the Taiwan Stock Exchange and had top twenty transaction volume futures contracts in the derivatives market during our sample period, to examine the substitution and complementary effects on credit transactions of the underlying stock during the sample period from 13 May 2009 to 4 September 2013. We also employ different company characteristics variables, which are market capitalization, PE ratio, price to book ratio and stock turnover ratio of the underlying companies, to evaluate if there are any significant substitution and complementary effects on margin trading under the firm characteristics. The empirical results indicate that the complementary effect and the substitution effect exist at the same time and various firm characteristics do lead to different degree of substitution or complementary effects on margin trading after SSFs list.

Keywords: *single stock futures, margin trading, substitution effect, complementary effect.*

1. Introduction

Single Stock Futures (SSFs) are futures contracts on individual shares (stocks) between two parties to buy or sell the underlying shares of a particular listed company at a pre-determined price on a pre-determined date. SSFs were first introduced in Australia, Hungary, Holland, Sweden and Hong Kong in the mid-1990s. Taiwan's financial regulator allowed futures trading in individual stocks listed on the Taiwan stock exchange in 2010. While most studies on SSFs have examined the impact on the underlying share prices and volatility, there has been little work on their potential impact on margin trading in the spot market. The main contribution of futures market stems from a reduction in costs that permit transactions and price discovery to occur more efficiently. In this paper we will analyze how the introduction of SSFs impacts on the margin trading. Although both the SSFs and margin trading have the same underlying shares, but they belong to different markets. Stock futures may stimulate margin trading by improving stock price discovery and increase the efficiency of the spot market. Thus, introduction of SSFs is expected to lead to a complement or substitute for margin trading.

Many researchers are interested in the link between the derivatives and their underlying assets. Miller (1977) points out that derivative (more specifically put options) might remove short-sale constraints. Chau, F. et al. (2008) indicate that the introduction of cheaply traded derivatives may allow for leveraged positions that destabilize speculation. Danielsen et al. (2009) find that short selling in the underlying securities declines, after futures are introduced. In the spot market, informed traders transfer to the futures market for less information asymmetry and less transaction costs, indicating the presence of substitution effect on credit transaction. Many empirical studies examine the influence of futures trading on the volatility of underlying spot market. Previous investigations from Weller and Yano (1987) and Detemple and Jorion (1990) support the conclusion that the introduction of derivatives can reduce volatility of the underlying stocks. Lee and Tong (1998) state that stock market trading volume increase but the volatility of the underlying stocks does not increase after the introduction of stock futures. Dennis and Sim (1999) examine a small number of shares to find the relationship between futures trading and spot market volatility. McKenzie et al. (2001) find a general reduction in systematic risk on individual stocks after the introduction of individual share futures. Lien and Yang (2003) find that the availability of the futures contracts attenuate the expiration effects on price volatility and trading volume of individual stocks in Australia. The introduction of stock futures in the American market was also the focus of a study done by Ang and Cheng (2005b). Xie and Huang (2014) investigate the impact of index futures trading on the volatility of the spot market in China and find the launch of index futures does not decrease the volatility of the spot market.

Several articles have examined the effect of the futures trading on the quality and efficiency of the spot market. Ang and Cheng (2005a) find SSFs trading increases market efficiency. Shastri et al. (2008) indicate that in the United States option listings improve the market quality of the underlying stocks.

Hopefully our work can contribute to the literature in the following ways. First, there have been few studies examining substitution and complementary effects of SSFs on margin trading. Second, margin-purchase and margin-sale are separately investigated. Third, the complementary effect and the substitution effect might exist at the same time. Fourth, various firm characteristics do lead to different degree of substitution or complementary effects on margin trading after SSFs list.

2. Theory and Hypotheses

2.1 Substitution effect of stock futures on margin trading

Although SSFs and margin trading have the same underlying asset, but belong to different market. Low-cost SSFs contracts and their relative less access restriction may cause informed investors to shift their activities away from the underlying share and towards the futures market. Thus, introduction of single-stock futures is expected to lead to a substitute and competing market for margin-purchase and short-sale.

Chau, et al. (2008) study the introduction of the Universal Stock Futures (USF) and find the level of feedback trading is low in both the pre-futures and post-futures periods for USF and control stocks. Danielsen, et al. (2009) examine how the introduction of single-stock futures impacts short-sale market and find that short selling in the underlying securities declines, after futures are introduced. Gygax, et al.(2009) point out that the average proportional spreads decrease significantly after SSFs introduction. The average daily trading volume in the NYSE stock spot market is reduced by 389,000 shares. This pattern means a migration of liquidity trading to the SSFs market. Empirical microstructure also said that the contract easier emptying and lower transaction costs to attract informed traders migrate from the spot market to the futures market. Miller (1977), Phillips (2010) find that options act as an effective substitute to short-sales, significantly contributing to the informational efficiency of the market.

In consideration of low-cost, less access restriction and trading strategies diversity of SSFs, our first hypothesis can be stated as follows:

Hypothesis 1: The SSFs contracts serve as a substitute for margin-purchase and short-sale in the underlying stock market.

2.2 Complementary effect of stock futures on margin trading

Many studies indicate that futures market serve as an important medium for price discovery. Lien and Yang (2003) show that that the availability of the futures contracts reduces the expiration effects on price volatility and trading volume of underlying stocks. Cao, et al. (2005) point out that the options market plays an important role in information revelation, whereas during normal market times, the stock market is the primary place of price discovery. Chau, et al. (2008) investigate the impact of the introduction of Universal Stock Futures on underlying market and find that the level of feedback trading is low in both the pre-futures and post-futures periods for USF and control stocks, with the pre-futures period exhibiting marginally more feedback trading. Shastri et al. (2008) indicate that there are increases in trading volume, trading frequency and transaction size for the underlying stocks after option listings. It means option listings improve the market quality of the underlying stocks. Kumar and Tse (2009) analyze SSFs in the Indian market to understand their contribution in price leadership. They find that trades in the stock market contribute more to price discovery than trades in the SSF market, while quotes in the SSF market are more price innovative than quotes in the stock market. Martins, et al. (2012) study Indian SSFs and conclude that a significant relationship exists between the trading volumes of the underlying stocks and the single stock futures on them. Siddiqi, et al. (2012) indicate that the impact of SSFs on trading volume, the number of trades, and the trading value for most the underlying stocks is positively and significantly. They conclude that liquidity of the underlying stocks has increased with the introduction of the SSF in the Pakistan's market.

Based on the above, SSFs trading can help to improve the quality and efficiency of the spot market, and thus increase the trading volume and liquidity for the underlying securities. These features lead to the following hypothesis

.

Hypothesis 2: The introduction of SSFs will increase the efficiency and trading volume of the underlying stock market.

Hypothesis 3: The SSFs contracts serve as a complement for margin trading.

2.3 Substitution and complementary effects on margin trading under firm characteristics

Previous studies have found that stock returns are associated with various firm characteristics. Fama and French (1992, 1993, 1996) bring together beta, size, leverage, book-to-market and EP in a cross-section study. They find that firm size and book-to-market ratio explain most of the variations in US stock returns. Daniel and Titman (1997) find that it is characteristics rather than factor loadings that determine expected returns. Datar, et al. (1998) liquidity plays a significant role in explaining the cross-sectional variation in stock returns even after controlling for the firm characteristics like firm-size, book-to-market ratio and the firm beta. Jarjir (2005) argues that only the size premium is significant and help explaining returns in cross-sectional regressions. In time-series regressions, the three factors (SMB, HML and leverage), with the market portfolio, do have an affect on stock returns in France.

In studying SSFs that have explanatory power for margin trading, one should consider their underlying firm characteristics that have been found to be significant by researchers. These issues lead to the following hypothesis.

Hypothesis 4: Various firm characteristics lead to different degree of substitution or complementary effects on margin trading after SSFs list.

3. Research Methods

3.1 Data

SSFs were introduced on Taiwan Futures Exchange in Taiwan. 252 SSFs listed on Taiwan Futures Exchange are analyzed. We examine SSFs listing events from 13 May 2009 to 4 September 2013. SSFs and margin trading data are obtained from the Taiwan Economic Journal (TEJ), Taiwan Futures Exchange (TAIFEX), Taiwan Stock Exchange (TWSE) and Market Observation Post System (MOPS). In order to avoid dilution of overall research results, we choose only the top 20 daily transaction volume of SSFs as our research focus.

The research variables we use in this paper are defined as follows:

1. Stock Trading Volume (STVol): spot market trading volume of underlying shares (1000-share lot)
2. Margin Trading Volume (MTVol): MTLV+MTSV (1000-share lot)
3. Non-Margin Trading Volume (NMTVol): STVol – MTVol (1000-share lot)
4. Margin-purchase Volume (MTLV) (1000-share lot)
5. Margin-sale Volume (MTSV) (1000-share lot)
6. Dummy variables (D), 0 for pre-introduction of SSFs and 1 for post-introduction of SSFs

Control variables of relevant transaction data are defined as follows:

1. TWSE shares daily trading volume (Volume)
2. TAIEX daily closing value (Price)
3. TAIEX daily high-low range (HMLP)

Firm Characteristics variables of underlying shares:

1. Market value (MV) (in millions NT$)
2. Price-to-Earnings Ratio (PE)
3. Price-to-Book Ratio (PB)
4. Stock Turnover Ratio (TR)

Table 1 displays the summary statistics of the main variables we use in our regressions. The average value of the underlying stock futures is 266,118.5 million. This means that most of the analyzed companies are large-sized. The average Price-to-Earnings Ratio (39.19) is higher than Price-to-Book Ratio (1.87). It implies a steady growth of underlying companies. The stock turnover ratio averaged 0.67 percent and indicated better liquidity.

Table 1 Summary statistics

Variable	Minimum	Maximum	Mean	Std. Dev	Observations
STVol	341	267289	28756.97	26440.49	7200
MTVol	0	93781	9590.95	10797.61	7200
NMTVol	-237	201327	19166.02	18318.52	7200
MTLV	0	56944	4413.91	5329.03	7200
MTSV	0	15643	440.19	895.91	7200
MV	12916	1683543	266118.5	392316.26	7200
PE	0	2550	39.186	177.90	7200
PB	0.35	14.27	1.8721	1.98	7200
TR	0.0281	12.7046	0.668279	0.91	7200

Note: STVol is spot market trading volume of underlying shares; MTVol is margin trading volume; NMTVol is difference between STVol and MTVol; MTLV is Margin-purchase Volume; MTSV is Margin-sale Volume; MV: outstanding shares (stocks) ×Closing price (in million NT$); PE is Price-to-Earnings Ratio; PB is Price-to-Book Ratio; TR is Stock Turnover Ratio (Volume / Shares × 100 (%)).

3.2 Empirical model

3.2.1 The synergistic effect on underlying spot market and credit transactions

This paper investigates first the impact of the introduction of SSFs on the underlying spot market and margin trading. With 180 pre- and post-initial listing of SSFs transaction data, we use event-study methods to examine the synergistic effect. We mainly study the research paper of Gygax et al. (2009) and Madhavan et al. (2005) and use the following regression models.

$$Y_t(STVol_t, MTVol_t, NMTVol_t, MTLV_t, MTSV_t) = a_0 + a_1 D + a_2 Volume_t + a_3 Price_t + a_4 HMLP_t + \mathcal{E}_t \qquad (1)$$

Where t indicates day t; $\mathrm{STVol_t}$ is stock trading volume; $\mathrm{MTVol_t}$ is margin trading volume; $\mathrm{NMTVol_t}$ is non-margin trading volume; $\mathrm{MTLV_t}$ is margin-purchase volume; $\mathrm{MTSV_t}$ is margin-sale; D is the SSFs introduction timing dummy variable; $\mathrm{Volume_t}$is TWSE shares daily trading volume; $\mathrm{Price_t}$ is TAIEX daily closing value; $\mathrm{HMLP_t}$ is TAIEX daily high-low range.

3.2.2 The substitution and complementary effects on margin trading

We use the following regression models to examine the substitution and complementary effects of SSFs introduction on margin trading. In order to explore the implicit implication of a complementary effect in the substitution effect we add an interaction term of $D \times NMTVol_t$.

$$\mathrm{Y}_t(MTLV_t, MTSV_t) = a_0 + a_1 D + a_2 D \times NMTVol_t + a_3 Volume_t + a_4 Price_t + a_5 \mathrm{HMLP}_t + \mathcal{E}_t \qquad (2)$$

Where t indicates day t; $\mathrm{STVol_t}$ is stock trading volume; $\mathrm{MTVol_t}$ is margin trading volume; $\mathrm{NMTVol_t}$ is non-margin trading volume; $\mathrm{MTLV_t}$ is margin-purchase volume; $\mathrm{MTSV_t}$ is margin-sale; D is the SSFs introduction timing dummy variable; NMTVolt is the difference between stock trading volume and margin trading volume; $\mathrm{Volume_t}$ is TWSE shares daily trading volume; $\mathrm{Price_t}$ is TAIEX daily closing value; $\mathrm{HMLP_t}$ is TAIEX daily high-low range.

3.2.3 Substitution and complementary effects on credit transactions under firm characteristics

It can be the situation to reduce the credit transactions for investors that the higher the risk of the underlying stock, the higher the relative risk of its credit transactions. From the above point of view, we can further investigate whether the firm risk of the underlying stock influences the substitution and complementary effects on credit transactions. From the literature discussed previously, we use the market value (MV), stock turnover ratio (TR), Price-to-Earnings Ratio (PE) and Price-to-Book

Ratio (PB) of the company to be the proxy variables for company risk.

$$Y_t(MTLV_t,MTSV_t) = a_0+a_1D+a_2D\times NMTVol_t+a_3D\times FC_t+a_4D\times NMTVol_t\times FC_t+a_5Volume_t+a_6Price_t+a_7HMLP_t+\varepsilon_t \quad (3)$$

Where t indicates day t; $STVol_t$ is stock trading volume; $MTVol_t$ is margin trading volume; $NMTVol_t$ is non-margin trading volume; $MTLV_t$ is margin-purchase volume; $MTSV_t$ is margin-sale; D is the SSFs introduction timing dummy variable; NMTVolt is the difference between stock trading volume and margin trading volume; FC_t is firm characteristics variables which include MV, PE, PB and TR; $Volume_t$ is TWSE shares daily trading volume; $Price_t$ is TAIEX daily closing value; $HMLP_t$ is TAIEX daily high-low range.

4. Empirical results and analysis

4.1 t test

Table 2 shows the independent t-tests of average trading volume comparisons for the pre-introduction and post-introduction periods. As a result, for all the STVol, MTVol, NMTVol and MTLV of the underlying stocks are significantly lower after the introduction of SSFs. This indicates a possible substitution effect of stock futures on spot market and margin trading

.

Table 2 independent sample t test before and after the two stock futures market

Variable	Pre mean	Post mean	Difference	t value
STVol	30998.45	26515.48	-4482.97	7.22***
MTVol	10837.26	8344.63	-2492.63	9.86***
NMTVol	20161.2	18170.85	-1990.35	4.62***
MTLV	5002.94	3824.87	-1178.07	9.44***
MTSV	444.26	436.11	-8.15	0.39

Note: Paired t tests for 180 days pre/post-introduction of SSFs. STVol is spot market trading volume of underlying shares; MTVol is margin purchases volume and short sales volume; NMTVol is difference between STVol and MTVol; MTLV is Margin Trading-Long Volume; MTSV is Margin Trading-Short Volume, *, ** and *** denote significant at 10%, 5% and 1% respectively.

4.2 Synergistic effect on underlying stock market and margin trading

In Table 3 we examine the first model for synergistic effect on underlying stock market and margin trading. The results indicate clearly all variables STVol, MTVol, NMTVol, MTLV and MTSV increased significantly after the introduction of SSFs when other factors of Volume, Price and HMLP under control. We accept the second hypothesis that introduction of SSFs will increase the efficiency and trading volume of the underlying stock market and margin trading. It is puzzling that the results are contrary to independent t test in table 2. The contradiction holds as long as the relationship between substitution effect and complementary effect are not clarified. The complementary effect and the substitution effect might exist at the same time, but in different degree. A more empirical precise study in the following sections is necessary to explain these phenomena.

Table 3 Synergistic effect on underlying spot market and credit transactions

Variable	STVol	MTVol	NMTVol	MTLV	MTSV
Constant	90979.88 (23.36)***	29274.51 (18.24)***	61705.37 (22.33)***	13480.5 (16.9)***	1419.29 (9.79)***

Price	-13.49 (-27.22)***	-4.71 (-23.05)***	-8.78 (-24.99)***	-2.21 (-21.8)***	-0.17 (-9.32)***
HMLP	-19.65 (-3.04)***	-12.19 (-4.58)***	-7.46 (-1.63)	-6.74 (-5.09)***	0.35 (1.47)
Adj. R^2	0.19	0.17	0.15	0.16	0.02
F stat	411.71	371.99	309.25	343.09	34.42

Note: Paired t tests for 180 days pre/post-introduction of SSFs. STVol is spot market trading volume of underlying shares; MTVol is margin purchases volume and short sales volume; NMTVol is difference between STVol and MTVol; MTLV is Margin Trading-Long Volume; MTSV is Margin Trading-Short Volume; D *is* the SSFs introduction timing dummy variable; Volume is day market trading volume; Price is day market closing price; HMLP is daily high-low range, *, ** and *** denote significant at 10%, 5% and 1% respectively.

4.3 Substitution and complementary effects on margin trading

A significant reduction in the amount of margin trading after the introduction of SSFs means a greater complementary effect. In contrast, a significant increase in the amount of margin trading after the introduction of SSFs means a greater substitution effect. The results in table 3 indicate that introduction of SSFs will increase the efficiency and trading volume of the underlying stock market and margin trading. These results are different with the findings in table 2. The great power relationship between substitution effect and complementary effect is still not clarified. Therefore, in order to clarify the relationship between substitution effect and complementary effect, we add an interaction term of the timing dummy variable (D) with Non-Margin Trading Volume (NMTVol) in the regression model.

As shown in table 4, the significance of dummy variables indicates a substitution effect on margin trading after the introduction of SSFs. The results are consistent with our first substitution hypothesis between margin trading and SSFs. On the other hand, the interaction term (D* NMTVol) in both regressions is significant positive. It indicates the presence of a complementary effect under control of the substitution effect. This evidence is consistent with the third hypothesis that The SSFs contracts serve as a complement for margin trading.

Table 4 substitution effect and complementary effect on trading margin

Variable	MTLV	MTSV

Note: MTLV is Margin Trading-Long Volume; MTSV is Margin Trading-Short Volume; D *is* the SSFs introduction timing dummy variable; NMTVol is difference between STVol and MTVol ; Volume is day market trading volume; Price is day market closing price; HMLP is daily high-low range, *, ** and *** denote significant at 10%, 5% and 1% respectively.

4.4 Substitution and complementary effects on margin trading under firm characteristics

Previous studies found that the firm characteristics can capture the variation in stock returns. The substitution effect comes from the incentive provided for investors to shift their activities away from the margin trading and towards SSFs. The speculative incentive depends on the magnitude of investment risk. Cautious investors are likely to be comfortable with investments that have lower risk. Firm characteristics are proxy for risk factors in the stock market. Our research aims to link effect of SSFs to firm characteristics.

In this paper, we evaluate if there are any significant substitution and complementary effects on margin trading under the firm characteristics. Four firm characteristics variables were selected based on previous literature namely company size, price-to-earnings ratio, price-to-book ratio and stock turnover ratio. We add the interaction terms of D*NMTVol, D*FC and D*FC*NMTVol in the regression model. The empirical results are shown in Table 5. Panel A shows substitution and complementary effects on margin trading under consideration of market value. A significantly negative coefficient for dummy variable by MTLV and MTSV implies a substitution effect between margin trading and SSFs. The coefficient on the interaction term D*NMTVoL is positive by MTLV and MTSV, telling us the presence of a complementary effect on margin trading. The coefficient on the interaction term D*MV is negative by MTLV, indicating that a substitution effect on margin-purchase exists for the underlying firms with higher market value. A possible reason is that a larger firm is likely to be perceived as a lower risk. This leads to more leveraged transactions like SSFs. There is no significant effect on margin-sale. The last interaction term D*FC*NMTVol is negative by margin-purchase and margin-sale. It indicates a negative relationship between firm size and complementary effect. The possible reason for this result is because stocks of large-sized firms originally tend to be more liquid than small-sized firms. The complementary effect on margin trading increases less for large-sized firms than for small-sized firms.

Panel B shows substitution and complementary effects on margin trading under consideration of price-to-earnings ratio. A significantly negative coefficient for dummy variable by MTLV and MTSV implies a substitution effect between margin trading and SSFs. The coefficient on the interaction term D*NMTVoL is positive by MTLV and MTSV, telling us the presence of a complementary effect on margin trading. The coefficient on the interaction term D*PE is positive by MTLV and MTSV, indicating that a less substitution effect on both margin-purchase and margin-sale exists for the underlying firms with higher price-to-earnings ratio. A possible reason is that investing in a company with high PE ratio is risky. This leads to less leveraged transactions like SSFs. The last interaction term D*FC*NMTVol is positive by margin-purchase and margin-sale. It indicates a positive relationship between PE and complementary effect. The possible reason for this result is because stocks with higher PE tend to be less liquid than small-sized firms. This leads to better price discovery. The complementary effects on margin trading increase more for high PE firms than for lower PE firms.

Panel C shows substitution and complementary effects on margin trading under consideration of price-to-book ratio. A significantly negative coefficient for dummy variable by MTLV and MTSV implies a substitution effect between margin trading and SSFs. The coefficient on the interaction term D*NMTVoL is positive by MTLV and MTSV, telling us the presence of a complementary effect on margin trading. The coefficient on the interaction term D*PE is positive by MTLV and MTSV, indicating that a less substitution effect on both margin-purchase and margin-sale exists for the underlying firms with higher price-to-book ratio. A possible reason is that investing in a company with a high PB ratio is risky. This leads to less leveraged transactions like SSFs. The last interaction term D*FC*NMTVol is negative by margin-purchase and positive by margin-sale. It indicates a negative relationship between PB and complementary effect by margin-purchase. The possible reason for this result is because stocks with higher PB can be overpriced. This leads to less margin-purchase transactions. The complementary effect on margin-purchase increases less for high PB firms than for lower PB firms. On the other hand, higher PB leads to more margin-sale transactions. The complementary effect on margin-sale increases more for high PB firms than for low PB firms.

Panel D shows substitution and complementary effects on margin trading under consideration of stock turnover ratio. A significantly negative coefficient for dummy variable by MTLV and MTSV implies a substitution effect between margin trading and SSFs. The coefficient on the interaction term D*NMTVoL is positive by MTLV and MTSV, telling us the presence of a complementary effect on margin trading. The coefficient on the interaction term D*TR is positive by MTLV and MTSV, indicating that a less substitution effect on both margin-purchase and margin-sale exists for the underlying firms with higher stock turnover ratio. A possible reason is that investing in a company with high TR is risky. This leads to less leveraged transactions like SSFs. The last interaction term D*FC*NMTVol is negative by margin-sale. It indicates a negative relationship between TR and complementary effect by margin-sale. The possible reason for this result is because higher TR is associated with information asymmetry. This leads to less margin-sale transactions. The complementary effect on margin-sale increases less for high TR firms than for lower TR firms.

In summary, the above empirical results are generally consistent with our fourth hypothesis. Various firm characteristics do lead to different degree of substitution or complementary effects on margin trading after SSFs list. We find also that a less substitution effect on margin trading is associated with higher risk of the underlying firms. In contrast, a more complementary effect on margin trading is associated with higher risk of the underlying firms.

5. Conclusions

To meet the demand of various futures trading strategies and to provide market participants with a convenient way to transact efficiently in the regular market, TAIFEX introduced SSFs in 2010. SSFs have two main advantages compared to margin trading. First, the SSFs premium and commissions are cheaper. Investors can get leverages that are much higher and potentially make much higher profits than margin trading. Second, SSFs provide for numerous trading strategies and can be applied to a variety of portfolio management needs. Even though, margin trading also has advantages over SSFs in lower risk and higher transaction volume. SSFs can be used to replace or compliment margin trading. In this paper we analyze how the introduction of SSFs impacts on the margin trading.

This article has the following several empirical findings: first, the results of independent t-tests indicate that all the STVol, MTVol, NMTVol and MTLV of the underlying stocks are significantly lower after the introduction of SSFs. This indicates a possible substitution effect of stock futures on spot market and margin trading. The results are contrary to the synergistic effect examination of our first model. The contradiction holds as long as the relationship between substitution effect and complementary effect are not clarified. The complementary effect and the substitution effect might exist at the same time, but in different degree. Second, in order to clarify the relationship between substitution effect and complementary effect, we have examined model 2 and found that a complementary effect exists under control of the substitution effect. Third, various firm characteristics do lead to different degree of substitution or complementary effects on margin trading after SSFs list. We find also that a less substitution effect on margin trading is associated with higher risk of the underlying firms. In contrast, a more complementary effect on margin trading is associated with higher risk of the underlying firms.

Liquidity Risk Premium: A comparative analysis

vasilios.sogiakas@glasgow.ac.uk

During the last decades the investigation of liquidity has attracted the interest of many researchers and practitioners. Liquidity plays a pivotal role in the determination of the risk-return trade-off of securities, comprising several aspects of trading such as transaction cost, trading activity and price impact, leading more often than usual to an ambiguous risk-return foundation, on an asset pricing framework.
This paper empirically investigates the most important liquidity components and aims to conduct a comparative analysis on the liquidity risk premia of securities. Moreover, a causality analysis is implemented that focuses on the interrelationship between the liquidity components and the market dynamics.
According to the empirical findings of the paper the significance of liquidity is model and time specific. Most importantly, the heterogeneity between liquidity components exhibits a strong business cycle effect
Keywords: liquidity risk premium, transaction cost, trading activity, price impact.

JEL Classifications: G11, G12, G14

1. Introduction

The easiness to buy and sell stocks bears no clear cut role on expected stock returns. Theoretical and empirical models adhere to two separate schools, one set out by Amihud and Mendelson (1986) advocating that increased illiquidity commands higher returns and another by Constantinides (1986) claiming that transaction costs do not affect asset pricing. This paper aims to contribute to this discussion by investigating the pricing of stock liquidity's effect. Six established liquidity proxies spanning three categories of liquidity dimensions, namely - transaction costs, trading activity, and price impact are employed.

According to the first component of liquidity, stock return is an increasing and concave function of transaction cost and thus investors require higher returns for holding illiquid assets. Likewise, according to the trading activity component, investors' holding period is positively associated with transaction cost and consequently affects liquidity. Finally, the price impact accounts for the price response to order flow.

A higher tendency for transactions is commonly observed when the liquidity is higher. Based on the assumption that the liquidity states determine the trading timing for investors, Pereira and Zhang (2010) investigated the strategies of maximizing the investors' utility in an equilibrium model. Investors prefer trading on more liquid days; otherwise, higher return is required as compensation for illiquidity, as a result of lower asset prices in the state of low liquidity, which is less favourable for investor. This argument is addressed by Chordia, Roll, and Subrahmanyam (2001) who claim that liquidity effect is self-perpetuating, and in particular, agents tend to abate or even refrain from further trading after noticing a liquidity anomaly, which, in turn intensifies the anomaly by further reducing liquidity in those periods.

Empirical evidence of the relevant literature involves heterogeneity between the liquidity constituents that varies through time. For instance, while Brennan, Chordia, and Subrahmanyam (1998) detect a significant price impact effect on asset prices, Gervais, Kaniel, and Mingelgrin (2001) find that share prices tend to increase (decrease) over the subsequent days due to unanticipated high (low) past volume. They claim that the high trading activity could be the signal of information or attention instead, resulting in high return. Both of the above-mentioned hypotheses are reasonable and in-line with theory, but, none of them would account adequately for the risk-return trade-off. A comprehensive empirical analysis would potentially enlighten the investigation of liquidity effect across its dimensions.

Among the determinants of liquidity special emphasis is given on inventory risk and information (see Brennan and Subrahmanyam (1996)). According to Chordia, Roll and Subrahmanyam (2001) inventory risk affects the incentive to trading and determines the market depth, hence one of the most essential indicators of market liquidity. On the other hand, if informed speculators and liquidity-motivated investors have differential access to private information, then information is not uniformly distributed to all investors. In particular, adjustments on spreads against speculators would potentially diminish trading activity and consequently the liquidity.

Considering the impact of information on transactions, the liquidity provider makes profit from uninformed investor and loses money to informed investor. The uninformed investor is motivated by exogenous demand, while the informed investor is motivated by the private information advantage. The classic adverse selection theory claims that the market maker determines the ask or bid price by observing the market whether the informed trader has arrived. The bid-ask spread increases in the likelihood of an informed trader, in order that the market maker can protect from the loss to the counterpart.

However, the concept of liquidity in financial markets is intrinsically complicated (Amihud, Mendelson, and Pedersen (2005)) and requires the adoption of a comprehensive liquidity metric. Since the liquidity is commonly reflected on the easiness that an asset is traded at low transaction cost with little price impact, the dimensions include trading quantity, trading speed, trading cost and price impact. In this respect, previous measurement considered in literature includes bid-ask spread of Amihud and Mendelson (1986), the turnover ratio of Datar, Naik, and Radcliffe (1998), the dollar trading volume of Brennan, Chordia, and Subrahmanyam (1998), the return to dollar volume ratio of Amihud (2002) and the return to turnover ratio of Florakis, Gregoriou and Kostakis (2011).

We define liquidity as the ability to trade a certain quantity of assets quickly, with minimal price impact and trading cost. A liquid investment is one where the participant can unwind the position easily and quickly, without affecting the asset price. One source of illiquidity is the exogenous transaction cost. Another source is demand pressure and inventory risk (the market maker is exposed to the risk of price change while holding the assets in inventory). Moreover, the private (asymmetric) information also causes the illiquidity. The cost of illiquidity and the exposure to the liquidity risk render the risk-averse investors to require compensation for bearing the cost or risk. Constantinides (1986) defines the liquidity premium as the compensation to investors so that he is indifferent between a perfect liquid asset and an asset with certain liquidity risk.

The objective of this paper is to investigate empirically the liquidity effect on the risk-return trade-off. Our aim is implemented through the investigation of the liquidity premium dynamics on an asset pricing framework. Specifically, our aim is to quantify the liquidity risk premium comparatively with respect to its main dimensions and to investigate further its time dynamics.

Using US data for the period from 1962 to 2011, we conduct a cross-sectional analysis considering the US Business Cycle Expansions and Contractions. We further consider the liquidity measures on a market wide level and analyse their causality with aggregated market characteristics. Our findings suggest that there exist a heterogeneity in terms of the liquidity constituents which is time specific, though during non-tranquil periods illiquidity yields high returns. Moreover, we find bidirectional causal relationships between liquidity and market characteristics according to Gervais, Kaniel, and Mingelgrin (2001).

The paper is organized as follows; section 2 explains the main liquidity measures under investigation while section 3 analyses the data and constructs the liquidity measures. Section 4 presents the research methodology the results of which are presented on section 5. Finally, section 6 concludes the paper.

2. Literature review

The transaction cost component of liquidity refers to the (relative) bid-ask spread. According to this liquidity metric high (relative) bid-ask spread is associated with high illiquidity and long holding period of investments. Consequently, investors would require compensation for securities with high bid-ask spread and this would result in high (expected) returns.

Specifically, Amihud and Mendelson (1986) claim that risk-neutral investors buy assets and sell them later in a premium which represents the trading cost and is absorbed in the transaction prices. Thus, the price discount would be the present value of the transaction costs:

$$E(r^i) = r^f + \mu \frac{C^i}{P^i} \tag{1}$$

where $E(r^i)$ is the expected return of asset i, r^f is the risk-free rate to proxy the perfect liquid asset return, μ is trading intensity (which is related to the reciprocal of holding period) and $\frac{C^i}{P^i}$ is the relative transaction cost. The last term $\mu \frac{C^i}{P^i}$ is per-period percentage transaction cost. Amihud and Mendelson (1986) employ relative spread (dollar bid-ask spread to transaction price) to proxy the relative transaction cost $\frac{C^i}{P^i}$ and found that the expected return is an increasing function of the spread. Glosten and Harris (1988) studied the market microstructure and trading mechanism, where the market maker loses money from informed investors and earn money from uninformed ones. Thus, the higher possibility of trading with informed trader, the higher bid-ask spread should be set by market makers, that is, the liquidity is lower. Specifically, market makers submit the order by observing and learning from the market data to determine whether informed traders are involved in the market. The market marker submits an order to sell at ask price and an order to buy at bid price. However, due to the effect of adverse selection, the bid price is discounted because the selling order constitutes bad news to the uninformed market participants, similarly, a premium is added to the ask price as a result of the good news signal brought by the buy order. The difference between the discounted bid price and the raised ask price is the bid-ask spread. As a result, higher spreads are imposed in order to offset potential losses from informed investors. Moreover, while the bid-ask spread provides a mean for reducing the losses or increasing the profits for the market maker who is dealing with informed and un-informed investors, respectively, in the same time it might advocate to the opposite direction by dampening the trading activity of informed market participants or by eliminating the marginal benefit for market makers. It is obvious then, that the trade-off between these opposite effects that the increments of the bid-ask spreads cause, would consequently lead market makers to formulate optimum choices regarding the premiums and the corresponding discounts that should be imposed in the trading mechanism. Hence, spread is a measure of liquidity, not only to proxy the transaction cost, but also reflect the (the degree of) asymmetric information.

The next important liquidity component is the trading activity. According to this liquidity metric low turnover ratio is associated with long holding periods of investments and high spread. Consequently, investors would require a compensation for securities with low TR and this would result in high (expected) returns. Amihud and Mendelson (1986) argued that less liquid assets are allocated to investors with longer investment horizons. In addition, Atkins and Dyl (1994) found a positive relationship between the average holding horizon and the spread. Since turnover ratio is the reciprocal of average holding period and is related to how quickly a dealer expects to turn around her position, the turnover ratio (trading volume divided by share of outstanding) is also used as one of the liquidity measures. Datar, Naik and Radcliff (1998), Rouwenhorst (1999) and Nguyen, Mishra, Prakash and Ghosh (2007) used turnover ratio to measure liquidity, motivated by the fact that low turnover ratio implies long holding horizon and large spread, thus, lower turnover ratio indicates lower liquidity. Datar, Naik and Radcliff (1998), used data from US stock exchanges and investigated the cross sectional effects of turnover ratio controlling for several firm characteristics and they found that turnover ratio is negatively related to expected asset returns. Similarly, Nguyen et.al (2007) concluded on a negative relationship between turnover ratio and expected returns. However, the findings of Rouwenhorst (1999) are different; using a sample of 20 emerging stock exchanges it was found that the turnover effect is insignificant while its values differ among different clusters of firms with respect to the beta coefficient. Moreover, there are some extended studies on the interaction between turnover ratio and returns' momentum. Conrad, Allaudeen, and Cathy (1994) argued that high-turnover-ratio stocks experience short-term return reversal in the following week, while low-turnover ratio stocks experience return continuations. Lee and Swaminathan (1998) found that the price momentum effect is stronger in high-turnover-ratio stocks than in low-turnover-ratio stocks in intermediate terms. Brown, Crocker, and Foerster (2009) concluded in a positive relationship between the turnover ratio and return for high capitalized stocks (liquid) only. They argued that this finding depends on market conditions (bull or bear) and potentially on the momentum effect. All these exemplified findings are not consistent with the principles of liquidity unless the turnover ratio is positively associated with illiquidity. The latter is implied by Stoll (1978), who applied the turnover ratio metric to proxy the adverse information effect. The intuition is that the private information would lead higher level of trading relative to the outstanding shares. Thus, higher level of turnover ratio indicates the adverse information, which results in the higher spread and higher illiquidity.

Another liquidity measure that accounts for the trading activity is the dollar trading volume which is defined as the product of the total number of shares traded by the average price per share. It was firstly studied by Stoll (1978) and it is supposed to be the most important determinant of the bid-ask spread. The bid-ask spread serves as the proxy of transaction cost, of which three components are inventory cost, order processing cost and adverse selection cost. Stoll (1978) considered the inventory cost or holding cost of stocks as a function of holding period, in turn, the holding period is function of trading volume since it is easy for traders to reverse the position if the asset is being heavily traded. Thus, the spread is negatively related to dollar volume. Moreover, Glosten and Harris (1988) provide the evidence that the adverse selection cost is the significant component of bid-ask spread, as well as trading size (order flow) is inversely related to spread. Furthermore, Brennan and Subrahmanyam (1995) estimate the transitory and permanent components of transaction cost as the illiquidity measures and they claim that the trading volume is a primary determinant of the adverse selection cost of transaction. Dollar volume measures the speed of transaction to unwind the position. In particular, low dollar volume in specific transaction indicates illiquidity, since the position could be difficult to get out of and the trading opportunities are fewer than high dollar volume case; likewise, the high dollar volume implies high liquidity. Higher volume typically results in narrower spreads, less slippage (slippage is the difference between the last trade price and the price realized by the next order), and less volatility, according to Chordia, Roll and Subrahmanyam (2000), who document a strong cross-sectional relationship between dollar volume and various measures of the bid-ask spread and market depth. Numerous researchers work on the dollar volume, served as the proxy of liquidity. Brennan, Chordia, and Subrahmanyam (1998) examine a multi-factor asset pricing model where one of the stock characteristics is liquidity level, measured by dollar volume. In their study, the dependent variable is the excess return (1966-1995) of individual stocks, while the right-hand variables are the stock characteristics, including size, B/M, price, and dollar volume. They find the dollar volume and stock expected return has negative relationship. Chordia, Subrahmanyam and Anshuman (2001) document the significant and negative relationship between the return and the dollar volume, as well as the negative relation between return and second moment of dollar volume (the unconditional realized and the conditional GARCH type volatility the standard deviation of past 36 month dollar volume or conditional volatility calculated by GARCH). The response variables in the empirical tests are stock excess returns and FF risk-adjusted returns, respectively, and produce similar estimation of coefficients. The abovementioned negative relation between returns and dollar volume is considered in a cross-sectional dimension. However, in the time-series dimension, Gervais, Kaniel, and Mingelgrin (2001) find a short-term (1, 10, 20 days) positive relation between stock return and dollar volume exploiting further the short and long term dynamics of liquidity. They claim that higher trading activity attracts more investors causing higher prices due to greater demand in the subsequent days.

The third component of liquidity is the price impact that is “trading without changing the price”. The first proposed measure is the Aminvest ratio which is defined as the ratio of the dollar volume over the absolute return. This ratio is a measure of how much dollar volume is required to move a stock's price up or down by one percentage point. A high ratio means that large amounts of stock can be traded with little effect on prices, thus, the stock is very liquid. Kyle (1985) investigated the price change per unit of the net order flow in stock market and found that he impact increases with the asymmetry information and decreases with uninformed order flow. Amihud (2002) proposed the ratio of absolute return to the dollar volume as an alternative expression of the price impact. In particular, this measure indicates the average daily price change to $1 trading volume for individual stocks, where the extremely liquid stocks should be able to absorb more trading volume without corresponding price movements; likewise, substantial response of price to each transaction implies this stock is less liquid. Thus, this measure proxies the illiquidity of a stock. Florakis, Gregoriou, and Kostakis (2011) argued that the Amihud measure has strong size-bias because of the fact that the higher volume traded in bigger stocks and forcing conclude that the bigger stocks are more illiquid. Moreover, this measure ignores the importance of trading frequency, which is also involved in the determination of the required liquidity premium and potentially dominates the transaction cost dimension. Hence, Florakis et.al (2011) proposed to use the ratio of absolute return to turnover ratio, with regard that the turnover ratio has no bias of size effect.

3. Data and Liquidity measures

The data are collected from CRSP and COMPUSTAT tape. The firms are common securities listed in NYSE-AMEX, providing market data for closing price, closing bid and ask, trading volume, outstanding shares and daily close-to-close returns. In addition accounting data for historical (realized) book value, earnings per share and dividend yield are obtained. The closing bid/ask prices are only available after 1990 in the CRSP data file. The dataset of other variables ranges from Jan., 1962 to Dec., 2011. The risk free rate is proxied by the one-month US T-bill rate. Historical prices for the US Fama-French factors are downloaded from the website French's library .

The data are filtered excluding:

- shares that are traded at Nasdaq
- shares that are not available in either CRSP or COMPUSTAT tape
- the first and last trading month for each firm
- shares that have fewer than two years prices or fewer than 15 trading days in one month
- shares with extreme ask/bid prices (less than $5 or larger than $1000, or the closing bid prices are higher than ask prices)
- shares with negative BM values and those which are in the financial services sector
- shares with extreme dollar market capitalisation, B/M, DY, and EP (less than 0.5% or lager than 99.5% percentile)

Overall, the number of firms in each month varies from 745 to 3154 with an average of 2050. The daily data from CRSP are transformed into monthly security characteristics by averaging or summing, in order to obtain monthly closing bid/ask prices and returns, trading volume, share of outstanding and market capitalization.

Moreover, we define three variables related with the short and long term momentum effects, RET23, RET46, RET712, as the cumulative asset return from the last three to last two months, from last six to four months, from last twelve to seven months, respectively. In addition, fundamental data are drawn from COMPUSTAT on an annual basis and then transformed into monthly. The dividend yield (DY) is measured by the sum of all dividends paid over the previous months, divided by the share price at the end of the second to last month (Price-end). Similarly, we calculate the book-to-market value (B/M) and the earnings-price ratio (EP). The monthly data statistics description corresponds to the pooled time-series averages of the cross-sections as presented in Table 1 of the appendix.

Table 1. Descriptive Statistics of cross section variables

Table 1 **Statistics description of cross section variables**

This table domenstrates the statistics of monthly variables, which are going to be used in the cross-sectional regrssions. The mean, median, standard deviation are obtained by the time-series average of monthly cross-sectional mean, median, standard deviation. The listed variables are observed or calculated from a sample of average 2050 NYSE-AMEX firms from Jan., 1962 to Dec., 2011 recorded in CRSP tape. The control variables are reported in Panel A. RET is the monthly return of assets. CAP is the market capitalizations of firms. PRICE denotes the closing prices at the end of month. B/M is the book-to-market ratio, obtained by the ratio of last year's book value to the market prices at the end of each month. EP is the earning price ratio. DY is the divided yield, which is calculated by the sum of last year's dividend over the prices at the end of each month. Ret 23, Ret46, Ret712 are cumulative returns of over the second through third, forth through sixth, and seventh through twelfith months prior to the present months, respectively. The six variables measure liquidity in Panel B. DVOL denotes sum of daily dollar trading volumes within month for each stock. S is the value of absolute monthly spreads, which are obtained by taking average of the daily absolute spread within each month. RS represents relative spread, namely, the ratio of absolute spread to share closing prices, and the monthly relative spread is the average of daily relative spread. TR is the monthly turnover ratio , calculated by monthly trading volume over number of shares outstanding in each month. R/DVOL denotes the ratio of absolute return to dollar volume, while the monthly R/DVOL is the average daily R/DVOL. R/TR is defined similar to the previous variable, but the absolute return is divided by daily turnover ratio.

Panel A:	Monthly control variables								
	RET	CAP(10^6)	PRICE	B/M	EP	DY	Ret23	Ret46	Ret712
Mean	0.0131	1.4247	27.05	0.7711	0.0801	0.0344	0.0245	0.0365	0.0745
Median	0.0068	0.3331	21.50	0.6039	0.0676	0.0246	0.0181	0.0293	0.0639
Standard deviation	0.0944	3.5107	23.45	0.7790	0.1470	0.0494	0.1297	0.1555	0.2144

Panel B:	monthly liquidity measures					
	DVOL(10^6)	S	RS	TR	R/DVOL(10^-6)	R/TR
Mean	130.05	0.2284	0.0122	68.2268	0.2421	0.0185
Median	25.95	0.1978	0.0101	45.6211	0.1126	0.0136
Std.deviation	251.79	0.1410	0.0078	99.6094	0.3296	0.0165

RET is the monthly return for stocks, CAP stands for the market capitalization, P is the closing prices at the last trading day of each month, B/M is the monthly book-to-market ratio, EP is the earning-price ratio, DY is the dividend yield, Ret23, Ret46, Ret712 are the cumulative monthly returns as defined above.

We construct the monthly liquidity measures based on the daily liquidity measures, removing first the outliers (lower and upper 0.5%) of each daily liquidity measure. In the following formulas i is the asset indicator, t and m stand for the day and month indicators and n is the number of available trading days in each month.

The daily absolute spread is calculated as the difference between bid price and ask price. For a single stock, its monthly spread is calculated by averaging the daily spread over the month:

$$S_{i,m} = \frac{1}{n}\sum_{t=1}^{n}(ask_{i,t} - bid_{i.t}) \quad (2)$$

The daily relative spread is calculated as the ratio of the absolute spread over the price. For a single stock, its monthly spread is calculated by averaging the daily spread over the month:

$$RS_{i,m} = \frac{1}{n}\sum_{t=1}^{n}\frac{ask_{i,t} - bid_{i.t}}{price_{i,t}} \quad (3)$$

The turnover ratio at month m is calculated as the ratio of the number of shares traded in month m over the number of share outstanding:

$$TR_{i,m} = \frac{\sum_{t=1}^{n} trading\_volume_{i,t}}{share\_of\_outs\tan ding_{i,m}} \quad (4)$$

The dollar volume is the sum of the daily dollar volume, over month m:

$$DVOL_{i,m} = \sum_{t=1}^{n} DVOL_{i,t} \quad (5)$$

The return to dollar volume is the ratio of the average absolute return over the dollar volume, over month m:

$$R/DVOL_{i,m} = \frac{1}{n}\sum_{t=1}^{n}\left(\frac{|RET_{i,t}|}{DVOL_{i,t}}\right) \quad (6)$$

The return to turn over ratio over month m is the average daily ratio of absolute return over turnover ratio, over month m, where daily turnover ratio is obtained by the ratio of daily trading volume over the number of shares outstanding:

$$R/TR_{i,m} = \frac{1}{n}\sum_{t=1}^{n}\left(\frac{|RET_{i,t}|}{TR_{i,t}}\right) \quad (7)$$

The monthly liquidity measures descriptive statistics, obtained by the time-series averages of the cross-section data, is displayed in Table 1 Panel B. Furthermore, we also report the time-series average of the monthly cross-sectional contemporaneous correlations coefficient of the above variables (monthly characteristics and liquidity measures) in Table 2.

The past performance indicator is based on the cumulative return of the past information as shown below:

RET23: cumulative market return from (t-66) to (t-44), the prior 3 to 2 months cumulative daily return;

$$RET23_t = \prod_{n=44}^{66}(1 + RET_{t-n}) - 1 \tag{8}$$

RET46: cumulative market return from (t-132) to (t-88), the prior 6 to 4 months cumulative daily return;

$$RET46_t = \prod_{n=88}^{132}(1 + RET_{t-n}) - 1 \tag{9}$$

RET712: cumulative market return from (t-264) to (t-154), the prior 12 to 7 months cumulative daily return;

$$RET712_t = \prod_{n=154}^{264}(1 + RET_{t-n}) - 1 \tag{10}$$

Table 2. Monthly pairwise Correlation between liquidity components and firm characteristics

Table 2 **Monthly Correlation - Pairwise**

This table present time-series of monthly cross-sectional correlations between the firm characteristics using in the pricing model. The listed variables are observed or calculated from a sample of average 2050 NYSE-AMEX firms from Jan., 1962 to Dec., 2011 recorded in CRSP tape. The first six variables measure liquidity. DVOL denotes the logarithm of sum of daily dollar trading volumes within month for each stock. S is the logarithm value of absolute monthly spreads, which are obtained by taking average of the daily absolute spread within each month. RS represents logarithm of relative spread, namely, the ratio of absolute spread to share closing prices, and the monthly relative spread is the average of daily relative spread. TR is the logarithm of monthly turnover ratio , where the monthly turnover ratio is calculated by monthly trading volume over number of shares outstanding in each month. R/DVOL denotes the logarithm of the ratio of absolute return to dollar volume, while the monthly R/DVOL is the average daily R/DVOL. R/TR is defined similar to the previous variable, but the absolute return is divided by daily turnover ratio. RET is the monthly return of assets. CAP is the logarithm of market capitalizations of firms. PRICE denotes the logarithm of closing prices at the end of month. B/M is the logarithm of book-to-market ratio, which is obtained by the ratio of last year's book value to the market prices at the end of each month. DY is the divided yield, which is calculated by the sum of last year's dividend over the prices at the end of each month. Ret 23, Ret46, Ret712 are cumulative returns of over the second through third, forth through sixth, and seventh through twelfith months prior to the present months, respectively. We use * to denote the significance of the coefficients at 1%.

There exist significant correlations between the components of liquidity with an exception on the relationship between spread and trading activity. Within all liquidity components, positive and significant correlations are observed. The trading activity measures are negatively correlated with transaction cost components and positively with price impact constituents. The turnover ratio is positively correlated with monthly cumulative returns, while the share price related measures, such as dollar volume, R/DVOL and relative spread, are correlated with market capitalisation. For the rest of the market-wide variables, prices of shares at the end of month are significantly correlated with market capitalizations, while the three indicators of firm value and firm performance (BM, EP and DY) and past performance are significantly correlated with each other.

We are also interested in the market-wide liquidity measures accompanied with other market-wide variables based on the six liquidity components. Besides the daily return process of the market portfolio other related variables are also used such as the market portfolio volatility and its bullish and bearish components. Moreover, we consider the momentum effect of market portfolio, by recruiting three variables: RET2, 3, RET4, 6 and RET7, 12, which represent the cumulative return from the last three to last two months, from last six to four months and from last twelve to seven months, respectively.

The market-wide variables are computed by aggregating the daily observations of common shares as shown below (i is the securities indicator, N is the number of assets in each trading day t).

The average market-wide spread and relative spread in each trading day are calculated by the following equations:

$$MS_t = \frac{1}{N}\sum_{i=1}^{N}(bid_{i,t} - ask_{i,t}) \tag{11}$$

$$MRS_t = \frac{1}{N}\sum_{i=1}^{N}\left(\frac{bid_{i,t} - ask_{i,t}}{price_{i,t}}\right) \tag{12}$$

The market-wide turnover ratio is the value weighted average of all available shares' TR in each trading day according to the following equation:

$$MTR_t = \sum_{i=1}^{N}\left(\frac{trading\_volume_{i,t}}{number\_of\_shares\_outs\tan ding_{i,t}} * \frac{Cap_{i,t}}{\sum_{i=1}^{N} Cap_{i,t}}\right) \tag{13}$$

The market-wide dollar volume is calculated as the summation of all the available shares' dollar volume in each trading day:

$$MDVOL_t = \sum_{i=1}^{N} DVOL_{i,t} \tag{14}$$

The market-wide return to dollar volume is calculated by the average of all available shares' measure in each trading day:

$$MR/DVOL_t = \frac{1}{N}\sum_{i=1}^{N}\left(\frac{|return|_{i,t}}{Dvol_{i,t}}\right) \tag{15}$$

The market-wide return to turnover ratio is calculated by the average of all available shares' measure in each trading day:

$$MR/TR_t = \frac{1}{N}\sum_{i=1}^{N}(\frac{|return|_{i,t}}{TR_{i,t}}) \tag{16}$$

There are several market-wide variables that are based on the market portfolio, its variance and its bullish and bearish regimes:

The market return is defined as the value weighted daily return according to the following formula:

$$MRET_t = \sum_{i=1}^{N}(RET_{i,t} * \frac{Cap_{i,t}}{\sum_{i=1}^{N} Cap_{i,t}}) \tag{17}$$

The market-wide volatility is defined as the squared market return:

$$VOL_t = MRET_t^2 \tag{18}$$

The bullish/bearish components of the market portfolio are given by the following equations:

$$PRET = \max(0, MRET) \tag{19}$$

$$NRET = \min(0, MRET) \tag{20}$$

Table 3. Descriptive statistics of market-wide cross section characteristics

Table 3	Daily market-wide variable
	This table documents the statistics of market-wide variables on the daily basis.The listed variables are observed or calculated from a sample of average 2050 NYSE-AMEX firms from Jan., 1962 to Dec., 2011 recorded in CRSP tape. Except spread and relative spread are only avaiable after 1990, other variables are available over 1962 to 2011. The market variables are aggregated by all of the avaiable assets in the daily data sample. Panel A demonstrates the market return related vairbales. MRET denotes the market return, which are calculated by the value-weighted daily return of shares. PRET and NRET are decomposed from MRET into the positive and negative strings, namely, positive return process are max (0, MRET), while negative return process are min (0, MRET). VOl is the volatility of market return, calculated by (MRET)^2. Ret23, Ret46, Ret712 are cumulative market returns of over the second through third, forth through sixth, and seventh through twelfth months prior to the present months, respectively. Note, we assume 22 trading days in one month. The variables in Panel B are market-wide liquidity measures process, where MDVOL is market dollar volume, the sum of all available share dollar volume in each trading day. MS is the market spread, calculated by the average of cross-sectional shares spread on daily basis. MRS is the market relative spread, calculated by the average of cross-sectional shares relative spread on daily basis. MTR indicates market turnover ratio, obtained by value-weighted average of assets turnover ratio. MR/DVOL and MR/TR denote the market return to dollar volume and market return to turnover ratio, respectively, and they are derived from daily average of return to dollar volume and return to turnover ratio.

4. Research methodology

We conduct an APT analysis on an asset pricing framework incorporating the liquidity risk premium and a time series causality analysis between the market-wide liquidity measures and several market characteristics.

Moreover, considering the impact of financial conditions on the effect of liquidity on asset returns, we split the whole sample horizon into eight non-overlapping sub-periods according to the most recent announcement of the US Business Cycle Expansions and Contractions from NBER's Business Cycle Dating Committee. The peak month to next peak month is recognized as one Business Cycle. In specific, we have the following sub-periods in our sample: from Jan. 1962 to Dec. 1969, from Jan. 1970 to Nov. 1973, from Dec. 1973 to Jan. 1980, from Feb. 1980 to July 1981, from Aug. 1981 to July 1990, from Aug. 1990 to March 2001, from April 2001 to Dec. 2007, from Jan. 2008 to Dec. 2011.

For the purposes of our analysis we form portfolios on the six liquidity components. In each month m, we rank stocks by liquidity in month m-1 constructing 5 portfolios on the corresponding percentiles, i.e. [0-20], [20-40], [40-60], [60-80] and [80-100]. The monthly equal-weighted portfolio returns are calculated while a long-short trading strategy is formed, according to which a portfolio of undervalued (illiquid) shares is bought and a portfolio of overvalued (liquid) is short-sold. Insights about the statistical significance of the strategy's payoff, is obtained through the t-test:

$$t_{illiquid\text{-}liquid} = \frac{(\overline{r_{illiquid}} - \overline{r_{liquid}})}{\sqrt{\sigma_{illiquid} / T + \sigma_{liquid} / T}} \qquad (21)$$

where $r_{illiquid}$ and r_{liquid} are monthly equal-weighted returns for the illiquid and the liquid portfolios, respectively and T is the number of observations for portfolio returns in the examined period.

Table 4 of the appendix, provides a descriptive analysis of the liquidity portfolios' performance and the long-short trading strategy for the whole period and for the eight sub-periods. Panel A refers to the transaction cost, panel B to the trading activity and finally panel C, to the price impact component.

Please insert Table 4 about here

Furthermore, we adopt Liu's (2006) approach and empirically examine the risk-return trade-off of the trading strategies on liquidity, applying the Fama-MacBeth (1973) cross-sectional model, controlling for several effects on firm fundamentals. The Arbitrage Pricing Theory (APT) specification that we apply in this paper is the following:

$$R_{i,m} - R_{f,m} = c_0 + \sum_{k=1}^{K} \beta_{i,k} f_{k,m} + \sum_{n=1}^{N} c_n Z_{n,i,m} + \varepsilon_{i,m} \qquad (22)$$

where $R_{i,m}$ is the monthly asset return and $R_{f,m}$ is the risk free rate which is proxied by the US one-month T-bill rate. The first term of the model, $\sum_{k=1}^{K} \beta_{i,k} f_{k,m}$, adjusts the return according to the Fama-French factors, i.e. market risk premium, SMB and HML, while the second one, $\sum_{n=1}^{N} c_n Z_{n,i,m} + \varepsilon_{i,m}$, represents the liquidity risk premium and several stylized control variables. Specifically, adjusting the returns according to the Fama-French factors yields to the following re-parameterization of the model:

$$R^{*}{}_{i,m} = c_0 + \sum_{n=1}^{N} c_n Z_{n,i,m} + \omega_{i,m} \quad (23)$$

where $R^{*}{}_{i,m}$ is the risk-adjusted return, i.e. $R^{*}{}_{i,m} = R_{i,m} - R_{f,m} - \sum_{k=1}^{K} \beta_{i,k} f_{k,m}$. The terms of the risk adjusted components, $\beta_{i,k}$, are estimated using a 60 months rolling window[1].

Thus, using two different specifications for the dependent variable (excess return, $R_{i,m} - R_{f,m}$, and risk adjusted return, $R^{*}{}_{i,m}$) we examine empirically the cross sectionality of asset returns and the existence of various liquidity risk premia. The Fama-MacBeth analysis is conducted using two lags in the set of the independent variables (*m-2*). The lag of firm characteristics is adopted in extant literature (e.g. Brennan, Chordia, and Subrahmanyam (1998), Chordia, Subrahmanyam and Anshuman (2001), Pereira and Zhang (2010)) in order to overcome the thin trading effect.

Particularly, the control variables consist of the firm size (CAP), the Book-to-Market ratio (BM), the Dividend Yield (DY), the Earnings-Price ratio (EP), three momentum specifications (RET23, RET46, RET712) and the reciprocal of the monthly prices (1/P). All of these firm characteristics have been used extensively in the literature. Particularly, Lee and Swaminathan's (1998) argued that the turnover liquidity measure may be less than a perfect proxy for liquidity due to its relationship with past performance. Thus, the Jegadeesh and Titman (1993) past performance dynamics are accounted for by the cumulative monthly return, RET23, RET46, RET712. Finally, based on Miller and Scholes (1992), the low priced assets are in financial distress and for that reason we use the share price in our model to control for this effect.

The examination of the multifactor model is implemented through the t-statistic of the Fama-MecBeth (1973) approach:

$$\bar{c}_{i,j} = \frac{1}{M} \sum_{m=1}^{M} \hat{c}_{i,j,m}$$

(24)

$$se(c) = \sigma(c) / \sqrt{M}$$

(25)

$$t_c = \frac{\bar{c}}{se(c)}$$

(26)

[1] For the purposes of the rolling window estimation we require at least 24 in 60 monthly data for each stock. The first rolling estimation is based on 30 monthly observations and is extended to account for 60 observations.

where $\widehat{c}_{i,j,m}$ is the estimated coefficient of the j[th] characteristic of the i[th] asset in month *m*, *σ(c)* is the sample standard deviation of the cross-section regressions estimates and M is the number of observations.

The comparative analysis of the liquidity risk premia is followed by a time series analysis that aims to account for the potential bidirectional relationships between liquidity and market characteristics. We employ a VAR representation of the market-wide liquidity measures and the market characteristics, investigating the potential causality effects between the liquidity components and the market dynamics.

The market-wide liquidity components refer to transaction cost, trading activity and price impact, while the market conditions, refer to the return sign (PRET, NRET), the market volatility (VOL) and the momentum proxies (RET23, RET46, and RET712).

The Dickey-Fuller test would dictate that the return-based variables (MR/DVOL, MR/TR, MRET, VOL, PRET, NRET, RET23, RET46, RET712) are stationary. For the price-based variables (MDVOL, MTR, MS, MRS) we use the first difference: $\Delta x_t = x_t - x_{t-1}$, where x denotes MDVOL, MTR, MS and MRS, respectively. Therefore, we employ these variables in a VAR representation and conduct the Granger Causality test:

$$X_t = \sum_{l=1}^{L} A_i X_{t-l} + u_t \tag{27}$$

where X_t is a matrix consisting of the following thirteen variables, MR/DVOL, MR/TR, MRET, VOL, PRET, NRET, RET23, RET46, RET712, ΔMDVOL, ΔMTR, ΔMS and ΔMRS on a daily basis. In our empirical estimation, we use 20 lags, following the convention of one month (20-22 trading days). The pair of the hypotheses under investigation is:

H_0: one specific variable k does not Granger cause other variables (the 20 coefficients associated with the one specific variable are jointly zero in the VAR estimation equation) and H_1: not H_0

5. Empirical findings

The results of our analysis consist of a descriptive analysis and a model-based one and refer to the three components of liquidity, that is, the transaction cost, the trading activity and the price impact. Consequently, the effect of liquidity on asset returns is investigated via the presence of significant long-short payoffs on liquidity portfolios and through the significance of the liquidity risk premium on an asset pricing framework. The descriptive results of portfolios are presented in Table 4 while the Fama-MacBeth regressions, in Table 5. The Fama-MacBeth analysis with the excess and the abnormal return are similar, and thus for parsimonious reasons, we discuss the results on the excess returns only.

Table 4. Mimicking portfolios on liquidity measures

Table 4 Mean of time-series monthly return of portfolios constructed by liquidity meaures

All the stocks are ranked on the basis of its monthly liquidity measures, in an ascending order. The portfolios are named by their liquidity measures, and the number in the names of portfolios indicates the rank of liquidity measures' quantity. e.g. in the groups of spread (S), P1 indicates the stocks in this portfolio have lowest spread; while in the groups of R/DVOL, the stocks in portfolio of P5 have the highest R/Dvol. The portfolios are monthly rebalanced, on the basis of month (t-1) liquidity measures, and we report the time-series average return of portfolios in month t. The returns of portfolios are calculated by equal-weighted. The data ranges from:1962 to 2011, where the whole sample horizon is divided into 8 sub-periods according to the Business Cylces, Jan 1962 to Dec. 1969, Jan 1970 to Nov 1973, Dec 1973 to Jan 1980, Feb 1980 to July 1981, Aug 1981 to July 1990, Aug 1990 to March 2001, April 2001 to Dec 2007, Jan 2008 to Dec 2011. The last row in each panel reports values for t-tests referring to the null hypothesis of no difference in means between P1 and P5. We use * to denote the significance of the difference at 5%.

The portfolios are monthly rebalanced, on the basis of month (t-1) liquidity measures, and we report the time-series average return of portfolios in month t. The returns of portfolios are calculated by equal-weighted. The data ranges from:1962 to 2011, where the whole sample horizon is divided into 8 sub-periods according to the Business Cylces, Jan 1962 to Dec. 1969, Jan 1970 to Nov 1973, Dec 1973 to Jan 1980, Feb 1980 to July 1981, Aug 1981 to July 1990, Aug 1990 to March 2001, April 2001 to Dec 2007, Jan 2008 to Dec 2011. The last [illegible]

Table 5 **Cross-sctional regression**

This table reports the cross-sectional regressions results. The data use in the cross-section regressions are from a sample of average 2050 NYSE-AMEX common listed firms from Jan., 1962 to Dec., 2011 recorded in CRSP tape. The dependent variables in the row are monthly individual asset excess return. The independent variables (first column) are liquidity measures, CAP, BM, EP, DY, RET23, RET 46, RET712 and 1/P, where CAP is the market capitalizations of firms, BM is the book-to-market ratio, obtained by the ratio of last year's book value to the market prices at the end of each month. EP is the earning-price ratio, calculated by the earnings over the prior year divided by the share prices at the end of each month. DY is the dividend yield, which is calculated by the sum of last year's dividend over the prices at the end of each month. Ret 23, Ret46, Ret712 are cumulative returns of over the second through third, fourth through sixth, and seventh through twelfth months prior to the present months, respectively. 1/P denotes the reciprocal of closing prices at the end of month. Each Panel reports results from one specific liquidity measure: S is the value of absolute monthly spreads, which are obtained by taking average of the daily absolute spread within each month, the results are in Panel A. RS represents relative spread, namely, the ratio of absolute spread to share closing prices, and the monthly relative spread is the average of daily relative spread, the results are in Panel B. DVOL denotes sum of daily dollar trading volumes within month for each stock, the results are in Panel C. TR is the monthly turnover ratio, calculated by monthly trading volume over number of shares outstanding in each month, the results are in Panel D. R/DVOL denotes the ratio of absolute return to dollar volume, while the monthly R/DVOL is the average daily R/DVOL, the results are in Panel E. R/TR is defined similar to the previous variable, but the absolute return is divided by daily turnover ratio, the results are in Panel F. The cross-sectional regression generate monthly coefficients for each independent variable The coefficients reported in the table are obtained by the time-series mean of monthly estimation results. The t-statistics are calculated by the time-series coefficients estimation; the results are displayed on the right hand of the coefficients estimation. All the results are demonstrated in 8 sub-periods (Period 1 to 8) and whole sample horizon (1990-2011 for Panel A and B, 1962-2011 for Panel C,D,E,F). We use * to denote the significance of the coefficients at 5%.

Table 5 **Cross-sctional regression**

This table reports the cross-sectional regressions results. The data use in the cross-section regressions are from a sample of average 2050 NYSE-AMEX common listed firms from Jan., 1962 to Dec., 2011 recorded in CRSP tape. The dependent variables in the row are monthly individual asset excess return. The independent variables (first column) are liquidity measures, CAP, BM, EP, DY, RET23, RET 46, RET712 and 1/P, where CAP is the market capitalizations of firms, BM is the book-to-market ratio, obtained by the ratio of last year's book value to the market prices at the end of each month. EP is the earning-price ratio, calculated by the earnings over the prior year divided by the share prices at the end of each month. DY is the dividend yield, which is calculated by the sum of last year's dividend over the prices at the end of each month. Ret 23, Ret46, Ret712 are cumulative returns of over the second through third, fourth through sixth, and seventh through twelfth months prior to the present months, respectively. 1/P denotes the reciprocal of closing prices at the end of month. Each Panel reports results from one specific liquidity measure: S is the value of absolute monthly spreads, which are obtained by taking average of the daily absolute spread within each month, the results are in Panel A. RS represents relative spread, namely, the ratio of absolute spread to share closing prices, and the monthly relative spread is the average of daily relative spread, the results are in Panel B. DVOL denotes sum of daily dollar trading volumes within month for each stock, the results are in Panel C. TR is the monthly turnover ratio, calculated by monthly trading volume over number of shares outstanding in each month, the results are in Panel D. R/DVOL denotes the ratio of absolute return to dollar volume, while the monthly R/DVOL is the average daily R/DVOL, the results are in Panel E. R/TR is defined similar to the previous variable, but the absolute return is divided by daily turnover ratio, the results are in Panel F. The cross-sectional regression generate monthly coefficients for each independent variable The coefficients reported in the table are obtained by the time-series mean of monthly estimation results. The t-statistics are calculated by the time-series coefficients estimation; the results are displayed on the right hand of the coefficients estimation. All the results are demonstrated in 8 sub-periods (Period 1 to 8) and whole sample horizon (1990-2011 for Panel A and B, 1962-2011 for Panel C,D,E,F). We use * to denote the significance of the coefficients at 5%.

Regarding the transaction cost, there are two liquidity measures. The value of monthly spread is averaged by the daily spreads (the difference between ask prices and bid prices), while the relative spreads are obtained by the ratio of the absolute spreads over prices. Both of the two measures are adopted to present the transaction costs of shares. We first focus on the mimicking portfolios' patterns in Table 4, where excess return increases from portfolio 1 to portfolio 5 for both the S and the RS. However, only the RS could provide a significant pattern. We further explore this through the cross-sectional regressions and we find that both of the measures (S, RS) are priced in the market providing a liquidity risk premium. We also found that the control variables that refer to profitability (EP and DY) along with the prices and the past performance are significant in this model. Turning to the sub-period analysis on Business Cycles, we observe that the results from the mimicking portfolios as well those from the asset pricing model are similar. Furthermore, during the last sub-period the portfolios provide a negative pattern on liquidity which is actually not priced on the asset pricing model, though the Capitalization variable becomes significant at this period.

Regarding the trading activity, we use the turnover ratio and the dollar volume measures. The mimicking portfolio analysis suggest that high values of the turnover ratio and low values of the dollar volume are associated with higher returns a result which is also consistent with the risk premia analysis only for the dollar volume measure. Through our descriptive analysis we find a positive relationship between TR and returns which is in line with Brown, Crocker, and Foerster (2009) (for big size firms) and a negative one regarding the DV consistently with Brennan, Chordia, and Subrahmanyam (1998), and Chordia, Subrahmanyam and Anshuman (2001). Furthermore, the inclusion of the control variables in our analysis (CAP, B/M, EP, 1/P and momentum proxies) seems to play a significant role on this relationship and offsets the positive significant TR effect. Moreover, the CAP variable is more significantly priced along with TR than with DVOL. This might be due to the high correlation between DVOL and CAP which possibly implies a size domination effect. The presence of R46 coefficients is more significant than RET23 and RET712, in both cases. The results obtained for the sub-periods are flat for the TR measure, i.e. we observe a positive effect of the TR on asset returns for all sub-periods. However, the DVOL measure provides negative returns during the analysis (either with the mimicking portfolios or the cross-sectional analysis) with an exemption to the last two sub-periods. Similar results have been found in the literature. Brennan, Chordia, and Subrahmanyam (1998), and Chordia, Subrahmanyam and Anshuman (2001) suggest that assets with high turnover ratio or dollar trading volume are supposed to yield negative premium. In contrast, Brown, Crocker, and Foerster (2009) found a positive association between turnover ratio and asset return in big firms, and suggest that the effect of turnover ratio might be dominated by information and momentum effects. Similar findings have been reported in Pástor and Stambaugh (2003). It should also mentioned that the magnitude of trading activity is higher during the second sub-period (i.e. Jan. 1970 to Nov. 1973), a result which is in line with Brennan, Huh, Subrahmanyam (2012), who claim that the liquidity risk premium is apparent mostly in down-side market conditions.

The price impact dimension of liquidity risk is analysed through the R/DVOL and R/TR measures. The first measure is positively and significantly associated with returns while the second one, negatively. Our findings are consistent with those of Florakis et.al. (2011). The insignificant results of the momentum and size control variables indicate that the R/DVOL dominate the size and the past performance effects. Moreover, the price impact incorporates several structural changes with respect to the Business Cycles. R/DVOL is significantly positive in sub-periods 1, 4 and 8 and in the whole horizon, while the R/TR is positive and significant in period 2 and 5 and in the whole sample horizon. The loadings of price impact in other sub-periods are statistically insignificant. In specific, the positive relationship between R/TR and asset excess return is stronger in period 2, which is in line with the finding of trading activity, i.e. DVOL and TR. The momentum variables (RET 23, RET46, RET712) are insignificant when using the R/DVOL in the whole sample period, in contrast to the R/TR.

By investigation of the market-wide variables we examine the coherence between the liquidity measures as shown in Panel A, of Table 6. We observe that the six market-aggregated liquidity measures are all significantly correlated with each other. The correlation relationship is, in general, consistent with the results of the mimicking portfolios which display the cross-sectional correlation of individual asset monthly liquidity measures. Each pair of liquidity measures which are in the same dimension of liquidity (i.e. transaction cost, trading activity and price impact) are positively correlated with each other. Moreover, the trading activity measures, MDVOL and MTR, are significantly negative correlated with any other measures, while the transaction cost measures, MS and MRS, are significantly positive correlated with price impact measures, MR/DVOL and MR/TR. Besides, the correlation between the three categories of market-wide liquidity measure and the market portfolio return-related variables are also very interesting. Specifically, the correlation coefficient between MDVOL and VOL, PRET, NRET is 0.16, 0.15 and -0.14, respectively; while the correlation coefficient between MTR and VOL, PRET, NRET presume a similar pattern. Thus, the market volatility affect the inventory risk and due to its impact on market liquidity via trading activity. The opposite signs of the coefficients between the trading activity (MDVOL and MTR) and PRET or NRET, provide insights on that the trading could be heavier in either up-market or down-market, an assumption which is also addressed by Pástor and Stambaugh (2003). In addition, the correlation coefficient between the price impact measures (MR/DVOL and MR/TR) and momentum variables (RET23, RET46 and RET712) are also significantly positive. It is suggestive that the past performance has relative high influence on price impact measures. This argument is not in line with the individual liquidity measure case, where TR is significantly correlated with the momentum variables (RET23, RET46 and RET712).

Table 6 **Contemporaneous correlation and Granger causality tests between VAR innovations**

This table reports the contemporaneous correlation and granger causaliy tests results between the listed variables of interest. The market variables are aggregated by the all the avaiable assets in the daily data sample. Except spread and relative spread are only avaiable after 1990, other variables are available over 1962 to 2011. In Panel A, the first six variables are market-wide liquidity measures process, where MDVOL is market dollar volume, the sum of all available share dollar volume in each trading day. MS is the market spread, calculated by the average of cross-sectional shares spread on daily basis. MRS is the market relative spread, calculated by the average of cross-sectional shares relative spread on daily basis. MTR indicates market turnover ratio, obtained by value-weighted average of assets turnover ratio. MR/DVOL and MR/TR denote the market return to dollar volume and market return to turnover ratio, respectively, and they are derived from daily average of return to dollar volume and return to turnover ratio.MRET denotes the market return, which are calculated by the value-weighted daily return of shares. PRET and NRET are decomposed from MRET into the positive and negative strings, namely, positive return process are max (0, MRET), while negative return process are min (0, MRET). VOl is the volatility of market return, calculated by (MRET)^2. Ret23, Ret46, Ret712 are cumulative market returns of over the second through third, forth through sixth, and seventh through twelfith months prior to the present months, respectively. Note, we assume 22 trading days in one month. The matrix in Panel A demonstrates the contemporaneous correaltion between each pair of market variable processes. The pair wise correlation coefficients are in the intersections of the variables in row and in column. In Panel B, the results from Granger Causality tests are reported. Since it requires stationary process in Granger Causality tests, the non-staionary price-related variables, MDVOL, MTR, MS and MRS, are transformed by first difference. diff(xt) = xt - x(t-1). The p-value in matrix indicats the possibility of each variable in row does not granger cause the corresponding variable in column. The p-value lower than 0.1 are indicated by *. Panel C is equivalent to the results in Panel B.The resluts of REJECT to the bull hypothsis is according to the p-values in Panle B.

The pair-wise Granger-causality tests between the market-wide variables of the VAR are presented in Panel B and C of Table 6. In order to examine the null hypothesis that variable k does not Granger-cause variable q, we test whether the lag coefficients of k are jointly zero when q is the dependent variable in the VAR. MDVOL explains MTR, MR/DVOL, MR/TR while MTR does not have a causal relationship with transaction cost variables. All liquidity measures have a unidirectional causal relationship with trading activity measures. The bidirectional relationships exist within each category of liquidity measures.

Finally, with respect to the market wide characteristics and liquidity measures we find that bidirectional effects exist between liquidity and VOL, PRET or NRET. Specifically, these characteristics are associated with price impact or trading activity measures in a bidirectional relationship, that explain past performance and subsequently the market-wide trading activity.

Figure 1. The Granger causality between three dimensions of liquidity measure at the market level. The arrow represents the causality between measures.

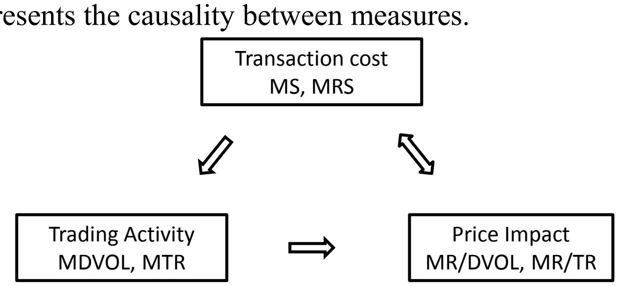

Figure 2. The Granger causality between the market indicators and three dimensions of liquidity measure at the market level. The arrow represents the causality between variables.

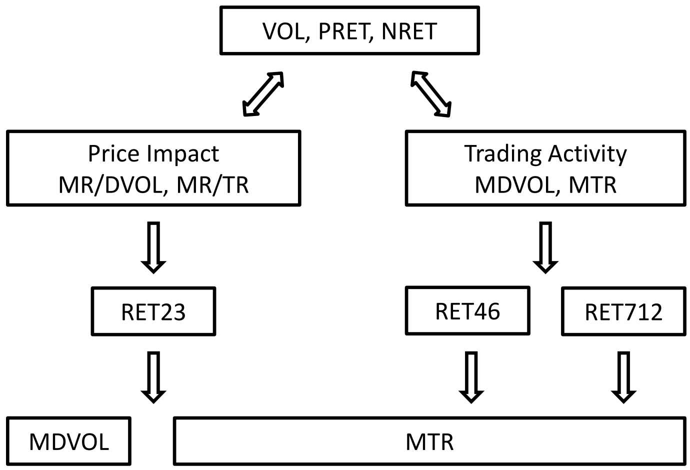

Conclusion

Liquidity is commonly reflected on the easiness that an asset is traded at low transaction cost with little price impact and this is quantified by different proxies on trading quantity, trading speed, trading cost and price impact. According to the extant literature the most important components of liquidity are the transaction cost, the trading activity and the price impact.

Our paper focuses on the liquidity measures in a comparative framework. Using data from CRSP over the period 1962 to 2011 we adopt the conventional Fama-MacBeth approach controlling for several factors on firm fundamentals.

The empirical findings of the paper are consistent with the foundations of the constituents of liquidity measures though several structural changes have taken place during the examined time period. The liquidity risk premium is strengthened during downturns of the market conditions. Moreover, there is evidence that the trading activity component of liquidity dominates conventional risk factors such as the size effect. Similar results are obtained with the R/VOL which dominates the size and the momentum effects.

Moreover, we investigate the Granger Causality between three classes of liquidity indicators and the market characteristics. Bidirectional causality exists within the same category of liquidity measures, and between transaction cost and price impact measures, while the three liquidity measures are Granger caused by transaction costs and trading activity. Finally, we found that the market-wide characteristics (VOL, PRET or NRET) affect the trading activity and the price impact liquidity components and subsequently the past performance of asset returns

Equity-linked insurance products are very appealing to the insurance policy holder. Compared to the traditional annuity product, equity-linked insurance products have the advantage of offering additional return when the linked equities perform well. How- ever, due to their complicated payoff structure, their valuation and risk management are challenges to the insurance company. In this paper, we study valuation methods for quanto variable annuity contract with cliquet options. We propose an efficient Monte Carlo method to price such contract. Numerical examples suggest our approach is quite effective.

Key words and phrases: Monte Carlo method, Variable Annuities, Cliquet Options, Quanto.

JEL Classifications: F31, F37, F47

1 INTRODUCTION

Equity-linked annuity contracts has become very popular in the market. There are two major types of equity-linked annuity contracts: variable annuity (VA) and equity-linked annuity (EIA). The markets of VA and EIA are very large. According to LIMRA International and Advantage Compendiumm, VA and EIA contracts have very high sales volume (Table 1) in United States.

Table 1: VA and EIA sales volume in billion dollars in United States, 2003-2009.

Year	VA	EIA
2003	129.4	14.0
2004	132.9	23.4
2005	137.6	27.3
2006	184.2	25.3
2007	182.2	25.1
2008	154.8	26.7
2009	127.0	30.1

Compared to the traditional annuity product, VA and EIA have the advantage of offering additional return when the linked equities perform well. Although VA and EIA share this commonality, they are different in various aspects:

1. A typical (non-registered) EIA is an insurance company "general account" product. This means that EIA is treated as a liability item on insurance company's balance sheet. On the other hand, VA is a "separate account" product. Except the guarantees embedded in the contract, any gains or losses to the underlying

assets in the VA separate account are reflected directly and immediately in the VA contract owners' accumulation values.

2. Owners of variable annuities are generally allowed to modify their investment allocations periodically, sometimes as often as daily, and VA contract values change according to the performance of the selected investment portfolios. Therefore, VA contracts provide their owners with considerably greater investment flexibility than do EIA contracts. The linked indices in EIA contracts are usually the well known indices such as S&P 500. So, EIA owners basically cannot have direct influence on the values of linked indices.

3. VAs are considered to be securities and must be registered with the Securities and Exchange Commission (SEC). On contrary, EIAs are not required to register with SEC and most EIAs are not registered.

4. At maturity, the guarantees embedded in EIA contracts are usually in-the-money. On the other hand, VA's guarantees are usually out-of-the-money.

Above differences between VAs and EIAs exist in US market. Asia markets for VA and EIA have a different story. For example, equity-linked insurance contracts must be premium protected and must be "separate account" products in Taiwan. Regulator set a very high "capital requirement" standard for insurers for providing guarantees in equity-linked insurance. For this reason, insurers in Taiwan have to transfer their risks associated with these guarantees to a third party. Reinsurance is one way for transferring these risks, but it is usually too expensive for insurers. A more popular way is to package premium-protected structure products as equity-linked insurance contracts. Such premium-protected structure products are designed and sold by investment banks. In order to be a qualified provider for such structure products, the investment bank must maintain a high credit rating. These structure products are classified as variable annuities in Taiwan, because they are separate account products. However, their financial property are more like EIA products in United States. These products have exotic payoff functions and their valuation becomes an important issue for the insurers. In this paper, we focus on one of such structured products. The variable annuity contract under consideration has quanto feature and embedded cliquet options. Such contracts are attractive to the investor because of their protection against downside risk and significant upside potential. We discuss the Monte Carlo valuation approach and then propose efficient algorithms. In particular, we applied variance reduction technique of control variates to improve the performance of Monte Carlo approach.

This paper is organized as follows. In Section 2, we describe the variable annuity contract under consideration. In Section 3, we first describe the stochastic models for the linked index and exchange rate. Then we present the risk neutral valuation formulas under the stochastic models. In Section 4, we devise a few control variates and test their effectiveness via numerical examples. Finally, Section 5 offers some concluding remarks.

2 VARIABLE ANNUITY CONTRACTS WITH CLIQUET OPTIONS

The payoff of the variable annuity contracts under consideration is very similar to simple ratchet EIA contracts with maturity guarantee; see, Hardy (2003) and Hsieh and Chiu (2007) for more information. The VA contracts might also be called cliquet options with global floor Kjaer (2006). However, there is one major difference between the VA contracts considered and simple ratchet EIA contracts: the VA contracts considered are quantos. That is, the linked-index is dominated in a different currency. For example, the contracts pay off in Australian dollar and the linked-index is S&P 500 which is dominated in United States dollar.

The index participation is evaluated annually. Let T be the maturity of a VA contract and $S(t)$ be the linked-index at time $t \leq T$. We set

$$R_t = \frac{S(t)}{S(t-1)}, \quad t = 1, \ldots, T, \tag{1}$$

which are the annual returns of linked-index. The effective annual returns of the VA contract are defined as

$$\tilde{R}_t = 1 + \min(\max(\alpha(R_t - 1), f), c) \tag{2}$$

where f is the annual guarantee rate, c is the annual cap rate, and α is the participation rate in the linked-index.

Treat these effective annual returns as simple returns and sum them arithmetically, then the total return at maturity is

$$R_M = 1 + \sum_{t=1}^{T} (\tilde{R}_t - 1) = 1 - T + \sum_{t=1}^{T} \tilde{R}_t, \tag{3}$$

In addition to annual guarantee rate f, the VA contract also provides guarantee at maturity. This type of guarantee is sometimes called global guarantee. Let the initial investment be P. If the maturity guarantee promises a maturity guarantee rate G, then the payoff of the VA contract is

$$P \cdot \max(R_M, G), \tag{4}$$

3 VALUATION FORMULAS FOR THE VA CONTRACT CONSIDERED

Most of the previous related research in insurance field (Hardy (2004), Lee (2003), Tiong (2000), and Gerber and Shiu (2003)) adopted the Black-Scholes assumptions Black and Scholes (1973) for the linked-index and interest rate. We follow these assumptions. But, since the VA contract is quanto, we need to add exchange rate model.

More specifically, the linked-index $S(t)$ and exchange rate $C(t)$ follow geometric Brownian motions and the interest rate r (local currency) and r_f (foreign currency) are constants.

$$\begin{aligned}
\frac{dS(t)}{S(t)} &= \mu_S dt + \sigma_S dz_1(t), \\
\frac{dC(t)}{C(t)} &= \mu_C dt + \sigma_C[\rho dz_1(t) + \bar{\rho} dz_2(t)], \\
\frac{dB(t)}{B(t)} &= r dt, \\
\frac{dD(t)}{D(t)} &= r_f dt,
\end{aligned} \tag{5}$$

where $z_i(t)$, $i = 1,2$ are independent standard Brownian motions, σ_S is the volatility of the linked index, σ_C is the volatility of the exchange rate, ρ is the correlation coefficient between $\log(S(t))$ and $\log(C(t))$, $\bar{\rho} = \sqrt{1-\rho^2}$ is the orthogonal complement of ρ and $B(t)$ and $D(t)$ denote the local and foreign money market accounts, respectively. We call the models defined in (5) Black-Scholes quanto model Baxter and Rennie (1996). To make the model more concrete, we might assume that the local current currency is Australian dollar and the foreign currency is US dollar. So, there are three tradables in Australian dollar: $B(t)$, $C(t)D(t)$, and $C(t)S(t)$. Based on Girsanov's and martingale representation theorems (see Baxter and Rennie (1996), for example), there exists a unique measure Q such that, under which, both $C(t)D(t)/B(t)$ and $C(t)S(t)/B(t)$ are martingales. And under measure Q, the processes $S(t)$ and $C(t)$ can be written as

$$\begin{aligned}
\frac{dS(t)}{S(t)} &= (r_f - \rho\sigma_S\sigma_C)dt + \sigma_S d\tilde{z}_1(t), \\
\frac{dC(t)}{C(t)} &= (r - r_f)dt + \sigma_C[\rho d\tilde{z}_1(t) + \bar{\rho} d\tilde{z}_2(t)],
\end{aligned} \tag{6}$$

where $\tilde{z}_1$ and $\tilde{z}_2$ are independent standard Brownian motions under measure Q.

If a derivative's payoff depends only on $S(t)$ and/or $C(t)$, then its fair value can be represented as expectation under measure Q Baxter and Rennie (1996). This fair value is actually equal to the initial value of a (dynamic) replicating portfolio. Such valuation approach is usually called risk neutral valuation (see, for example, Harrison and Kreps (1979) and Harrison and Pliska (1981)) and measure Q is called risk neutral measure. Therefore, the fair value of the VA contract defined in Section 2 can be written as

$$V = E_Q[e^{-rT} P \cdot \max(R_M, G)], \tag{7}$$

where $E_Q[\cdot]$ denotes the expectation operator under measure Q.

4 MONTE CARLO APPROACH

It is well known that, under the risk neutral measure Q, $\log(R_t)$ are independent normal random variables with common mean

$$r_f - \rho\sigma_S\sigma_C - \frac{\sigma_S^2}{2}$$

and common variance σ_S^2 Hull (2006). Since R_M is just a function of $R_t, t = 1,\ldots,T$. Equation (7) implies Monte Carlo approach can be used to price the contract. We shall use control variates (see, e.g., Bratley et al. (1983) and Law and Kelton (2000)) to speedup the Monte Carlo method.

From Equation (7), it is easy to see that R_M can be a good control variate. To make R_M a valid control variate, we need to compute $E_Q[R_M]$. To this end, we follow the idea in Hsieh and Chiu (2007).

Using (2) we can get

$$\tilde{R}_t = (1-\alpha) + \alpha \min(\max(f_\alpha, R_t), c_\alpha), \tag{8}$$

where $f_\alpha = 1 + f/\alpha$ and $c_\alpha = 1 + c/\alpha$. Set

$$X_t = \min(\max(f_\alpha, R_t), c_\alpha). \tag{9}$$

Then it is easy to see that X_t's are independent censored lognormal random variables with censored values f_α and c_α.

We use (3) to obtain

$$\begin{aligned} E_Q[R_M] &= E_Q[1 - T + \sum_{t=1}^{T} \tilde{R}_t] \\ &= E_Q[(1-\alpha T) + \alpha T X_1] \\ &= 1 - \alpha T + \alpha T E_Q[X_1] \end{aligned} \tag{10}$$

Therefore, we reduce the task of computing $E_Q[R_M]$ to the task of computing $E_Q[X_1]$.

To compute $E_Q[X_1]$, we first write

$$\begin{aligned} E_Q[X_1] = {} & f_\alpha P(R_1 \le f_\alpha) + E_Q[[R_1; f_\alpha \le R_1 \le c_\alpha] \\ & + c_\alpha P(R_1 \ge c_\alpha). \end{aligned}$$

Then, by representing R_1 as

$$\exp(r_f - \rho\sigma_S\sigma_C - \sigma_S^2/2 + \sigma_S N(0,1))$$

and letting

$$d_1 = \frac{\log f_\alpha - r_f}{\sigma_S} + \frac{2\rho\sigma_C + \sigma_S}{2}, \tag{11}$$

and

$$d_2 = \frac{\log c_\alpha - r_f}{\sigma_S} + \frac{2\rho\sigma_C + \sigma_S}{2}, \tag{12}$$

we obtain

$$\begin{aligned} P(R_1 \le f_\alpha) &= P(N(0,1) \le d_1) = \Phi(d_1), \\ P(R_1 \ge c_\alpha) &= P(N(0,1) \ge d_2) = \Phi(-d_2), \end{aligned}$$

and

$$\begin{aligned} & E[R_1; f_\alpha \leq R_1 \leq c_\alpha] \\ = & \int_{d_1}^{d_2} e^{r_f - \rho\sigma_S\sigma_C - \sigma_S^2/2 + \sigma_S z} \cdot \phi(z) dz \\ = & e^{r_f - \rho\sigma_S\sigma_C}[\Phi(d_2 - \sigma_S) - \Phi(d_1 - \sigma_S)] \end{aligned}$$

where $\phi(\cdot)$ and $\Phi(\cdot)$ are the density function and the cumulative distribution function of standard normal random variable, respectively.

Combining these three terms, we get the explicit formula for $E_Q[X_1]$:

$$\begin{aligned} E_Q[X_1] = & f_\alpha\Phi(d_1) + c_\alpha\Phi(-d_2) \\ & + e^{r_f - \rho\sigma_S\sigma_C}[\Phi(d_2 - \sigma_S) - \Phi(d_1 - \sigma_S)] \end{aligned} \tag{13}$$

With (13) and (10), the following proposition is straightforward.

Proposition 1

$$\begin{aligned} E_Q[R_M] = & 1 - \alpha T \\ & + \alpha T(f_\alpha\Phi(d_1) + c_\alpha\Phi(-d_2)) \\ & + \alpha T e^{r_f - \rho\sigma_S\sigma_C}[\Phi(d_2 - \sigma_S) - \Phi(d_1 - \sigma_S)], \end{aligned}$$

where d_1, d_2 are defined in (11) and (12).

Now, we are ready to test some numerical examples. We begin with a description of the parameters of Black-Scholes quanto model for the VA contracts: the contract maturity $T = 5$, initial investment $P = 100$, floor rate $f = 1\%$, the volatility of the linked-index $\sigma_s = 25\%$, the volatility of the exchange rate $\sigma_C = 10\%$, the correlation coefficient $\rho = -0.1$, local currency interest rates $r = 6\%$, foreign currency interest rates $r_f = 4\%$, and the global guarantee rate $G = 110\%$.

We simulate 1000 independent runs of $(\tilde{R}_1, \cdots, \tilde{R}_T)$. From these 1000 simulated paths, we can easily obtain 1000 independent replications of $e^{-rT}P \cdot \max(R_M, G)$. Based on these independent copies, standard point estimates of $E[e^{-rT}P \cdot \max(R_M, G)]$, and their standard errors are computed and presented in Table 2.

The accuracy of the point estimates in Table 2 are not very satisfactory. We shall apply the variance reduction technique of control variate. In particular, we take advantage of Proposition 1 and select control variate

$$C = R_M - E_Q[R_M], \tag{14}$$

Using the same 1000 replications of $(\tilde{R}_1, \cdots, \tilde{R}_T)$, we can also obtain 1000 independent replications of C. Let λ_1 and λ_2 be any real numbers and set

$$Y(\lambda) = e^{-rT}P \cdot \max(R_M, G) - \lambda C$$

Since $E_Q[C] = 0$, it is easy to see that $E[Y(\lambda)]$ equal to the fair value of the VA contract. Therefore, it provides alternative mean of computing the price. It is well known that

Table 2: Fair value of the VA contract computed by naive Monte carlo method. The upper table contains point estimates and the lower table contains their standard errors.

the optimal (variance-minimizing) weight λ^* of the control variate is Cov(Y,C)/Var(C) Bratley et al. (1983). The quantities of Cov(Y,C) and Var(C) are estimated by the sample covariance and variance.

It turns out that control variate $Y(\lambda)$ is quite effective. Table 3 show the results. These results indicate that the accuracy of the estimates has been improved significantly with control variate C.

To further quantify the effectiveness of control variate C, we define variance reduction ratio as follows.

$$\mathrm{VRR} = \frac{\text{Var(naive estimator)}}{\text{Var(estimator with control variate)}} \tag{15}$$

Because most of the computational effort was used to generate the sample paths of $(\tilde{R}_1,\cdots,\tilde{R}_T)$, the additional work needed to compute C is minor. Therefore, it seems reasonable to use VRR as a proxy of computational gain. Table 4 shows that the quantities of variance reduction ratio range from 88 to 2070. This indicates control variate C is very effective in reducing the estimator's variance.

5 CONCLUDING REMARKS

In this paper, we introduced a variable annuity contract in Taiwan market. The variable annuity contract has quanto feature and embedded cliquet options. Such contracts are

Table 3: Fair value of the VA contract computed by Monte carlo method with control variate $C = R_M - E_Q[R_M]$. The upper table contains point estimates and the lower table contains their standard errors.

attractive to the investor because of their protection against downside risk and significant upside potential. We proposed a control variate for improving the computation efficiency of valuing such contracts. The numerical results show that the control variate is quite effective. This also suggests that Monte Carlo methods can be a very efficient computational tool for pricing complex insurance products.

Our study also provides computational tools for analyzing the trade-off among various parameters for such contracts. For example, the following information can be obtained from our study:

1. The effect of participation rate α on cost;
2. The effect of ceiling rate c on cost;
3. The effect of floor rate f on cost; and
4. The effect of the global guarantee rate G on cost.

We use the data of Taiwanese financial institutions from 2006:Q1 to 2012:Q4 to examine the effects of corporate governance mechanisms on idiosyncratic risk. Our results show that the firms with better corporate governance mechanisms (including more independent board, better transparency) tend to have a lower idiosyncratic risk. However, firms with higher foreign ownership appear to have a higher idiosyncratic risk.

Keywords: dynamic panel regression, corporate governance, idiosyncratic Risk.

1. Introduction

The financial industry is an indicator of national economic development and plays an important role in economic activities. If the financial industry is mismanagement, financial institutions will lose financial intermediation functions, and affects the development of other industries. In addition, if a financial crisis occurs, the crisis would seriously affect the financial order and economic development. Therefore, some series of financial industry problems, like the Iceland financial crisis and the Lehman Brothers bankruptcy, raised the global financial crisis. Thus, in the academic field, find out the mechanisms of avoiding malpractice and reducing risk of financial industry is critical.

Since the opening to establishing private banks in Taiwan in 1991, Taiwan has adopted a series of financial reforms, which have substantially increased the number of financial institutions in Taiwan. Consequently, harsh competition has occurred between financial institutions, and credit quality have deteriorated, bank profits have decreased, and non-performing loan ratios have increased, thereby increasing the risk and damaging the rights of stakeholders. Therefore, how to decrease the risk and avoid financial crisis of Taiwan is an important issue.

BASEL III suggested to strengthened corporate governance to prevent the risk occurring from the financial industry. Besides, previous studies also indicate that corporate governance serve as a type of a mechanism, protect minority shareholders and stakeholders, and enhance the wealth of shareholders. Lin, et al. (2010) specified that through the design of the corporate governance mechanism could reduce the agency problems and decrease idiosyncratic risk. Firms with better corporate governance mechanisms have fewer agency problems. The idiosyncratic risk of the firm and capital costs would be reduced, thereby enhancing corporate performance and shareholder wealth. Hence, if financial institutes establish better corporate governance mechanisms can reduce the risk to improve the financial industry environment and to avoid malpractice of the financial industry.

However, the literatures regarding the effects of corporate governance quality on the risk of financial institutions is lack. Furthermore, after reviewing the literature, numerous studies have focused on exploring the relationship between partial corporate governance mechanisms and firm performance. Few studies have explained the relationship between corporate governance and risk. Thus, to make up the gap in the literatures, this study provides direct empirical evidences of the effects of corporate governance quality on risk. This paper follows Lin et al. (2010) to use idiosyncratic risk as the proxy for the level of risk in financial industry. The idiosyncratic risk represents the risk link with how the financial institutes operate their own business and systems.

In this study, the financial holding industry, banking industry, and securities industry in Taiwan were the research subjects. Empirical evidence was used to analyze the relationship between financial corporate governance mechanisms and idiosyncratic risk. Flannery and Hankins (2013) indicated that dynamic panel data regression has become increasingly vital in the corporate finance field. In addition, if explained variables of lag periods are included in independent variables, dynamic panel data regression must be used to avoid biased parameter estimates. Thus, this paper modified the empirical model by Lin et al. (2010) and used dynamic panel data regression in this study. This study also referred to Arellano and Bond (1991) and conducted generalized method of moments (GMM) regression to estimate the regression parameters. Furthermore, the Sargan test was used to examine the effectiveness of the instrumental variables adopted by the dynamic panel data regression.

This study explored the effects of corporate governance quality on idiosyncratic risk. Corporate governance involves ownership structure, board structure, executive incentive, and information disclosure. The results show that when the high proportion of independent directors and supervisors in the board associated with lower idiosyncratic risk. Moreover, higher information transparency indicates less idiosyncratic risk. The main contribution of this study is the comprehensive investigation on the effects of the corporate governance mechanism on idiosyncratic risk in financial industry.

The literature mainly focuses on exploring the effects of the corporate governance mechanism on operating performance or conceptually explains the influence of parts of the corporate governance mechanism on idiosyncratic risk. These studies have failed to examine the effects of the entire corporate governance mechanism on idiosyncratic risk. Only Lin et al. (2010) used general industry as the research subject and comprehensively focused on the effect of internal and external corporate governance mechanisms on idiosyncratic risk. However, they did not examine the financial industry. Because the financial sector is a franchise industry and is closely related to the public, a firm must possess a strong corporate governance mechanism. We conducted comprehensive analysis to determine how the corporate governance mechanisms influence idiosyncratic risk. This study can serve as a reference for government agencies and financial institutions in promoting corporate governance so that the essence of corporate governance can be implemented to maintain stakeholder interests. Thus, corporate organizations and operations can develop steadily. Section II presents a literature review; Section III introduces data sources, variable definitions, and the research model; Section IV shows the empirical analysis results; and Section V the conclusions

2. Literature Review

2.1. *Financial Institutions and Corporate Governance*

The financial industry is the primary industry in a nation. However, Taiwan’s financial industry lacks industrial competitiveness. Since 1980, to adapt to the globalization and liberalization trends in the global financial markets, the government has gradually relaxed the financial regulatory measures and reduced the regulatory thresholds for establishing banks. The government hope that by enabling fully competition in the financial industry, the industry could improve efficiency and establish fair competition in the financial system.

Because of the special nature of the financial industry, poor operations affect the firm role as funding agencies and the national economic development. Chen (2005) presented characteristics of the financial industry and the necessity of strengthening corporate governance. First, the financial industry is the economic lifeline of a nation. Corporate borrowing, fund collection, and international trade are dependent on the financial sector. If the financial sector possesses poor corporate governance, the funding agency function would be compromised and would affect the economic sector. Major funding in the financial institution is obtained from the public. Specifically, banking funds are primarily obtained from the community. Although banks possess low equity funds, they operate large-scale businesses. With this operation from a high financial leverage, corporate governance must be implemented to safeguard the rights and interests of depositors. Regarding the financial industry, integrity and trust are essential; therefore, the managerial style and ethical standards determine the stability of a bank and bank performance. Taiwan's financial institutions have focused on a personal-network and family-oriented business model in financial institutions, which is a substantial barrier to corporate governance. Taiwan's financial institution requires a stable corporate governance mechanism to reduce the risks and problems in moral issues.

To implement a stable corporate governance system and promote the healthy development of the financial market, the Taiwanese government has made several major revisions to the legal regulations and initiated a series of complementary measures and reform items.

2.1.1. Improving the independency of board

To prevent the board from becoming a formality, the Securities and Futures Commission of Ministry of Finance, beginning in February 22, 2002, implemented an independent director and supervisor system in two stages. During the first stage, initial public offering (IPO) and over the counter (OTC) firms must disclose in their annual report whether the board of directors comply with crucial resolutions made by directors and supervisors and the opinions of both parties. In addition, to apply for becoming a listed or OTC firm, firms must establish at least two independent directors and one independent supervisor. If these firms failed to follow these requirements, they could not be listed. The second stage involved publically promoting these regulations to encourage all the listed and OTC firms to implement these regulations.

2.1.2. Strengthen the information transparency

Financial holding corporations should disclose all net operating income. This included a financial holding corporation's banks, insurance, securities, and investment firms; current regulations do not specifically require that corporations reveal all of their businesses and regions of operation. Consequently, corporate profit sources are vague to the public. Regarding corporate expansion and globalization, financial institutions must revise disclosure items to respond to global trends. Domestic banking businesses focus on lending, but the competent authority has not regulated the disclosure lending structure. Consequently, investors are unable to obtain the lending policies of various banks or subsequently assess potential credit risks.

2.1.3. The Best-Practice Principles of Corporate Governance

To implement a corporate governance system, the Taiwanese government released the Corporate Governance Best-Practice Principles for TSEC/GTSM Listed Companies, which was approved by the Securities and Futures Commission, in October 2002. The content contains provisions regarding protecting shareholder equity, strengthening board responsibilities, exerting the supervisor functions, respecting stakeholder rights and interests, and enhancing information transparency.

2.2. *The Corporate Governance and Risk in Financial Industry*

The majority of the literature explores only the relationship between partial corporate governance mechanisms and risk. Regarding internal corporate governance mechanisms, empirical studies have indicated that strong corporate governance could reduce the capital costs of firms, but they failed to explain the relationship between corporate governance and the idiosyncratic risk of capital cost. Himmelberg et al. (1999) stated that when managers possessed high shareholding ratio idiosyncratic risk was reduced. Regarding the external governance mechanism, Jin and Myers (2006) conducted an empirical study from a national perspective. They found that firms possessing less information transparency exhibited high idiosyncratic risk. However, they did not research the quality of firm-level governance and its effects on idiosyncratic risk. Moreover, Gasper and Messa (2006) used data obtained from CRSP Compustat to analyze the effects of product market competition on idiosyncratic risk. The study showed that highly competitive product markets exhibited increased idiosyncratic risk. Ferreira and Laux (2007) explored the effects of the market for corporate control on idiosyncratic risk. Their results indicated that firms that possessed numerous anti-takeover provisions had low idiosyncratic risk. Unlike previous studies, Lin et al. (2010) examined the effects that comprehensive corporate governance, which involved internal and external mechanisms, has on idiosyncratic risk. The results indicated that when the shareholding ratio by external blockholders, ratio of independent directors and supervisors on boards, and shareholding ratio by managers were high, and when information was obtained in a timely manner, then idiosyncratic risk was reduced. In other words, improved internal corporate governance mechanisms effectively reduce idiosyncratic risk. Legal regulations and product market competitiveness have no substantial effects on idiosyncratic risk, thereby indicating that external corporate governance mechanisms cannot reduce idiosyncratic risk.

Regarding the financial industry, scholars have mostly focused on parts of corporate governance mechanisms and their effects on system risk or corporate governance mechanisms and their influence on partial idiosyncratic risk. Saunders et al. (1990) examined the relationship between bank ownership structure and risk taking. The results indicated that total risk, non-system risk, and the shareholding ratio of operators are significantly positively correlated. In addition, the non-significant relationship between system risk and the shareholding ratio of operators indicated the importance of idiosyncratic risk. Chen (2003) examined factors from 1996 to 2001 (i.e., the period of Taiwanese bank recession) that influenced bank risk-taking behavior. They found that corporate governance mechanisms had a significant effect on bank credit risks and overall risks. Chen et al. (1998) used 302 banks from 1988 to 1993 as their sample. The study indicated that the shareholding ratio of management (including managers and directors) was negatively correlated with the risk proxy variables in two-factor market models.

In other words, when the shareholding ratio of management increased, risk aversion behaviors also increased, thereby supporting the relative risk aversion hypothesis. Cebenoyan et al. (1995) found that when institution investors possessed high shareholding ratios, the risk-taking rate of the bank was reduced, thereby supporting the efficient monitoring hypothesis. However, Li (2002) showed that high shareholding ratios by institution investors increased bank credit risk, market risk, and overall risk. This relationship supported the conflict of interest hypothesis. Kan (2003) indicated that no significant correlation was observed between the shareholding ratio by legal personalities of institutions and the nonperforming loan ratio of a bank.

3. Methodology

3.1. *The Data*

Financial institutions issued by the Taiwan Stock Exchange were recruited as research subjects, including independent banks of the listed and OTC firms, financial holding banks, and securities industry. Research data included the Taiwan stock index, firm stock price, and financial reports. All data were obtained from the Taiwan Economic Journal (TEJ) and Market Observation Post System based on public-issued listed and OTC firms.

Because the insurance industry lacks information disclosure mechanisms, these firms were not included in this study. For the research sample, 33 firms were selected including nine independent banks, 14 financial holding banks, and 10 securities firms. Prior to 2006, TEJ only collected semiannual reports of the financial industry firms and not quarterly reports; therefore, this study began its examination from the first quarter of 2006 to the fourth quarter of 2012; the period was 7 years, overall. The study examined the data of the quarterly reports for each year.

3.2. *The Variable Definitions*

3.2.1. Ownership structure

This study used the shareholding ratio by external blockholders and by institutional legal personalities as the proxy variables for the ownership structure. This study defined the external blockholder ownership (BOR) as the shareholding ratio of blockholders who were not identified as directors and managers. The institutional ownership (IOR) was defined as the sum of the ratio of foreign legal personality ownership from the investment sample firms (FOREIGN), investment trust and consulting ownership (ITCS), and the dealer shareholding ratio (DEALERS). This study predicted that when the external blockholder shareholding ratio and the institutional legal-personality shareholding ratio were high, then the supervising ability of a firm would be high and idiosyncratic risk would be low.

3.2.2. Managerial incentives

This study used managerial ownership ratio (MOR) as the proxy variable of the managerial incentive mechanism. We predicted that when the managerial shareholding ratio was high, the interests of the managers and shareholders would be consistent and idiosyncratic risk would be low.

3.2.3. Board composition

This study defined the independent director and supervisor ratio to the overall director and supervisor seats (INDR) as the number of seats of independent directors and supervisors of the sample firm divided by the total seats of the board of directors and supervisors. This study predicted that a high ratio of independent directors and supervisors to the director and supervisor seats would elicit a highly independent board. Thus, the managerial supervisory capacity would be strong and the idiosyncratic risk low.

3.2.4. Information transparency

This study used information timeliness and disclosure rating as proxy variables of information transparency. This study predicted that when the information transparency is high, the quality of corporate governance is strong and therefore idiosyncratic risk is low.

3.2.4.1. Information timeliness

Timeliness of information (TIMELINESS) was used as the first proxy variable of information transparency (Ashbaugh et al., 2006). The regression equation is established as follow:

$$RET_{i,\tau} = \beta_0 + \beta_1 NIBE_{i,\tau} + \beta_2 LOSS_{i,\tau} + \beta_3 NIBE_{i,\tau} \times LOSS_{i,\tau} + \beta_4 \Delta NIBE_{i,\tau} + \varepsilon_{i,\tau} \quad (1)$$

where $RET_{i,\tau}$ represents the average stock return of firm i in quarter τ; $NIBE_{i,\tau}$ denotes the quarterly net income of firm i in quarter τ divided by the shareholder equity market cap at the beginning of the quarter; $LOSS_{i,\tau}$ represents a dummy variable. When $NIBE_{i,\tau}$ is a negative number, $LOSS_{i,\tau}$ is 1; otherwise, $LOSS_{i,\tau}$ is 0; ($\Delta NIBE_{i,\tau}$) represents the quarterly net income change of firm i in quarter τ divided by the shareholder equity market cap at the beginning of the quarter. Regression analysis on data of quarter τ of all firms is conducted using (1). The regression residual i resulting from the regression analysis is squared and multiplied by -1. The product is information timeliness ($TIMELINESS_{i,\tau}$) of firm i in quarter. When $TIMELINESS$ is high, the data respond to return in a timely manner; therefore, firm information transparency level is high.

3.2.4.2. Disclosure rating

Information disclosure assessment (INF) was used as the second proxy variable representing information transparency. To measure the degree of information disclosure, this study cited the assessment results of the information disclosure and transparence ranking system provided by the Taiwan Securities and Futures Institute. The following paragraphs present the assessment ranks converted into numeral codes for measurements, as shown in Table 1.

Table 1 The rating scale of information transparency

The Rating Scale	Codes
A+	5
A	4
B	3
C	2
C−	1

3.2.5. The measurement of idiosyncratic risk

This study follows the direct decomposition method by Xu and Malkiel (2003) to estimate idiosyncratic risk. In addition, by establishing the market model, we estimated the volatility sequence of idiosyncratic and systemic risks. To solve the heteroscedasticity and heavy-tailed distribution patterns concerns that the sequence of returns possessed, when estimating idiosyncratic risk, we used a GARCH model to modify the direct decomposition method by Xu and Malkiel (2003).

$$r_{i,\tau} = \alpha_i + \beta_i r_{m,t} + \varepsilon_{i,t} \tag{2}$$

$$r_{i,t} = \alpha_i + \beta_i r_{m,t} + \gamma_i r_{mv,t} + \kappa_i r_{b/v,t} + \varepsilon_{i,t} \tag{3}$$

(2) is the market model, where α_i and β_i represent parameters to be estimated; $r_{i,t}$ denotes the excess return of stock i on day t; $r_{m,t}$ depicts the excess return of the market portfolio on day t, and $\varepsilon_{i,t}$ represents the residuals. The equation (3) is three factor model proposed by Fama and French (1993), where r_i, k_i represent parameters to be estimated; $r_{mv,t}$ represent the market size factor, $r_{b/v,t}$ represents the book to market value factor.

In general, (2) and (3) disregards the issue that data in financial asset time series possesses heteroscedasticity, which leads to inefficient estimations of the parameters. Thus, Xu and Malkiel (2003) used rolling methods to estimate the idiosyncratic risk of individual stocks to solve conditional heteroscedasticity. In (2) and (3), the residuals appeared to possess a GARCH-model effect. Because of this effect, the idiosyncratic risk of market factors was estimated.

$$\varepsilon_{i,t} \mid \psi_{t-1} \sim N(0, h_{i,t}^2) \tag{4}$$

$$h_{i,t}^2 = \phi_0 + \phi_1 \varepsilon_{i,t-1}^2 + \phi_2 h_{i,t-1}^2 \tag{5}$$

where ψ_{t-1} represents the total information collection prior to period $t-1$; ϕ_0, ϕ_1, ϕ_2 are parameters that are not negative numbers, and $\phi_0 + \phi_1 < 1$; $h^2_{i,t-1}$ denotes the estimate of idiosyncratic risk of stock i at period t; $\varepsilon^2_{i,t-1}$ represents the residual square of idiosyncratic risk of stock i during period $t-1$; if $h^2_{i,t}$ were calculated using market model; $hF^2_{i,t}$ were calculated using three factor model.

Because relevant financial variables could only be obtained from quarterly data reports, we converted the other research variables into variables representing quarterly data. Daily idiosyncratic risk $h^2_{i,t}$ and $hF^2_{i,t}$ were converted into quarterly idiosyncratic risk by adding all trading days in that quarter. The converted idiosyncratic risks are denoted by $IV_{ij,\tau}$ and $FIV_{ij,\tau}$

.3.2.6. Control variables

This study establishes 8 control variables in the study model. The following control variables were converted into quarterly data. The 8 control variables were firm size ($LNSIZE_{i,\tau}$), market-to-book ratio ($MTB_{i,\tau}$), leverage rate ($LEV_{i,\tau}$), stock turnover ratio ($TURN_{i,\tau}$), capital expenditure ratio ($CE_{i,\tau}$), return on assets ($ROA_{i,\tau}$), non-performing loans ($NPL_{i,\tau}$), and bank of international settlement ratio ($BIS_{i,\tau}$).

3.3. Empirical Model

Because the data in this study were panel data that involved cross-sectional and time-series data of the listed firms in Taiwan's financial industry from 2006:Q1 to 2012:Q4, the data were suitable for constructing a panel-data model for statistics analysis, thereby reducing the collinearity problem. Flannery and Hankins (2013) indicated that when a lagged period of an explained variable was included in the explanatory variables, a dynamic panel data-regression model was used to conduct empirical analysis to avoid deviated parameter estimates. Thus, the dynamic panel data-regression model was established as follows:

$$Y_{i,\tau} = \beta_{oi} + \sum_{k=2}^{K} \beta_k X_{ki,\tau-1} + \varepsilon_{i,\tau},\ i = 1,\ldots,N, \tau = 1,\ldots,T \tag{6}$$

where $Y_{i,\tau}$ represents the idiosyncratic risk ($IV_{i,\tau}$ or $FIV_{ij,\tau}$) of firm i in quarter τ; $X_{ki,\tau}$ denotes the Kth explanatory variable of firm i in quarter τ; $\beta_0, \beta_1, \ldots, \beta_K$ represent the parameters to be estimated; and $\varepsilon_{i,\tau}$ denotes a random error item.

4. Results

4.1. Descriptive Statistics

This study used the Taiwan financial holdings, banks and securities firms from 2006:Q1 to 2012:Q2 as samples. Descriptive statistical analysis was conducted to obtain the mean, standard deviation, median, and quartiles of the various research variables. Table 2 presents the descriptive statistical analysis of the overall sample.

The results presented in Table 2 are the results of the descriptive statistics of all sample variables. First, by observing the blockholder shareholding ratio, the mean shareholding ratio of the external blockholders of the sample firms was established as 4.08% (SD 0.0833). The first quartile and the third quartile were 0, which indicated that the external blockholder shareholding ratio in the sample firms was generally low and the differences were not significant. Regarding the shareholding ratio of institutional legal personalities, foreign ownership possessed the highest shareholding ratio, with a mean of 16.12% and a median of 10.55%. The results indicated that foreign ownership was relatively strong compared with other types of legal-personality ownership.

In addition, the shareholding ratio presented a negative skew, thereby indicating that foreign ownership had a relatively high shareholding ratio in specific firms. The results in the table show that the mean value of the managerial shareholding ratio was 0.25%. The data indicated that in over half of the sampled firms, the managerial shareholding ratio was 0%. If these firms do not have a comprehensive and stable supervising mechanism or transparent information disclosure policy, then these firms have severe agency problems and information asymmetry concerns.

Regarding board composition, the mean value was 12.44 (SD 0.1001), and the sample firms showed only a slight difference, thereby indicating that employing independent directors and supervisors was common in the sample firms. Regarding operating performance, the mean value of the return on assets was 0.53% and the standard deviation was 0.0133, which indicated that the average performance of the financial industry from 2006 to 2012 was relatively poor.

	Average	St. Dev.	Q1	Median	Q3
$IV_{i,\tau}$	1.6953	0.2465	1.5525	1.6855	1.8896

Note: Q1 and Q3 are represented the firth and third quartile. $IV_{i,\tau}$ is represented the idiosyncratic risks of firm i at quarter τ. $BOR_{i,\tau}$, $IOR_{i,\tau}$, $MOR_{i,\tau}$ are represented the outside block-holder ownership, institutional ownership, managerial ownership of firm i at quarter τ. $INDR_{i,\tau}$ is represented the proportion of independent supervisor/director in the board of firm i at quarter τ. We take $TIMELINESS_{i,\tau}$ for estimating the information timeliness of firm i at quarter τ. $LNSIZE_{i,\tau}$, $MTB_{i,\tau}$, $LEV_{i,\tau}$, $TURN_{i,\tau}$, $CE_{i,\tau}$ and $ROA_{i,\tau}$ are the control variables.

4.2. Correlation Coefficient Analysis

Before a regression model could be established, high degrees of similarities between independent variables must be prevented from influencing the study results. We conducted Pearson correlation coefficient analysis to explore variables related to corporate governance regarding the extent of relationships and the trend of idiosyncratic risk. These variables were as follows: an external block-holder shareholding ratio; shareholding ratio by institutional ownership; shareholding ratio of foreign ownership; shareholding ratio by securities investment trust and consulting representatives; shareholding ratio by dealers; the number of independent directors and supervisors; shareholding ratio by managers; information timeliness; information transparency; and disclosure assessments.

Correlation coefficient analysis indicated that the current idiosyncratic risk and the idiosyncratic risk for the following period were positively correlated. Regarding internal corporate governance variables, the shareholding ratio by institutional leg personalities, shareholding ratio of foreign ownership, shareholding ratio by dealers, and the cost and price differences were all positively correlated with idiosyncratic risk. However, the correlations were not significant. All other variables showed significant correlations with idiosyncratic risk. When the external blockholder shareholding ratio, securities investment trust and consulting representatives, the ratio of independent directors and supervisors, and the shareholding ratio by managers were high, then idiosyncratic risk would also be high. In addition, the two variables related to information transparency (i.e., information timeliness and information disclosure assessment) were negatively correlated with idiosyncratic risk.

Note: The definitions of variables are reported in table 2. Bold-faced coefficients are significant at the 1% and 5% level, respectively.

4.3. Empirical Results

The results presented in Table 4 showed that the entire current idiosyncratic risk of the model and the idiosyncratic risk for the following period were positively correlated. These results indicated that the idiosyncratic risk of a firm could change over time. In addition, the effects of partial corporate governance on idiosyncratic risk were significant. One exception was that the shareholding ratio by blockholders was positively but not significantly correlated with idiosyncratic risk. The shareholding ratio by managers and was negatively, but not significantly, correlated with idiosyncratic risk. Reaching more than the 5% level of significance, the other variables, such as the ratio of independent directors and supervisors on the board, information timeliness, and information disclosure assessments, were negatively correlated to idiosyncratic risk. This trend showed that high information transparency levels indicate low idiosyncratic risk in financial institutions. When the ratio of independent directors and supervisors on the board was high, the idiosyncratic risk of the firm is low. These results were consistent with the study predictions. The shareholding ratio by institutional legal personalities and idiosyncratic risk were positively correlated, thereby indicating that when the shareholding ratio by institutional legal personalities was high, the idiosyncratic risk of the financial institution was also high. This result was inconsistent to our predictions.

To comprehensively understand the relationship of the shareholding ratio by institutional legal personalities to idiosyncratic risk, this study defined the shareholding ratio by institutional legal personalities separately as the shareholding ratio of foreign ownership, shareholding ratio by securities investment trust and consulting representatives, and shareholding ratio by dealers.

The results shown in Table 5 indicate that the current idiosyncratic risk and the idiosyncratic risk of the following period were positively correlated, thereby suggesting that idiosyncratic risk change over time. By reaching a level of significance of more than 5%, the ratio of independent directors and supervisors on the board and information transparency were negatively correlated to idiosyncratic risk. This indicated that a high number of independent director and supervisors on the board along with high information transparency lowers the idiosyncratic risk of financial institutions. The shareholding ratio by foreign investors and idiosyncratic risk were positively correlated. This indicated that when the shareholding ratio by foreign investors was high, the idiosyncratic risk was high. Regarding the control variable results, Tables 4 and 5 indicate that at a 5% level of significance, firm size and idiosyncratic risk were negatively correlated. A large-scale firm experiences low idiosyncratic risk. In addition, at a 5% level of significance, leverage ratio and idiosyncratic risk were positively correlated, thereby indicating that when high leverage ratios increase idiosyncratic risk increases.

This study also used idiosyncratic risk that was estimated by the three-factor model to verify the stability. The results shown in Tables 4 and 5 are consistent. Therefore, financial institutions must strengthen corporate governance quality to reduce idiosyncratic risk and protect the rights and interests of all stakeholders.

Previous studies have focused on exploring whether the corporate governance mechanisms in general industry could enhance corporate operating performance and shareholder wealth. These studies have rarely focused on the effects of the quality of corporate governance in the financial industry on idiosyncratic risk. In addition, relevant studies have been limited to the influence of partial corporate governance mechanism on idiosyncratic risk. These studies were not comprehensive investigations on the effect of corporate governance mechanisms in the financial industry on firm idiosyncratic risk. Only Lin et al. (2010) used general industry as the research subject and comprehensively explored the effect of the corporate governance mechanism on idiosyncratic risk.

Due to the financial sector is a franchise industry and is closely related to the public, a financial institution with a strong corporate governance mechanism is essential. This study comprehensively analyzed the factors of corporate governance that influenced the idiosyncratic risk in financial industry. These factors can serve as a reference for competent authorities in governmental sectors and financial institutions that are promoting corporate governance. Thus, the essence of corporate governance can be implemented to maintain stakeholder rights and interests and corporate organizations and operations can develop steadily.

This study was conducted from the corporate governance mechanism perspective for investigating idiosyncratic risk in financial institutions. By using dynamic panel data modeling and by using listed and OTC firms from 2006 to 2012 as the study sample, we explored vital corporate governance mechanisms, such as ownership structure, board composition, managerial incentive systems, and information transparency and their relationship with idiosyncratic risk in financial institutions.

First, the empirical results showed that regarding ownership structure, the institutional ownership was positively correlated to firm idiosyncratic risk. After further analysis, the results showed that the foreign investor shareholding ratio and idiosyncratic risk were positively correlated. The main reason for this result could be that foreign investment in Taiwan's financial institution is primarily short term. Thus, foreign investment did not achieve the effect of an institutional legal personality on monitoring corporate operations. Based on board composition, more independent directors and supervisors on the board are correlated to low idiosyncratic risk. This result indicated that when boards of directors of financial institutions in Taiwan possessed high independence, the firm idiosyncratic risk decreased. Finally, high information transparency in a financial institution was correlated to low idiosyncratic risk. Thus, we recommend that the financial industry increase the board of director independence and information transparency to reduce idiosyncratic risk.

□ □ □ □ □ □ Building automobile industrial cluster in Vietnam. Which factors are important in achieving successful industrial cluster formation?

***Nguyen Thi Duc Nguyen, Bui Nguyen Hung, Nguyen Thi Thanh, and Le Phuoc Luong**
School of Industrial Management,
University of Technology,
Ho Chi Minh City, Vietnam
**ntducnguyen@yahoo.co.jp; *ntdnguyen@hcmut.edu.vn*

This study aims to identify (1) factors that affect the formation of automobile industrial clusters in the world and (2) factors that lead to the successful formation of automobile industrial clusters in Vietnam. A literature review of industrial cluster and in-depth interviews with experts in the automobile industry in Vietnam are utilized in this study. Especially, three university's representatives, two institutes' representatives, three companies' representatives and one government representative in Vietnam are targeted. The collected data are classified, analyzed, and summarized upon Porter's industrial cluster theory. This study finds that an infrastructure, workforce, universities and research institutes, related and supporting industries, domestic demand, export demand, presence of anchor firms, government supporting policies are important factors in building the automobile industrial cluster in Vietnam. And among those factors, according to the automobile industrial cluster experts, the policies of the government is the most emphasized factor which importantly influence on the formation of automobile industrial cluster in Vietnam. Finally, this study offers new insights to assist policy makers in the process of forming automobile industrial cluster in Vietnam.

Key words : Automobile industry; Industry cluster; Industrial cluster formation; Porter's diamond model; Vietnam

I. INTRODUCTION

Automobile industry always plays an important role in the national economy as well as in the world economy. Automobile industry, however, is very complex and it's composed of many parts and components to assemble into a finished product. Each car usually has more than twenty thousand parts which require good quality and diversity of shapes. Thus, this industry needs a huge capital volume, long-term investment and many related and supporting industries.

For many years, the government of Vietnam has considered automobile industry as one of the most vital sectors contributing to the national economic growth. Vietnam's automobile industry starts late and the development is still very slow. The Vietnamese automobile production industry just stays at the assembling stage (Mai Ha, 2014). After 20-year development, there are many big automobile manufacturers who entered Vietnam through a sole proprietorship or joint-investment, such as Fiat, Ssangyong, GM Daewoo, Toyota, Honda, Isuzu, Ford, Hino, Mercedes-Benz, Mitsubishi... Meanwhile, Vietnam established domestic auto firms, for example, Truong Hai and Xuan Kien. Until now, there are about 18 FDI and 38 domestic businesses making and assembling cars, almost all these firms are small scale. They have a capacity of about 460,000 vehicles a year (Thai News Service, 2013). Most assembly lines are operating under production capacity. According CMRR (2014), there are hundreds of auto part manufacture firms, though, most of them are SMEs featured with low production capacity and low technology. Major parts are simple, e.g. seats, mirrors, glasses, plastics, tires, auto storage batteries. In general, auto parts and components in Vietnam depend on import. The localization rate is now still very low compared with the target. The goal is 40% by 2005, 60% by 2010 for type vehicles (trucks, buses, cars), however, the localization rate has risen from 7 to 10 percent for small car and 35-40 percent for light-duty trucks (Thai News Service, 2013).

Currently, Vietnam's automobile industry is competing with those ASEAN countries (Thailand, Malaysia, Indonesia) as well as those assigned with the ASEAN agreement (China, Korea, Japan). Under commitments to the ASEAN Free Trade Area (AFTA), Vietnam will apply a zero tariff policy to all automobiles imported from ASEAN countries by 2018 (Thai News Service, 2013). This could be a big threat to Vietnam's automobile industry because it is hard to compete with the price and quality of imports. To develop the local automobile industry, one of the solutions offered by the Vietnamese government is to form automobile industrial clusters (Phuong Nhi, 2014). In recent years, many automobile industrial clusters have been formed and operated successfully in the US, China, Thailand, Japan, India, Malaysia... The empirical researches on this issue in many countries around the world have shown the important factors that affect the formation and development of automobile industrial clusters like government, work-force, anchor firms, related and supporting industries, home demand ... However, up to now, there have not been much research and documentation related to the formation and development of automobile industrial cluster in Vietnam. Whether the factors mentioned above have the same to the context of Vietnam's automobile clusters? And which factors should be particularly concerned when building automobile industrial cluster in Vietnam? To find the answers, this study analyzes the strengths and weaknesses of the Vietnam's automobile industry, and combines this information with experts' opinions on the factors that lead to the successful formation of automobile industrial clusters in Vietnam. Accordingly, this study could offer references to policy makers in the strategic preparation for forming and developing the automobile industrial cluster in Vietnam in the future.

This study is organized as follows. After the introduction in section I, section II surveys the literature on cluster according to the theory of Porter and explains the differences between the concept of industrial cluster in Vietnam and in the world. Section III describes the method to collect data. Section IV presents the factors that have influenced the formation of automobile clusters in the world and the results of interviews. Section V discusses the factors that lead to the successful formation of automobile industrial clusters in Vietnam. Finally, section VI summarizes the findings and give some new research directions.

II. INDUSTRIAL CLUSTER CONCEPT

After being come up by Alpred Marshall, the concept of industrial cluster has gradually become a subject of intense research studies and economic analysis in recent years. According to Bekele & Jackson (2005), there are some theoretical perspectives of industrial cluster such as, Marshall (1890)'s classical agglomeration theory; Weber (1929)'s location industry theory; Krugman (1991)'s and Venables (1996)'s new economic geography; Porter (1990)'s competitiveness; Romer (1986)'s dynamic externalities and Lucas (1988)'s dynamic externalities … For many years now, much attention has been paid to the concept of industry cluster. Many latter studies on industry clusters were conducted in different industries around the world and each economist had his own definition of a cluster.

According to Kuchiki (2005), an industrial cluster is a geographic concentration of manufacturing companies, suppliers, service providers, and related institutions in a particular field.

Jie (2010) explained that an industrial cluster is large sums of enterprises and supporting institutes that linked in production or sale are collected in one area and form the strong and sustained competitive advantage.

Porter (1998) stated a very broad definition of the industrial cluster concept which is geographic concentrations of interconnected companies, specialized suppliers, service providers, firms in related industries and associated institutions. The basic configuration of any industrial cluster could be identified and mapped as a diamond model which includes four determinants: factor conditions; demand conditions; related and supporting industries; industry strategy, structure, and rivalry (Porter, 1990). Besides, chance and government are also considered as factors influencing on each determinant of diamond model (Porter, 1990).

Among theoretical approaches mentioned above, the theory of Porter about industry clusters and competitiveness is developed on the basis of the previous industrial cluster schools; developed the Porter's industrial clusters bring a new competitive advantage to related companies and institutions in the same geographic area. Porter advanced the cluster concept as a business strategy to increase competitiveness and productivity. Therefore, Porter's industrial cluster definition (Porter, 1998) is used to underline this study and the factors affecting the formation of automobile industrial cluster in Vietnam are upon Porter (1990)'s diamond model.

In Vietnam, the concept of industrial cluster is mentioned in Decision No. 105/2009/QD-TTg, which is issued on August 18, 2009 by the Prime Minister. This concept, however, is related but not identical to the concept of industrial cluster in the world (See Table 1).

Table 1: Differences between the concept of industrial cluster in Vietnam and in the world

Industrial cluster	In the world	In Vietnam
Nature	Referring to the phenomenon of concentration and links of economic activities. They can be formed spontaneously and are not necessarily in sequence.	Referring to the central location of economic activities. They are often established under the conditions and certain procedures.
Purpose of formation	To develop links between members, To improve the competitiveness of enterprises, To create workforce, goods and services of high quality.	To attract and remove kinds of business investment in production and business, To promote business production and reduce environmental pollution.
Participants	Including various firms and institutions that relate to each other and support the production value chain such as manufacturing, suppliers, universities, trade associations…	Including only production and business establishments, industrial production facilities, handicrafts, small and medium enterprises. Do not have an association with other organizations such as universities, research institutes, trade associations.

Scope	Not restricted in certain geographical range.	Having restricted geographical boundaries, size not exceeding 75 hectares

III. METHODOLOGY

This paper applies the research process of Creswell (2008) to conduct the study, the six steps, including: identifying a research problem, reviewing the literature, specifying a purpose for research, collecting data, analyzing and interpreting the data, reporting and evaluating. The purposes of this study is to identify (1) factors that affect the formation of automobile industrial clusters in the world and (2) factors that lead to the successful formation of automobile industrial clusters in Vietnam. The first purpose is resolved by literature review of published materials. This results are combined with the current status of Vietnam's automobile industry to design questionnaire for in-depth interview. The second purpose is resolved by in-depth interview method with experts in the automobile industry in Vietnam. Experts were asked to assess level of importance of the factors affecting the formation of automobile industry cluster as well as to give their opinion about the factors that lead to the successful formation of automobile industrial clusters in Vietnam. Experts who have knowledge of the Vietnam's automobile industry and at least 5 years working experience in this industry, including three university's representatives, two institutes' representatives, three companies' representatives and one government's representative in Vietnam.

The semi-structured questionnaires are designed to discuss the importance of each factor upon the five-point Likert type, (1: not at all important to 5: very important). There are also some open questions to get more information, ideas and opinions from the experts. The results are based on the convergence of from experts' opinions for each factor.

IV. FINDINGS

The results of factors affecting the formation of automobile industrial cluster in the world based on literature review

In this section, the factors affecting the formation of automobile industrial cluster are summarized according to theory of Porter's diamond model, including factor conditions; related and supporting industries; demand conditions; and industry strategy, structure, and rivalry (See Table 2). Besides, government which influenced on the formation of automobile industrial cluster is included, but the chance factor is unstable and rarely happens, out of this summary.

The results of factors affecting the formation of automobile industrial cluster in Vietnam based on interviews

After conducting in-depth interview with experts in automobile industry, the opinions of interviewees about each factor are collected. The experts' opinions on important level of each factor affecting the successful formation of automobile industrial clusters in Vietnam are summarized in Table 3 and are discussed in the following paragraphs. Consequently, to have an overview of the Vietnam's automobile industry, the strengths and weaknesses of automobile industry in Vietnam are figured out according to Porter's diamond model (see Fig.1).

Factor conditions

"Workforce" and "universities & research institutes" are considered as very important factors affecting the formation of automobile industrial cluster in Vietnam.

Workforce: automobile industry requires a huge amount of labor, including entrepreneurs, engineers, skilled workers, managers... No matter how the machinery and equipment are, they still are controlled by man. Labor is the source of creativity to enhance cluster's competitiveness. In the future, cheap labor is no longer the strength to create competitive advantage, so building a quality workforce will ensure the sustainable formation and development of automobile industry in Vietnam.

Universities & research institutes: although there are many experts' opinions commented the role of universities and research institutes in Vietnam for the development of the automobile industry is not prominent and lacks of cooperation, but experts still appreciated the importance of this factor. A solid base of education and research could help to form and develop automobile industrial cluster successfully.

The rest factors like "infrastructure ", "technology and R&D", "geographic location" and "quality of life" have not much important effect.

Demand conditions

"Domestic demand" and "export demand" are assessed as prerequisite factors affecting the formation of automobile industrial clusters. However, experts said that domestic demand should be more focused. Large domestic market will create conditions for auto firms to achieve economies of scale. The output of the products is the problem that auto part manufacture firms are concerned is the output of the products because the domestic market size is still small. Hence, they need to expand exports and to participate in global value chains.

Related and supporting industries

This is an extremely important factor that needs to develop urgently to form Vietnam's automobile industrial clusters. To produce a complete car, an automobile manufacturer cannot do it alone, so it needs suppliers of spare parts, raw materials, counseling services, logistics… The weakness of related and supporting industries has been the great obstacle for the formation and development of automobile industrial cluster in Vietnam.

Industry strategy, structure, and rivalry

"Presence of anchor firms" has a very important effect. Each automobile industrial cluster has at least one anchor firm. These anchor firms is to create motivation for the system development and to create links to promote cooperation development. They also play an important role in attracting other firms to participate in the automobile industrial cluster. "Cooperation among auto firms" also affects the formation of automobile industrial cluster but not too much.

Government

This is the most important factor affecting the formation of automobile industrial cluster in Vietnam according to experts' opinions. Government helps to build strategic directions and creating a favorable business environment. The mechanism of government support is fundamental conditions for the formation and development of automobile industrial clusters. In addition, government policies are the most important factor affecting industrial cluster by promoting and controlling the activities of firms in the industry.

A new factor from experts' opinions

During the interview process, a new factor is mentioned and emphasized by many experts which is "business capability". This factor is to create competitive advantages that affect the formation and development of automobile industrial cluster in Vietnam. This factor also paves the way for the existence of the automobile industrial cluster because it helps to increase cluster's competitiveness. Enterprises themselves have to identify their main vehicles and determine a clear business strategy to ensure sustainable development. Business capability is most evident in ensuring product quality and reducing costs to meet customer needs as well as to compete with foreign enterprises.

Chance

Although "chance" is not been got more attention based on the prior researc, it was still considered when conducting interview upon Porter (1990)'s theory. Through open interview questions, some experts give opinions on the chance of Vietnam's automobile industrial clusters.

This factor is not discussed about the level of importance, but some experts feel pessimistic about Vietnam's automobile industry in the future. They said that the chance of Vietnam's automobile industry was very small because there is not much time left from now to 2018. Just one expert believed that Vietnam's automobile industry could survive under the effect of TPP (Trans-Pacific Partnership). That means many big manufacturers are moving from China to Vietnam.

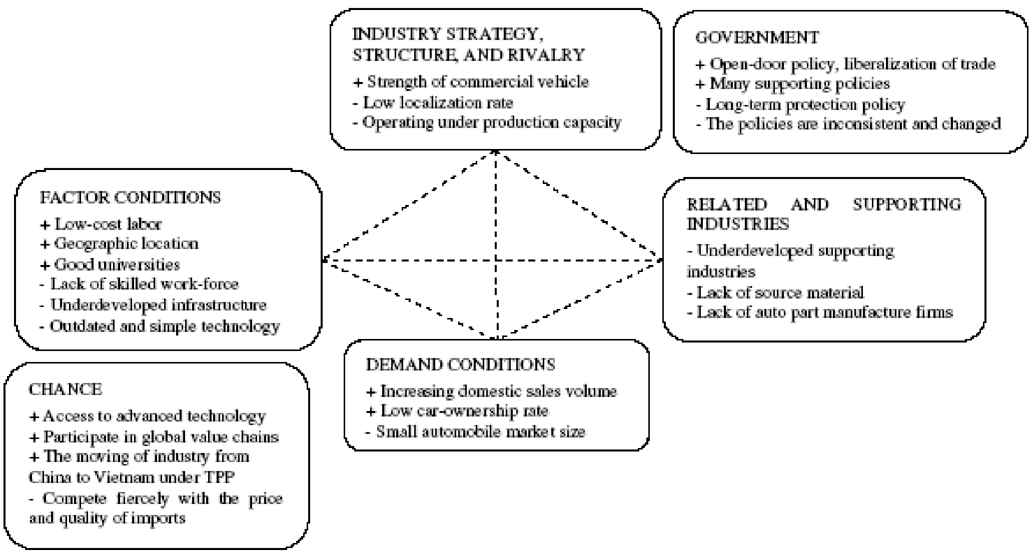

Fig 1: Diamond model for Vietnam's automobile industry (+ marks stand for strengths, while - marks stand for weaknesses)

V. DISCUSSION

In this section, the factors that lead to the successful formation of automobile industrial clusters in Vietnam are summarized based on the results of the literature review, experts' opinions and the specific context of Vietnam's automobile industry are discussed. From the above analysis in section III, there are many similarities between the factors that affecting the formation of automobile industrial cluster in Vietnam and in the world.

Factor "workforce", especially, the trained and good workmanship are considered as the significant factor that have a positive impact on the formation and development of the formation and development of automobile industrial cluster (Yoshida & Nakanishi, 2005; Kuchiki, 2007; Okada & Siddharthan, 2007; Bulic, et.al., 2012…). To develop a good workforce that best meet the needs of Vietnam's automobile industry, universities and vocational schools need more training programs, both theoretically and practically. Each automobile industrial clusters in the world normally has the presence of "universities & research institutes" which is also emphasized as an important factor for the successful formation and development of automobile industrial clusters. In the future, these factors should be more focused to maximize the efficiency of receiving modern automobile technologies, applying research and development (R&D) in automobile industry. In addition, the universities are also home to provide human resources that meet requirements in the sector. It is necessary to link the cooperation between enterprises and educational institutions to grow further. A successful automobile industrial cluster must base on education and science research (Komolavanij et.al, 2009; Contreras et.al, 2013…).

Demand conditions consist of "domestic demand" and "export demand" that are necessary factors for industrial cluster formation (Brzica, 2007; Kuchiki, 2007; Gupta, 2010; Contreras et al, 2013…). The Vietnam's automobile market is much potential with a population of more than 90 million people, but the auto sales volume is very small (over 100,000 units/year). It is essential to have many big automobile manufacturers for attracting more and more investment from auto part manufacture firms. The automobile market in Vietnam should be concerned and extended to motivate the development of automobile industry.

Related and supporting industries which include proximity of auto parts suppliers, materials suppliers and supporting services are mentioned as a very important factor in building an automobile industrial cluster (Yamawaki, 2002; Sakuramoto, 2004; Kuchiki, 2007; Ningyu & Yang, 2011 …). If we would like to have a strong automobile industry in Vietnam, we must develop urgently supporting industries. The development of related and supporting industries is only necessary for the formation and development of the automobile industry but also for the development of other industries.

Factor "presence of anchor firms" effectively influences the industrial cluster formation (Yamawaki, 2002; Kuchiki, 2007; Zamborsky, 2012; Contreras et.al, 2013 …). Vietnam's auto anchor firms should play as the central core of the formation of automobile industrial clusters. These firms help to create a good information network and to promote cooperation among auto firms. The anchor firms' growth will attract the concentration of many auto related and supporting industries.

The study of the experience of the successful formation of automobile industrial cluster in the world showed that government policies played a significant role (Kuchiki, 2007; Okada & Siddharthan, 2007; Ranawat & Tiwari, 2009; Ammarapala et al, 2010; Kim, 2011...). All experts assess that support policies of the government and local authorities have a significant influence on the formation of the automobile industrial cluster in Vietnam. Thus, why "government policies" is the most important factor that affecting the formation of automobile industrial cluster in Vietnam? Experts explained the reasons as below:

- University's representative emphasized that the government should establish a fund to support enterprises and develop appropriate strategies to promote the automobile industry development.
- Another university's representative stated that three main pillars need to cooperate to develop the Vietnam's automobile industry are governments, universities and auto firms. Specifically, government agencies must have appropriate policies and strategies for the development of the automobile industry with a clear purpose. Universities will play a key role in cooperation with enterprises, and application of advanced technology in manufacturing. Auto firms also have the responsibility to support the universities for the training of human resources and funding for research projects.
- An expert comes from Economic Institutes said that government must play a role in supporting policy, however, they should not interfere with industrial cluster's activities deeply. Besides, the government should have a mechanism to explore and resolve the difficulties of enterprises.
- The representative of the department of Industry and Trade said that the most important factor in the automobile industrial cluster formation is government policies. Implementing suitable policies is a good base to create conditions for the development of the automobile industry and to encourage participation of auto part firms as well as large manufacturers in the automobile industrial cluster.
- Companies' representatives highly appreciated the role of government in enacting tax policies to support the development of micro, small and medium-sized enterprises. The government needs to implement favorable policies to attract foreign direct investment and increase the localization rate. Moreover, the government should facilitate and support their business activities because many procedures must take a long time to be completed.

The new factor which is business capability has also affected the industrial cluster formation. Firstly, auto manufacturers must identify their product strategies to avoid falling into the major product changes. According to expert's opinion that Vietnam's automobile firms should focus on manufacturing buses, vans, cars ... Vietnamese enterprises are still weak in many areas such as manufacturing, design, marketing ..., therefore, they now need to improve their competitiveness by investing in technological innovation and productivity as well as taking advantage of training and consultancy services, reducing costs to compete with products imported from foreign countries. In addition, business capability also helps small and medium enterprises to involve in the value chain of the global automobile industry and to have the opportunity to become a supplier for the domestic and foreign manufacturers.

In summary, the successful formation of automobile industrial cluster in Vietnam is a complex task and it requires the participation and cooperation of multiple sectors. The determinant factors of the success of Vietnam's automobile industrial cluster in Vietnam include (1) Factor conditions: "trained and skilled workforce", "universities and research institutes", (2) Demand conditions: "domestic demand", "export demand", (3) Related and supporting industries, (4) "Presence of anchor firms", (5) Government supporting policies, and (6) Business capability. Among those factors, supporting policies of the government is the most significant factor that influence on the formation of the automobile industrial cluster in Vietnam. This result can be used as a reference for policy makers in the process of forming automobile industrial cluster in Vietnam and those factors should be verified when Vietnam is going to build the true automobile industrial clusters in the future.

It would be better to have a specific scale for measuring the level of success of the formation of automobile industrial clusters. On the basis of literature review, there are some criteria used to evaluate and to assess the success level of the formation of automobile industrial cluster, such as: ability to create new product innovation (Deeds et al., 1997, cited in Singh & Shrivastava, 2013); ability to increase specialization, to reduce transaction costs and to enhanced reputation (Eisingerichaet et.al., 2010, cited in Singh & Shrivastava, 2013); and extent to which sales enhanced, to which the quality of goods and processes are improved, to which profit is improved, to which the quality of relationships with customers are improved, to which the quality of relationships with suppliers are improved, and to which the visibility of business is enhanced (Singh & Shrivastava, 2013).

In the context of automobile industrial cluster in Vietnam, it is necessary to conduct further studies to get a deeper understanding of the formation of automobile industrial cluster in Vietnam and have appropriate criteria to evaluate the success level the formation of automobile industrial cluster.

VI. CONCLUSION

This study investigates the factors affecting the formation of automobile industrial cluster in the world and come up with some results about the factors that affect and lead to the successful formation of automobile industrial clusters in Vietnam upon the Porter's industrial cluster theory. Many factors affecting the formation of automobile industrial cluster in Vietnam are found such as, infrastructure, workforce, universities & research institutes, related and supporting industries, presence of anchor firms, government supporting policies… Among those factors, the government policies is considered as the most important factor affecting the successful formation of automobile industrial clusters in Vietnam.

The results of this study could contribute to the knowledge of industrial clusters in Vietnam, especially in the automobile industry. The results could be a reference for policy makers to enact policies to support and to promote the formation of automobile industrial clusters in Vietnam, and improving the competitiveness of the automobile industry in Vietnam. Future studies may continue studying to clarify the unclear and missed factors affecting the formation of automobile industrial clusters like geographic location, chance...; or building scale assessment of the formation which is used in quantitative study to determine the level of importance for each factor that lead to the successful formation of automobile industrial clusters in Vietnam.

ACKNOWLEDGMENT

This research is supported by Ho Chi Minh City Department of Science and Technology. The authors would like to thank the partners in project team for helping us conduct interviews. We would also like to gratefully acknowledge experts and organizations for spending time and giving a lot of precious information and comments on this subject.

In this research, we deal with a multi-item, multi-period capacitated facility location problem where manufacturing plants and distribution centers are decided to open or not at predetermined potential sites. The developed model is formulated as a mixed integer linear programming model (MILP) with the objective minimizing the total cost, including transportation cost, inventory holding cost, and fixed costs for opening facilities. We employ a Lagrangian relaxation algorithm for solving the developed model, the key defference of our algorithm is additional constraint sets added to two sub-problems. For validation testing, some numerical experiments were used for solving, and the solutions obtained from the Lagrangian relaxation algorithm are respectively compared with the solutions obtained by the LINGO solver. With good achievements of this research, our proposed model can be applicability and the proposed approach is advantage for getting the specific solutions..

Keywords: logistic, supply chain, mixed integer linear programming, Lagrangian relaxation, network design.

1. Introduction

In modern business environments, supply chain management has become common practice in all industries and has received growing interest in both academia and industrial practice. The essence of supply chain management and the conceptual framework for evaluating the performance of supply chains have attracted many researchers (e.g., Chan et al., 2003; Stadtler, 2005). Typically, a supply chain network can be considered as an alliance of many members involved, from upstream members (e.g., material suppliers, manufacturers) to downstream members (e.g., distributors, retailers, and end customers). Due to its complex structure, managing a supply chain network is always a challenging task, which combines and integrates all business functions, including inbound logistics, outbound logistics, marketing and sales, customer relationship, etc. In a highly competitive global market nowadays, supply chain management is a key issue in the strategic development of any enterprise (Chan and Qi, 2003).

Among the factors that affect the performance of a supply chain, the physical design of the supply chain plays a very important role. Top managers of many big enterprises increasingly paid attention on the structure of their supply chains as reported and discussed in various case studies presented in a book of Simchi-Levi et al. (2000). In order to help supply chain managers to make decision on supply chain structure, Blackhurst et al. (2005) proposed a decision support modeling methodology for supply chain design, which was integrated also with product and process design decisions. However, regardless of the fact that supply chain design problem is a critical problem, it is still a very challenging problem and not many research works have been conducted to tackle this problem.

Among the initial publications dealing with supply chain design issue is a capacitated facilities location model developed by Geoffrion and Graves (1974). In this research, the authors only focused on distribution function of a supply chain, and the objective of the design problem was to minimize the total cost which consists of transportation cost and fixed cost of opening distribution centers. The problem, which is a multi-item single-period problem, was formulated as a mixed integer linear program, and a Benders decomposition algorithm was also developed for solution purpose. In the same research line, Pirkul and Jayaraman (1998), Mazzola and Neebe (1999) studied multi-item and single-period distribution network design problem, however, they examined the use of Lagrangian relaxation technique for solution purpose. Focusing also on distribution function of supply chain, Melachrinoudis and Min (2007) studied a distribution network redesign problem where an existing distribution center may be closed while some new ones may be opened.

In another research line, Amiri (2006) tackled the single-item single-period supply chain network design problem that involves locating manufacturing plants and distribution centers, and determining the distribution strategy from the plants to the distribution centers and from the distribution centers to the customers, in this research, multiple levels of capacities of warehouses and plants were considered. Eksioglu et al. (2006) examined a single-item multi-period integrated production and distribution planning problem in which inventory is allowed to be carried over during the planning horizon. Later, Lee et al. (2010) proposed two mixed integer linear programs for supply chain network design, their models supports routing decision, this research is necessary for third party losgistics. To the best of our knowledge, the research works that took into consideration all realistic factors of the supply chain network design problem (i.e., multi-item, multi-period, possibility of inventory carrying over) are the ones conducted by Hinojosa et al. (2000, 2008). However, these research works dealt with network redesign problem. Moreover, one of conclusions in the review paper of Melo et al. (2009) said that the most of research structure of SC network is considerably simplified, and few papers attempt the full integration of forward and reserse activitives in SCM. Recently, in an overview work of Arabani and Farahani (2012) considered continuous models with dynamic problems as further trends, but we believe that compflex models with combination of many factors in SC network design are also necessary.

In the research work presented in this paper, we develop a mixed integer linear programming (MILP) model for supply chain network design problem which takes into consideration all the above realistic factors. The developed model will help make decisions on: (1) whether a facility (either a manufacturing plant or a distribution center) should be opened at a potential site among a set of predetermined potential sites; (2) at which period during the planning horizon, a facility is opened if it should be opened; and (3) for each type of product, which distribution centers a manufacturing plant should deliver the product to, and which distribution centers a retailer should place its order from. We then develop a Lagrangian relaxation algorithm for solving this problem. This algorithm is based on relaxing two constraint sets which lead to the decomposition of the MILP model into two sub-problems that can be easily solved to provide an efficient solution to the original problem.

The objective of our MILP model is to minimize the total cost, including transportation cost, inventory holding cost, and fixed costs for opening manufacturing plants and distribution centers. Commonly, the decisions of opening manufacturing plants and distribution centers are strategic or mid-term planning decisions, while the inventory and transportation costs are operational. However, similar to the works of Hinojosa et al. (2000, 2008), our research aims at developing a combined network design and distribution planning model. For distribution planning purpose, we have to decide on which distribution centers a manufacturing plant should deliver the product to, and on which distribution centers a retailer should place its order from. Dealing with this type of problem requires the incorporation of transportation cost as seen in some past research works (e.g., Geoffrion and Graves, 1974; Hinojosa et al., 2000). Related to the incorporation of inventory holding cost in the total cost function, past research works were either consider a single-period model (e.g., Geoffrion and Graves, 1974), or a multi-period model with the assumption that inventory cannot be carried over (due to perishability as in the work of Hinojosa et al., 2000). With the above model settings, exclusion of inventory cost is acceptable. However, in many practical supply networks, it is noted that inventory can be carried over from one period to the next period. Hence, for the proposed model to be more realistic, we also assume that inventory can be carried over during the planning horizon (similar to Hinojosa et al., 2008), and hence, incorporation of inventory cost is needed. It should be noted that in their model, Hinojosa et al. (2008) considered the expansion of an existing network in which new facilities can be opened at predetermined potential sites, while existing facilities can be closed and if an existing facility is closed it will not be reopened. The main difference between our model and the model of Hinojosa et al. (2008) is that we consider the establishment of a new supply network in which new facilities can be opened at predetermined potential sites, and if a new facility is opened, it will not be closed. It is also noted that in our model, a facility can be opened at any period during the planning horizon, not necessarily at the beginning of the planning horizon.

The remaining sections of our paper are organized as follows. In section 2, we derive the mathematical model for the problem. In section 3, we analyze the model developed in section 2 and derive a Lagrangian relaxation version of the original model. Sections 4 and 5 present a solution procedure based on Lagrangian relaxation technique and some numerical experiments. We then conclude the research with some concluding remarks in section 6.

2. Mathematical Model

In this section, the following notations are used:

Indices:

i	index of potential sites for manufacturing plants $i = 1, 2, .., I$
j	index of potential sites for distribution centers $j = 1, 2, .., J$
k	index of products $k = 1, 2, .., K$
r	index of retailers $r = 1, 2, .., R$
t	time index $t = 1, 2, .., T$

Parameters:

T	length of the planning horizon
f_i	fixed cost of opening manufacturing plant i
$f_j^{(1)}$	fixed cost of opening distribution center j
c_{ijk}	transportation cost of shipping a unit of product k from plant i to distribution center j
$c_{jrk}^{(1)}$	transportation cost of shipping a unit of product k from distribution center j to retailer r
p_{ik}	unit production cost of product k at plant i
h_{ik}	unit holding cost of product k at plant i in one period
$h_{jk}^{(1)}$	unit holding cost of product k at distribution center j in one period
$h_{rk}^{(2)}$	unit holding cost of product k at retailer r in one period
d_{rkt}	demand of product k at retailer r in period t
w_{ik}	production capacity associated with product k at plant i
$w_{jk}^{(1)}$	storage capacity associated with product k at distribution center j

Decision variables:

X_{ijkt}	amount of product k shipping from plant i to distribution center j in period t
Y_{jrkt}	amount of product k shipping from distribution center j to retailer r in period t
Z_{it}	a binary variable which indicates whether plant i is operated in period t or not
$Z_{jt}^{(1)}$	a binary variable which indicates whether distribution center j is operated in period t or not
V_{ikt}	amount of product k produced at plant i in period t
Q_{ikt}	amount of product k stored at plant i at the end of period t
$Q_{jkt}^{(1)}$	amount of product k stored at distribution center j at the end of period t
$Q_{rkt}^{(2)}$	amount of product k stored at retailer r at the end of period t

The following assumptions are used for model development:

1) If a plant or distribution center is opened at a certain site, it will not be closed;
2) All cost factors in the model are known in advanced, i.e. the setup costs of plants and distribution centers, the unit production cost, unit transportation cost, and unit inventory holding cost are given;
3) Initial inventory levels at plants, distribution centers, and retailers are zeros;
4) Storage capacity of retailer is large enough to fulfill demand.

The detailed mathematical model is derived as follows:

Objective function:

$$Min\ Z=\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T}c_{ijk}X_{ijkt}+\sum_{j=1}^{J}\sum_{r=1}^{R}\sum_{k=1}^{K}\sum_{t=1}^{T}c_{jrk}^{(1)}Y_{jrkt}+\sum_{i=1}^{I}\sum_{t=1}^{T}f_i\left(Z_{it}-Z_{i(t-1)}\right)+\sum_{j=1}^{J}\sum_{t=1}^{T}f_j^{(1)}\left(Z_{jt}^{(1)}-Z_{j(t-1)}^{(1)}\right)$$
$$+\sum_{i=1}^{I}\sum_{k=1}^{K}\sum_{t=1}^{T}p_{ik}V_{ikt}+\sum_{i=1}^{I}\sum_{k=1}^{K}\sum_{t=1}^{T}h_{ik}Q_{ikt}+\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T}h_{jk}^{(1)}Q_{jkt}^{(1)}+\sum_{r=1}^{R}\sum_{k=1}^{K}\sum_{t=1}^{T}h_{rk}^{(2)}Q_{rkt}^{(2)},\quad (1)$$

Subject to

$$Q_{rk(t-1)}^{(2)}+\sum_{j=1}^{J}Y_{jrkt}\ge d_{rkt}\quad \forall r\in R,\forall k\in K,\forall t\in T,\quad (2)$$

$$V_{ikt}\le w_{ik}Z_{it}\quad \forall i\in I,\forall k\in K,\forall t\in T,\quad (3)$$

$$\sum_{j=1}^{J}X_{ijkt}\le V_{ikt}+Q_{ik(t-1)}\quad \forall i\in I,\forall k\in K,\forall t\in T,\quad (4)$$

$$\sum_{i=1}^{I}X_{ijkt}+Q_{jk(t-1)}^{(1)}\le w_{jk}^{(1)}Z_{jt}^{(1)}\quad \forall j\in J,\forall k\in K,\forall t\in T,\quad (5)$$

$$\sum_{r=1}^{R}Y_{jrkt}\le \sum_{i=1}^{I}X_{ijkt}+Q_{jk(t-1)}^{(1)}\quad \forall j\in J,\forall k\in K,\forall t\in T,\quad (6)$$

$$Q_{rkt}^{(2)} = \sum_{j=1}^{J} Y_{jrkt} + Q_{rk(t-1)}^{(2)} - d_{rkt} \quad \forall r \in R, \forall k \in K, \forall t \in T, \tag{7}$$

$$Q_{ikt} = V_{ikt} + Q_{ik(t-1)} - \sum_{j=1}^{J} X_{ijkt} \quad \forall i \in I, \forall k \in K, \forall t \in T, \tag{8}$$

$$Q_{jkt}^{(1)} = \sum_{i=1}^{I} X_{ijkt} + Q_{jk(t-1)}^{(1)} - \sum_{r=1}^{R} Y_{jrkt} \quad \forall j \in J, \forall k \in K, \forall t \in T, \tag{9}$$

$$Z_{it} \geq Z_{i(t-1)} \quad \forall i \in I, \forall t \in T, \tag{10}$$

$$Z_{jt}^{(1)} \geq Z_{j(t-1)}^{(1)} \quad \forall j \in J, \forall t \in T, \tag{11}$$

$$X_{ijkt}, V_{ikt}, Q_{ikt} \geq 0 \quad \forall i \in I, \forall j \in J, \forall k \in K, \forall t \in T, \tag{12}$$

$$Y_{jrkt}, Q_{jkt}^{(1)}, Q_{rkt}^{(2)} \geq 0 \quad \forall j \in J, \forall r \in R, \forall k \in K, \forall t \in T, \tag{13}$$

$$Z_{it} = 0,1 \quad \forall i \in I, \forall t \in T, \tag{14}$$

$$Z_{jt}^{(1)} = 0,1 \quad \forall j \in J, \forall t \in T, \tag{15}$$

In the above model, the objective function is to minimize the total cost which includes transportation costs from plants to distribution centers; transportation costs from distribution centers to retailers; fixed costs of opening plants; fixed costs of opening distribution centers; production costs; and holding costs at plants, distribution centers, and retailers.

Related to the constraints, constraint set (2) ensures that demands at retailers are always satisfied. Constraint set (3) represents the capacity constraint at manufacturing plant. Constraint set (4) ensures that the amount of product shipped from a plant in each period will not exceed the on-hand inventory. Constraint set (5) ensures that the amount of product stored at a distribution center will not exceed the storage capacity of that distribution center. Constraint set (6) ensures that the amount of product shipped from a distribution center does not exceed the on-hand inventory at that distribution center. Constraint sets (7), (8), and (9) are flow balance constraints. Constraint sets (10) and (11) ensure that when a plant or distribution center is opened, it will not be closed. The other constraints are variable constraints.

As will be shown in the following paragraphs, there exist some redundant constraints in the initial formulation presents above. These redundant constraints will be discarded from the model so that the structure of the model can be simplified in such a way that the Lagrangian relaxation technique can be employed later.

Considering constraint sets (7), (8), and (9) which are the inventory balance equations at retailers, plants and distribution centers, respectively:

$$Q_{rkt}^{(2)} = \sum_{j=1}^{J} Y_{jrkt} + Q_{rk(t-1)}^{(2)} - d_{rkt} \quad \forall r \in R, \forall k \in K, \forall t \in T,$$

$$Q_{ikt} = V_{ikt} + Q_{ik(t-1)} - \sum_{j=1}^{J} X_{ijkt} \quad \forall i \in I, \forall k \in K, \forall t \in T, \quad \text{and}$$

$$Q_{jkt}^{(1)} = \sum_{i=1}^{I} X_{ijkt} + Q_{jk(t-1)}^{(1)} - \sum_{r=1}^{R} Y_{jrkt} \quad \forall j \in J, \forall k \in K, \forall t \in T,$$

The above equations can be rewritten as follows:

$$\sum_{j=1}^{J} Y_{jrkt} + Q_{rk(t-1)}^{(2)} - Q_{rkt}^{(2)} = d_{rkt} \quad \forall r \in R, \forall k \in K, \forall t \in T,$$

$$\sum_{j=1}^{J} X_{ijkt} = V_{ikt} + Q_{ik(t-1)} - Q_{ikt} \quad \forall i \in I, \forall k \in K, \forall t \in T, \text{ and}$$

$$\sum_{r=1}^{R} Y_{jrkt} = \sum_{i=1}^{I} X_{ijkt} + Q_{jk(t-1)}^{(1)} - Q_{jkt}^{(1)} \quad \forall j \in J, \forall k \in K, \forall t \in T,$$

It is noted that $Q_{rkt}^{(2)}, Q_{ikt}, Q_{jkt}^{(1)}$ are non-negative, and hence, it can be derived respectively from the above equations that

$$\sum_{j=1}^{J} Y_{jrkt} + Q_{rk(t-1)}^{(2)} \geq d_{rkt} \quad \forall r \in R, \forall k \in K, \forall t \in T,$$

$$\sum_{j=1}^{J} X_{ijkt} \leq V_{ikt} + Q_{ik(t-1)} \quad \forall i \in I, \forall k \in K, \forall t \in T, \text{ and}$$

$$\sum_{r=1}^{R} Y_{jrkt} \leq \sum_{i=1}^{I} X_{ijkt} + Q_{jk(t-1)}^{(1)} \quad \forall j \in J, \forall k \in K, \forall t \in T,$$

The above expressions are exactly the constraint sets (2), (4), and (6), respectively. Therefore, constraint sets (2), (4), and (6) are redundant constraints, and they can be discarded from the mathematical model. The structure of the revised mathematical model can now allow the Lagrangian relaxation technique to be employed to help find solution for large size problems. This issue will be discussed in details in the next section.

3. A Lagrangian relaxation version of the proposed model

It should be noted that the above-developed model is a mixed-integer linear program, and hence, it usually take time for finding solution, especially when dealing with large size problems. In this research, we will use Lagrangian relaxation technique for solving the problem. For more detailed discussions on the Lagrangian relaxation technique, the readers can refer to Fisher (1981).

Before applying Lagrangian relaxation technique, the model derived in section 2 will be modified as presented below

At first, considering constraint set (9), i.e.,

$$Q_{jkt}^{(1)} = \sum_{i=1}^{I} X_{ijkt} + Q_{jk(t-1)}^{(1)} - \sum_{r=1}^{R} Y_{jrkt} \quad \forall j \in J, \forall k \in K, \forall t \in T,$$

It is noted that $Q_{jk0}^{(1)} = 0$, and hence, constraints in (9) can be rewritten as follows:

$$Q_{jk1}^{(1)} = \sum_{i=1}^{I} X_{ijk1} - \sum_{r=1}^{R} Y_{jrk1}$$

$$Q_{jk2}^{(1)} = Q_{jk1}^{(1)} + \sum_{i=1}^{I} X_{ijk2} - \sum_{r=1}^{R} Y_{jrk2} = \sum_{i=1}^{I} X_{ijk1} - \sum_{r=1}^{R} Y_{jrk1} + \sum_{i=1}^{I} X_{ijk2} - \sum_{r=1}^{R} Y_{jrk2}$$

$$= \sum_{i=1}^{I} \sum_{\tau=1}^{2} X_{ijk\tau} - \sum_{r=1}^{R} \sum_{\tau=1}^{2} Y_{jrk\tau}$$

$$Q_{jk3}^{(1)} = Q_{jk2}^{(1)} + \sum_{i=1}^{I} X_{ijk3} - \sum_{r=1}^{R} Y_{jrk3} = \sum_{i=1}^{I}\sum_{\tau=1}^{3} X_{ijk\tau} - \sum_{r=1}^{R}\sum_{\tau=1}^{3} Y_{jrk\tau}$$

…

or generally,

$$Q_{jkt}^{(1)} = \sum_{i=1}^{I}\sum_{\tau=1}^{t} X_{ijk\tau} - \sum_{r=1}^{R}\sum_{\tau=1}^{t} Y_{jrk\tau} \quad \forall j \in J, \forall k \in K, \forall t \in T, \qquad (16)$$

It is noted that constraint set (16) ensures that at each distribution center j, the inventory level of product k in period t is equal to the cumulative amount of product k received from all manufacturing plants subtracted by the cumulative amount of product k delivered to all retailers from distribution center j.

The expression of $Q_{jkt}^{(1)}$ derived in (16) will be replaced in the expression of the objective function, and hence, constraint set (9) can be discarded from the sets of constraints. In addition, the constraints that $Q_{jkt}^{(1)} \geq 0$ ($\forall j \in J, \forall k \in K, \forall t \in T$) will be replaced by

$$\sum_{i=1}^{I}\sum_{\tau=1}^{t} X_{ijk\tau} - \sum_{r=1}^{R}\sum_{\tau=1}^{t} Y_{jrk\tau} \geq 0 \quad \forall j \in J, \forall k \in K, \forall t \in T \qquad (17)$$

From (16), we also have:

$$\sum_{t=1}^{T} Q_{jkt}^{(1)} = \sum_{t=1}^{T}\left(\sum_{i=1}^{I}\sum_{\tau=1}^{t} X_{ijk\tau} - \sum_{r=1}^{R}\sum_{\tau=1}^{t} Y_{jrk\tau}\right) \quad \forall j \in J, \forall k \in K$$

So,

$$\sum_{t=1}^{1} Q_{jkt}^{(1)} = \sum_{i=1}^{I} X_{ijk1} - \sum_{r=1}^{R} Y_{jrk1}$$

$$\begin{aligned}\sum_{t=1}^{2} Q_{jkt}^{(1)} &= \sum_{t=1}^{2}\left(\sum_{i=1}^{I}\sum_{\tau=1}^{t} X_{ijk\tau} - \sum_{r=1}^{R}\sum_{\tau=1}^{t} Y_{jrk\tau}\right)\\ &= \left(\sum_{i=1}^{I} X_{ijk1} - \sum_{r=1}^{R} Y_{jrk1}\right) + \left(\sum_{i=1}^{I} X_{ijk1} - \sum_{r=1}^{R} Y_{jrk1} + \sum_{i=1}^{I} X_{ijk2} - \sum_{r=1}^{R} Y_{jrk2}\right)\\ &= 2\left(\sum_{i=1}^{I} X_{ijk1} - \sum_{r=1}^{R} Y_{jrk1}\right) + \left(\sum_{i=1}^{I} X_{ijk2} - \sum_{r=1}^{R} Y_{jrk2}\right)\end{aligned}$$

$$\begin{aligned}\sum_{t=1}^{3} Q_{jkt}^{(1)} &= \sum_{t=1}^{3}\left(\sum_{i=1}^{I}\sum_{\tau=1}^{t} X_{ijk\tau} - \sum_{r=1}^{R}\sum_{\tau=1}^{t} Y_{jrk\tau}\right)\\ &= 3\left(\sum_{i=1}^{I} X_{ijk1} - \sum_{r=1}^{R} Y_{jrk1}\right) + 2\left(\sum_{i=1}^{I} X_{ijk2} - \sum_{r=1}^{R} Y_{jrk2}\right) + \left(\sum_{i=1}^{I} X_{ijk3} - \sum_{r=1}^{R} Y_{jrk3}\right)\end{aligned}$$

or generally,

$$\sum_{t=1}^{T} Q_{jkt}^{(1)} = \sum_{t=1}^{T}(T-t+1)\left(\sum_{i=1}^{I} X_{ijkt} - \sum_{r=1}^{R} Y_{jrkt}\right) \quad \forall j \in J, \forall k \in K \qquad (18)$$

Using (18), the cost component related to total inventory holding cost at distribution centers in the total cost function can be rewritten as:

$$\begin{aligned}\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T} h_{jk}^{(1)} Q_{jkt}^{(1)} &= \sum_{j=1}^{J}\sum_{k=1}^{K} h_{jk}^{(1)} \sum_{t=1}^{T}(T-t+1)\left(\sum_{i=1}^{I} X_{ijkt} - \sum_{r=1}^{R} Y_{jrkt}\right)\\ &= \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T}(T-t+1)\, h_{jk}^{(1)} X_{ijkt} - \sum_{j=1}^{J}\sum_{r=1}^{R}\sum_{k=1}^{K}\sum_{t=1}^{T}(T-t+1)\, h_{jk}^{(1)} Y_{jrkt}\end{aligned} \qquad (19)$$

It is also noted that constraint set (5) can be rewritten via expression (16) as follows:

$$\sum_{i=1}^{I} X_{ijkt} + Q^{(1)}_{jk(t-1)} - w^{(1)}_{jk} Z^{(1)}_{jt} = \sum_{i=1}^{I} X_{ijkt} - w^{(1)}_{jk} Z^{(1)}_{jt} + \left(\sum_{i=1}^{I} \sum_{\tau=1}^{t-1} X_{ijk\tau} - \sum_{r=1}^{R} \sum_{\tau=1}^{t-1} Y_{jrk\tau} \right) \\ = \sum_{i=1}^{I} \sum_{\tau=1}^{t} X_{ijk\tau} - w^{(1)}_{jk} Z^{(1)}_{jt} - \sum_{r=1}^{R} \sum_{\tau=1}^{t-1} Y_{jrk\tau} \tag{20}$$

So, by introducing Lagrange multipliers $\lambda_{jkt}{}' s$ for the constraints in (5) and $\gamma_{jkt}{}' s$ for the constraints in (17), the objective of the Lagrangian relaxation problem (problem (L)) associated with the original mathematical model can now be derived as

$$Min\ Z_L = \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T} c_{ijk} X_{ijkt} + \sum_{j=1}^{J}\sum_{r=1}^{R}\sum_{k=1}^{K}\sum_{t=1}^{T} c^{(1)}_{jrk} Y_{jrkt} + \sum_{i=1}^{I}\sum_{t=1}^{T} f_i \left(Z_{it} - Z_{i(t-1)} \right) + \sum_{j=1}^{J}\sum_{t=1}^{T} f^{(1)}_j \left(Z^{(1)}_{jt} - Z^{(1)}_{j(t-1)} \right)$$
$$+ \sum_{i=1}^{I}\sum_{k=1}^{K}\sum_{t=1}^{T} p_{ik} V_{ikt} + \sum_{i=1}^{I}\sum_{k=1}^{K}\sum_{t=1}^{T} h_{ik} Q_{ikt} + \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T} (T-t+1) h^{(1)}_{jk} X_{ijkt} - \sum_{j=1}^{J}\sum_{r=1}^{R}\sum_{k=1}^{K}\sum_{t=1}^{T} (T-t+1) h^{(1)}_{jk} Y_{jrkt}$$
$$+ \sum_{r=1}^{R}\sum_{k=1}^{K}\sum_{t=1}^{T} h^{(2)}_{rk} Q^{(2)}_{rkt} + \sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T} \lambda_{jkt} \left(\sum_{i=1}^{I}\sum_{\tau=1}^{t} X_{ijk\tau} - w^{(1)}_{jk} Z^{(1)}_{jt} - \sum_{r=1}^{R}\sum_{\tau=1}^{t-1} Y_{jrk\tau} \right) + \sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T} \gamma_{jkt} \left(\sum_{r=1}^{R}\sum_{\tau=1}^{t} Y_{jrk\tau} - \sum_{i=1}^{I}\sum_{\tau=1}^{t} X_{ijk\tau} \right)$$

or,

$$Min\ Z_L = \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T} c_{ijk} X_{ijkt} + \sum_{j=1}^{J}\sum_{r=1}^{R}\sum_{k=1}^{K}\sum_{t=1}^{T} c^{(1)}_{jrk} Y_{jrkt} + \sum_{i=1}^{I}\sum_{t=1}^{T} f_i \left(Z_{it} - Z_{i(t-1)} \right) + \sum_{j=1}^{J}\sum_{t=1}^{T} f^{(1)}_j \left(Z^{(1)}_{jt} - Z^{(1)}_{j(t-1)} \right)$$
$$+ \sum_{i=1}^{I}\sum_{k=1}^{K}\sum_{t=1}^{T} p_{ik} V_{ikt} + \sum_{i=1}^{I}\sum_{k=1}^{K}\sum_{t=1}^{T} h_{ik} Q_{ikt} + \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T} (T-t+1) h^{(1)}_{jk} X_{ijkt} - \sum_{j=1}^{J}\sum_{r=1}^{R}\sum_{k=1}^{K}\sum_{t=1}^{T} (T-t+1) h^{(1)}_{jk} Y_{jrkt}$$
$$+ \sum_{r=1}^{R}\sum_{k=1}^{K}\sum_{t=1}^{T} h^{(2)}_{rk} Q^{(2)}_{rkt} + \sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T} \left(\lambda_{jkt} - \gamma_{jkt} \right) \left(\sum_{i=1}^{I}\sum_{\tau=1}^{t} X_{ijk\tau} \right) - \sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T} \lambda_{jkt} \left(\sum_{r=1}^{R}\sum_{\tau=1}^{t-1} Y_{jrk\tau} \right) + \sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T} \gamma_{jkt} \left(\sum_{r=1}^{R}\sum_{\tau=1}^{t} Y_{jrk\tau} \right)$$
$$- \sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T} \lambda_{jkt} w^{(1)}_{jk} Z^{(1)}_{jt}$$

in which,

$$\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T} \left(\lambda_{jkt} - \gamma_{jkt} \right) \left(\sum_{i=1}^{I}\sum_{\tau=1}^{t} X_{ijk\tau} \right) = \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T} \left(\lambda_{jkt} - \gamma_{jkt} \right) \left(\sum_{\tau=1}^{t} X_{ijk\tau} \right) = \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T} \left(\sum_{\tau=t}^{T} \left(\lambda_{jk\tau} - \gamma_{jk\tau} \right) \right) X_{ijkt}$$

$$\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T} \lambda_{jkt} \left(\sum_{r=1}^{R}\sum_{\tau=1}^{t-1} Y_{jrk\tau} \right) - \sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T} \gamma_{jkt} \left(\sum_{r=1}^{R}\sum_{\tau=1}^{t} Y_{jrk\tau} \right) = \sum_{j=1}^{J}\sum_{r=1}^{R}\sum_{k=1}^{K}\sum_{t=1}^{T} \left(\sum_{\tau=t+1}^{T} \lambda_{jk\tau} \right) Y_{jrkt} - \sum_{j=1}^{J}\sum_{r=1}^{R}\sum_{k=1}^{K}\sum_{t=1}^{T} \left(\sum_{\tau=t}^{T} \gamma_{jk\tau} \right) Y_{jrkt}$$
$$= \sum_{j=1}^{J}\sum_{r=1}^{R}\sum_{k=1}^{K}\sum_{t=1}^{T} \left(\sum_{\tau=t+1}^{T} \lambda_{jk\tau} - \sum_{\tau=t}^{T} \gamma_{jk\tau} \right) Y_{jrkt}$$

It can be easily recognized that Problem (L) can be decomposed into two sub-problems (L1) and (L2) as follows:

Sub-problem (L1):

$$Min\ Z_{L1}=\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T}\left[c_{ijk}+\sum_{\tau=t}^{T}\left(\lambda_{jk\tau}-\gamma_{jk\tau}\right)+\left(T-t+1\right)h_{jk}^{(1)}\right]X_{ijkt} \\ +\sum_{i=1}^{I}\sum_{t=1}^{T}f_i\left(Z_{it}-Z_{i(t-1)}\right)+\sum_{i=1}^{I}\sum_{k=1}^{K}\sum_{t=1}^{T}p_{ik}V_{ikt}+\sum_{i=1}^{I}\sum_{k=1}^{K}\sum_{t=1}^{T}h_{ik}Q_{ikt} \tag{21}$$

Subject to constraint sets (3), (8), (10), (12), and (14).

Sub-problem (L2):

$$Min\ Z(L2)=\sum_{j=1}^{J}\sum_{r=1}^{R}\sum_{k=1}^{K}\sum_{t=1}^{T}\left[c_{jrk}^{(1)}-\left(\sum_{\tau=t+1}^{T}\lambda_{jk\tau}-\sum_{\tau=t}^{T}\gamma_{jk\tau}\right)-\left(T-t+1\right)h_{jk}^{(1)}\right]Y_{jrkt}-\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T}\lambda_{jkt}w_{jk}^{(1)}Z_{jt}^{(1)} \\ +\sum_{j=1}^{J}\sum_{t=1}^{T}f_j^{(1)}\left(Z_{jt}^{(1)}-Z_{j(t-1)}^{(1)}\right)+\sum_{r=1}^{R}\sum_{k=1}^{K}\sum_{t=1}^{T}h_{rk}^{(2)}Q_{rkt}^{(2)} \tag{22}$$

Subject to constraint sets (7), (11), (13), and (15).

For fixed values of $\lambda_{jkt}'s$ and $\gamma_{jkt}'s$, it is noted that the value of the objective function of the original model can be determined via the solutions of the two sub-problems (L1) and (L2) as $Z=Z1+Z2$, in which

$$Z1=\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T}\left[c_{ijk}+\left(T-t+1\right)h_{jk}^{(1)}\right]X_{ijkt}+\sum_{i=1}^{I}\sum_{t=1}^{T}f_i\left(Z_{it}-Z_{i(t-1)}\right)+\sum_{i=1}^{I}\sum_{k=1}^{K}\sum_{t=1}^{T}p_{ik}V_{ikt}+\sum_{i=1}^{I}\sum_{k=1}^{K}\sum_{t=1}^{T}h_{ik}Q_{ikt},$$

$$Z2=\sum_{j=1}^{J}\sum_{r=1}^{R}\sum_{k=1}^{K}\sum_{t=1}^{T}\left[c_{jrk}^{(1)}-\left(T-t+1\right)h_{jk}^{(1)}\right]Y_{jrkt}+\sum_{j=1}^{J}\sum_{t=1}^{T}f_j^{(1)}\left(Z_{jt}^{(1)}-Z_{j(t-1)}^{(1)}\right)+\sum_{r=1}^{R}\sum_{k=1}^{K}\sum_{t=1}^{T}h_{rk}^{(2)}Q_{rkt}^{(2)}$$

Therefore, the value of the objective function of the original model is determinable if and only if the two sub-problems can give feasible solutions. However, with the current formulations of the two sub-problems, it might happen that the above requirement cannot be ensured. This issue will be discussed and tackled in the next paragraphs.

Considering sub-problem (L1), it can be seen that there exists no constraint that forces binary variables Z_{it} to receive positive values. This will lead to the fact that all $Z_{it}'s$ will be set to zeros when (L1) is solved. All other decision variables will also receive the value of zero, and hence, the objective value is always zero. Therefore, some additional constraint sets should be added to over this trouble as follows:

Additional constraint set 1:

$$\sum_{i=1}^{I}\sum_{\tau=1}^{t}V_{ik\tau}\geq\sum_{r=1}^{R}\sum_{\tau=1}^{t}d_{rk\tau}\quad\forall k\in K,\forall t\in T, \tag{23}$$

This constraint is added to sub-problem (L1) to help ensure that the cumulative production quantity of product k at time period t from all manufacturing plants will exceed the total cumulative demand of retailers.

Additional constraint set 2:

$$\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{\tau=1}^{t}X_{ijk\tau}\geq\sum_{r=1}^{R}\sum_{\tau=1}^{t}d_{rk\tau}\quad\forall k\in K,\forall t\in T, \tag{24}$$

This constraint is also added to sub-problem (L1) to help ensure that the cumulative shipping quantity of product k at time period t from all manufacturing plants to distribution centers will exceed the total cumulative demand of retailers.

For sub-problem (L2), the same situation occurs, i.e., there is no constraint that forces binary variables $Z_{jt}^{(1)}$ to receive positive values, and hence, all $Z_{jt}^{(1)}{}'s$ will be set to zeros. However, $Y_{jrkt}{}'s$ are not all zeros due to constraints (7). This leads to the situation that some retailers will receive shipments from non-operating distribution centers. Similarity, one additional constraint set must be introduced into sub-problems (L2) as follows:

Additional constraint set 3:

$$\sum_{r=1}^{R} Y_{jrkt} \le w_{jk}^{(1)} Z_{jt}^{(1)} \quad \forall j \in J, \forall k \in K, \forall t \in T, \tag{25}$$

This constraint is added to sub-problem (L2) to help ensure that the amount of product k shipped to all retailers from an operating DC j will not exceed the capacity of DC j. It should be noted that this constraint set can be derived from constraint sets (5) and (6) of the original model. However, due to the fact that constraint set (5) has been relaxed, there is a need to incorporate this constraint into sub-problem (L2).

4. Lagrangian relaxation algorithm

The following Lagrangian relaxation algorithm will be employed for solving purpose

Step 0: Setting initial values

- Set all initial values of Lagrange multipliers to zeros,
- Set initial value of step size multiplier (e.g.,),
- Set the value of - the maximum allowable consecutive iterations with no improvement (e.g.,),
- Set the value of - maximum number of iterations (e.g.,),
- Set initial iteration index ,
- Set initial value of number of iterations with no improvement ,
- Set the value of - the best value of the objective function obtained so far, to infinity.

Step 1: Solving sub-problems

- Find the solution of both sub-problems (L1) and (L2).

Step 2: Determining and updating the current objective value

- Determine the current objective value of the original proposed model , and the current objective value of the Lagrangian relaxation problem ,
- IF THEN {assign , and IF the relaxed constraint sets (5) and (17) are satisfied THEN , goto step 3; ELSE goto step 3} ELSE , goto step 3.

Step 3: Updating the Lagrange multipliers

- IF THEN and ,
- Update the current step size as follows

$$Stepsize_{Iter} = \delta \times \frac{[Z(L) - Z(Best)]}{\sum_{j=1}^{J}\sum_{k=1}^{K}\sum_{t=1}^{T}\left[\left(\sum_{i=1}^{I}\sum_{\tau=1}^{t} X_{ijk\tau} - w_{jk}^{(1)} Z_{jt}^{(1)} - \sum_{r=1}^{R}\sum_{\tau=1}^{t\text{-}1} Y_{jrk\tau}\right)^2 + \left(\sum_{i=1}^{I}\sum_{\tau=1}^{t} X_{ijk\tau} - \sum_{r=1}^{R}\sum_{\tau=1}^{t} Y_{jrk\tau}\right)^2\right]}$$

- Update the Lagrange multipliers

$$(\lambda_{jkt})_{(Iter+1)} = (\lambda_{jkt})_{Iter} + (Stepsize_{Iter})\left(\sum_{i=1}^{I}\sum_{\tau=1}^{t} X_{ijk\tau} - w_{jk}^{(1)} Z_{jt}^{(1)} - \sum_{r=1}^{R}\sum_{\tau=1}^{t\text{-}1} Y_{jrk\tau}\right)$$

$$(\gamma_{jkt})_{(Iter+1)} = (\gamma_{jkt})_{Iter} + (Stepsize_{Iter})\left(\sum_{r=1}^{R}\sum_{\tau=1}^{t} Y_{jrk\tau} - \sum_{i=1}^{I}\sum_{\tau=1}^{t} X_{ijk\tau}\right)$$

Step 4*:* Checking stopping condition

- IF $Iter = MaxIter$ THEN stop; ELSE $Iter = Iter + 1$, goto step 1.

5. Numerical experiments

In this section, we conduct numerical experiments to illustrate the applicability of our proposed approach and to compare the performance of our proposed approach with that of commercial Lingo solver. Fifteen test problems with predefined values of I, J, R, K, and T as presented in Table 1 are examined. Among these test problems, it is noted that five problems (S1 to S5) are considered as small size problems, five problems are medium size (M1 to M5), and five problems are large size (B1 to B5).

The input data for each test problem are randomly generated in predefined intervals. For each parameter, the number of data values generated depends upon values of I (number of potential sites for manufacturing plants), J (number of potential sites for distribution centers), R (number of retailers), K (number of product types), and T (length of planning horizon). Data range and the number of generated values for each parameter are summarized in Table 2 below.

Table 1: Test Problems

Problem	I	J	K	R	T
S1	4	3	3	2	3
S2	4	4	4	3	3
S3	5	5	5	5	5
S4	5	6	6	4	5
S5	5	8	8	5	6
M1	8	8	8	8	8
M2	6	10	10	8	8
M3	10	10	10	8	8
M4	10	10	10	10	10
M5	10	15	15	10	10
B1	10	20	20	20	10
B2	10	20	20	25	10
B3	20	20	20	20	10
B4	10	20	20	30	10
B5	40	40	20	20	10

Table 2: Data Ranges for Input Parameters

Parameters	Data Range	Number of generated values
f_i	50,000 to 150,000	I

$f_j^{(1)}$	30,000 to 100,000	J
w_{ik}	1000 to 5000	I*K
$w_{jk}^{(1)}$	1000 to 5000	J*K
p_{ik}	30 to 100	I*K
h_{ik}	1 to 10	I*K
$h_{jk}^{(1)}$	1 to 10	J*K
$h_{rk}^{(2)}$	1 to 10	R*K
c_{ijk}	5 to 20	I*J*K
$c_{jrk}^{(1)}$	5 to 20	J*R*K
d_{rkt}	500 to 2000	R*K*T

Table 3: Value of Total Cost Function with respect to parameter *MaxIter*

Problem	***MaxIter***				
	40	50	60	70	100
S1	2698352	2690700	2690700	2690700	2690700
S2	14038966	14009614	14009614	14009614	14009614
S3	52593508	52557330	52526350	52526350	52526350
S4	51112435	51096247	51071040	51071040	51071040
S5	170718832	170511760	170484970	170484970	170484970
M1	27977765	27813850	27813850	27813850	27813850
M2	36465740	36291680	36289540	36289540	36289540
M3	34332369	34188257	34069325	34069325	34069325
M4	52815222	52741445	52741445	52741445	52741445
M5	81536164	81317516	81215060	81215060	81215060

From the results presented in Table 3, it can be seen that the Lagrangian relaxation algorithm converges very fast when the value of MaxIter increases. For all small and medium size problems considered in our numerical experiment section, there is no change in total costs when MaxIter exceeds 60. However, for reservation purpose, we decide to use MaxIter = 200 in all test problems. It should be noted that even with this overestimated value of MaxIter, our proposed approach still outperform Lingo in terms of computational time for medium and large size problems.

Detailed results about value of total cost function and computational time obtained from Lingo and from the proposed approach are presented in Table 4. In Table 4, column (2) presents the total number of variables and the number of integer variables for each test problem; column (3) presents the number of constraints; columns (4) and (5) present the values of objective function obtained from Lingo and from the proposed approach, respectively; columns (7) and (8) presents computational times of Lingo and of the proposed approach, respectively. It should be noted that the solutions obtained from Lingo in Table 4 (if exists) are global optimums.

From the results presented in Table 4, it can be concluded that our proposed approach is comparable to Lingo in terms of solution quality for small and medium size problems. In addition, our developed approach performs better than Lingo for medium size problems in terms of computational time. For large size problems, our developed approach can help to find good solution in reasonable time while Lingo fails to give optimal solution in many cases.

Table 4: Summary of Numerical Results

Problem	Number of		Best Objective Value	Objective Value	Gap (%)	Comp. Time LINGO (hh:mm:ss)	Comp. time Proposed Method (hh:mm:ss)
	Variables*	Constraints

(*: the first value is the total number of variables, the value in parenthesis is the number of integer variables)

6. Conclusions

In this research paper, the main finding is that a mix integer linear programming model to deal with the capacitated facility location problem in supply chain network design, which incorporates also distribution planning decisions, is proposed. The developed model is a multi-item multi-period model which allows manufacturing plants / distribution centers to be opened at any period during the planning horizon. In addition, the model also takes into consideration the possibility for inventory at the end of one period to be carried over to the next period. The other finding is that a Lagrangian relaxation method is successful to help find solution for practical supply chain networks, which are usually large size problems. And special remark of our algorithm is additional constraint sets which are added to two sub-problems, all solutions can not be found without these additional constraint sets. This is the main difference among our algorithm and existing ones that try to drop some constraints to be simplified. Through numerical experiments, we can confirm that the performance of our proposed method is better than that of the commercial Lingo solver, especially for large size problems.

However, it should be noted that the decisions in our model are in place for a long time, and hence, it will be better if the time value of money is incorporated into the model. But, this will make the proposed model to become a very complicated one which is hard to find solution. Regardless of the fact that many similar research works in the past have also been conducted without considering the effect of time value of money, this is clearly a weakness of our proposed model that might limit its applicability in dealing with practical problems. We will try to address this weakness in our future research works.

This study examines the impact of board characteristics on bank performance and risk-taking behavior during the financial crisis and non-financial crisis periods, using a sample of 59 U.S. commercial banks and savings banks during 2000 to 2013. The empirical findings indicate that board structure does affect bank performance and their risk-taking behavior at different performing banks. For high-performing banks, CEO duality would decrease bank’s market performance either in crisis or non-crisis period, and it would also decrease market volatility. For low-performing banks, board structure plays more significant effect on bank performance and bank risks than it does on high-performing banks either crisis or non-crisis period. We find that independent board, CEO duality and board size have significantly positive effects on low-performing bank performance, but only CEO duality stays its influence in bank performance during financial financial tsunami of 2008. Moreover, board size, CEO duality and independent board have significantly negative effects on low-performing bank risks and only board size stay its significant influence in bank risks during financial tsunami.

Keywords: Bank Performance, Board structure, Financial Crisis.

1. Introduction

Since the Asian Financial crisis in year of 1997, the issue of corporate governance has been extensively addressed not only in the related research of financial studies but also in the practice of corporate business.

The definition and scope of corporate governance varied with the industries. In general, the board of director plays a key role in the corporate governance. The Sarbanes-Oxley Act (SOX) at year of 2002 mandated strict reforms to improve function of corporate governance for US-listed firms, it emphasizes the independence of auditing committee and board of director to enhance the financial transparency in order to achieve better shareholder's protection. This motivates to examine the impact of board structure on firm performance in this study.

The subprime crisis in 2008 heavily deteriorated bank performance due to high risk loan and high leverage operation, and the financial globalization speeded up the shocks to the other countries. Thus, the risk-taking behavior in banks that is seldom addressed in current literature deserves further investigation, especially in the role of board structure to bank's risk-taking. This study focuses on the influence of board structure in bank performance and risk-taking behavior, and compares the different influences between crisis period of 2008 and non-crisis period.

2. Literature review and hypothesis establishments

Changes of corporate governance at banks during past decades substantially altered the governance of banking organization. Adams and Mehran (2003) has documented the difference of corporate governance, especially in board structure, between US banking holding companies and manufactured firms. How does these changes in corporate governance affect bank performance and risk-taking behavior needs to be further addressed.

2.1 The impact of board structure on bank performance

Adams and Mehran (2003) pointed out that average board size of US BHC (bank holding company) during 1986 to 1999 is 18 directors on the board which is significantly higher than that in manufactured firms of 12 directors. Will larger board size improve bank performance ? Most literature indicated that there existed positive relationship between board size and firm performance (Dalton et al. ,1999; Mak and Li ,2001;Kiel and Nicholson,2003;Dalton and Dalton,2005). Andres and Vallelado (2008), using firm sample of six OECD countries, think larger board size would enhance firm performance due to various background and professional knowledge from larger board; the optimal board size is 19 directors in the board. They also found the inverse U shape relationship between bank performance and board size. Aebi, Sabato and Schmid (2012) also supported the positive relationship between board size and US bank performance during financial crisis.

Based on above, we establish the following hypotheses.

H_{1a} : The board size has positive effect on bank performance.
H_{1b}: The board size has positive effect on bank performance in financial crisis.

2.2 The impact of CEO duality on bank performance

Past literature have proposed that dual role of CEO also serving the president of the board plays certain influence on the firm performance. Fama and Jensen (1983) and Jensen (1993) think that CEO duality would weaken the independent monitoring of the board. However, according to Boyd (1995), CEO duality helps efficient decision making to improve firm performance in financial crisis, thus, the positive relationship between CEO duality and firm performance exists during financial distress period. Thus, we establish the following hypotheses.

H_{2a}: CEO duality has negative effect on bank performance.
H_{2b}: CEO duality has positive effect on bank performance during financial crisis.

2.3 The impact of independent board on bank performance

The function of independent board is to mitigate the potential opportunism of CEO so as to decrease the interest conflicts between managers and shareholders (Crespí-Cladera and Pascual-Fuster, 2013). Lee, Rosenstein and Wyatt(1999) and Byrd and Hickman (1992) also supported the positive relation between independent director and firm performance.

Whether above positive relation between independent director and firm performance exists during financial distress period had been barely documented. Francis et al. (2012) investigated the influence of corporate governance in firm performance. They found that firm performance during crisis period which is measured by accumulated stock return during crisis could be improved by higher ratio of independent director in the board. Based on above, we establish the following hypotheses.

H_{3a} : The board independence has positive effect on bank performance.

H_{3b} : The board independence has positive effect on bank performance during financial crisis.

This research is designed to test the relation between board characteristics and bank performance. Considering the higher risk-taking followed by greater profitability, we examine above hypotheses by measuring bank performance in terms of both bank performance and risk-adjusted bank performance.

2.4 The impact of board size on bank risks

Whether agency problems between management and shareholders with respect to risk-taking behavior may also vary with the bank's board characteristics. Past literature has documented whether bank risk-taking varies with bank's ownership structure (leaven and Levine, 2009; Jensen and Meckling, 1976) and with managerial incentives (Coles, Naveen and Naveen, 2006). Yet, few research has assessed how board structure shapes the risk taking behavior of banks. The way to meet capital requirement is either to reduce risk-taking incentives of banks by restricting banks from engaging in nonlending activities, such as securities and insurance underwriting or to raise bank capital. Some research suggested that loss for bank shareholders from stringent capital requirements might intensify shareholder's risk-taking incentives(Koehn and Santomero, 1980; Buser, Chen, and Kane,1981). We would investigate the role of board characteristics in the agency problems between management and shareholders with respect to bank risk-taking behavior in this study.

Pathan (2009) show the significantly positive relation between strong board and risk-taking behavior, that is, risk control capability is stronger for strong board in terms of smaller board, higher ratio of independent directors. Accordingly, we establish the following hypotheses.

H_{4a} : The board size has negative effect on bank's risk-taking behavior.

H_{4a} : The board size has negative effect on bank's risk-taking behavior during financial crisis.

2.5 The impact of CEO duality on bank risk

Amihud and Lev(1981),Pathan(2009),Castañer and Kavadis (2013) suggested the negative relation between CEO power and bank risk management. CEO power is measured by CEO duality and whether internally hired. The wealth of dual CEO is less likely to be diversified, considering the expected value of debt tax shield and bankrupt costs(Parrino et al., 2005), CEO would choose to be a risk-averter to avoid the wealth loss. Castañer and Kavadis (2013) indicated that dual CEO tends to decrease risk exposure in the way of diversification. However, Ferrero et al. (2012) presents insignificant relation between dual CEO and risk-averse in S&P500 firms during 2008 financial financial tsunami. Even though, we argue that dual CEO would help reduce bank's risks during financial crisis. Accordingly, we establish the following hypotheses.

H_{5a} : The dual CEO has a negative impact on bank risks.

H_{5b} : The dual CEO has a negative impact on bank risks during financial crisis.

2.6 The impact of independent board on bank risks

Fredrickson, Hambrick and Baumrin(1988), Connors(1989), Baysinger and Hoskisson(1990) indicated that independent board could effectively monitor CEO's decision making in the development of firms. Also, Ferrero, Izquierdo and Torres (2012) show that higher ratio of independent directors on the board could restrict over risk-taking during financial financial tsunami of 2008. Accordingly, we establish the following hypotheses.

H_{6a} : The independent board has a negative impact on bank's risk-taking.

H_{6b} : The independent board has a negative impact on bank's risk-taking during financial crisis.

3. Research methodology

3.1 sample description

We examine the impact of board structure on both bank performance and risks by using pooled sample of 59 US commercial banks during 2000 to 2013. The financial information and board structure data are obtained from Bankscope, Execucomp and U.S. Securities. Board information are hand-collected from Exchange Commission website.

3.2 Empirical model

The empirical models are established as follow.

$$\begin{aligned} perform_{it} = {} & \beta_0 + \beta_1 bosize_{it} + \beta_2 indepr_{it} + \beta_3 dual_{it} + \beta_4 lnass_{it} + \beta_5 debt_{it} \\ & + \beta_6 liqratio_{it} + \beta_7 capratio_{it} + \beta_8 yeardum_{it} + \beta_9 intbosz_{it} \\ & + \beta_{10} intdual_{it} + \beta_{11} intyrind_{it} + \varepsilon_{it} \end{aligned}$$

Where i=1,...,N ， t=1,...,T (1)

$$risk_{it} = \beta_0 + \beta_1 bosize_{it} + \beta_2 indepr_{it} + \beta_3 dual_{it} + \beta_4 lnass_{it} + \beta_5 debt_{it} + \beta_6 liqratio_{it} + \beta_7 capratio_{it} + \beta_8 yeardum_{it} + \beta_9 intbosz_{it} + \beta_{10} intdual_{it} + \beta_{11} intyrind_{it} + \varepsilon_{it}$$

Where i=1,...,N ， t=1,...,T (2)

Variable definition:

Dependent variables:

$perform_{it}$ is measured by ROA, ROE and one-year stock return (RET1YE).

$risk_{it}$ is measured by the standard deviation of performance of three-year at t, t-1 and t+1,VOLROA, VOLROE, and VOLRET.

Independent variables:

Board structure is measured by board size (BOSIZE), dual role of CEO (DUAL) and the ratio of independent directors (INDEPR).

(1) BOSIZE：number of directors on the board
(2) DUAL：1 if CEO also serves as the president of the board, otherwise, it is 0
(3) INDEPR： the ratio of independent directors on the board
(4) Yeardum：1 if the sample year is equal to 2008 or 2009, otherwise, it is 0
(5) Intbosz：interaction term of Yeardum and BOSIZE
(6) Intdual：interaction term of Yeardum and DUAL
(7) Intyrind：interaction term of Yeardum and INDEPR

Control variables

(1) CAPRATIO：bank's capital divided by total risky assets
(2) lnass：logarithm of total Assets。
(3) DEBT：total debt divided by total assets
(4) LIQRATIO：total liquidity assets divided by total assets

4. Empirical results

4.1 Descriptive statistics

Table 4.1 show the descriptive statistics of all variables. Panel A is the measure of bank performance with mean ROA of 0.89%, ROE of 8.15% and RET1YE of 8.94%, and the mean ADJROA of 11.04%, ADJROE of 11.55% and ADJRET of 8.94%. Panel B show the bank risks, both ROE and RET1YE have greater volatilities than that in ROA. We also list the performance and risks before, during and after financial financial tsunami year defined as year of 2008 and 2009. In general, we find the performances before and after financial tsunami year are better than that in financial tsunami year; and the risk of financial tsunami year is much higher than that before and after financial crisis. Comparing performance and risks before and after financial tsunami year, we find the performance is generally higher and risks is lower before crisis than those after crisis.

There is around 60% of the sample with CEO duality, and mean board size is 25 showing banks with greater board size. The average ratio of independent directors is 79%.

Table 4.1 Descriptive statistics

Variable name	N	mean	Standard deviation	Min	Max
Panel A：bank performance					
ROA	624	0.8976	1.4002	-6.53	12.15

4.2 Empirical results

All regression analyses are results of robust adjusted regressions. In section 4.2.1, Table 4.2 and 4.3 present the results for both bank performance and bank risks respectively. In section 4.2.2, the high and low bank performance empirical results are shown in Table 4.4, 4.5, 4.6 for high-performing banks and in Table 4.7,4.8 and 4.9 for low-performing banks.

4.2.1

From Table 4.2, we find that CEO duality has a significantly positive effect on bank performance in terms of ROA and ROE while they become insignificant after adjusting the risks, implying the risk increasing with higher performance. Board size has a significantly positive effect on adjusted ROA only. The independent board doesn't present any influence in bank performances. Therefore, H_{2a}, H_{2b}, H_{3a}, H_{3b} are not confirmed in this study. Taking a look at the results on financial crisis, we find bank performance does show significantly lower at ROA and ROE during financial tsunami (Yeardum), but, the adjusted performance presents to be insignificant which again might be due to the high volatilities during financial tsunami. As to the effect of board on bank performance during crisis period, we only find board size has significantly negative effect on adjusted stock return, meaning larger board size during crisis period would deteriorate bank adjusted performance. Most hypotheses for crisis period cannot be confirmed. We think the insignificant results might be because the cross out effects between high and low performance. Therefore, we further try to explore the analysis by dividing sample into high and low performance group based on median value of bank performance. Those results are shown in section 4.2.2 later.

Table 4.3 reveals the results of board effect on bank risks. We find significantly positive effect of board size on bank risks in terms of ROA volatility, that is, larger board help mitigate bank risks, confirming $H_{4a.}$ Besides, CEO duality also shows significantly negative influence in stock volatility, confirming $H_{5a.}$ During financial tsunami, there is not any board characteristics shown significant effects on bank risks.

In summary, we cannot find consistently significant results of the board structure on bank performance or banks risks from whole sample. However, we argue that the insignificant results might be because the cross out effects between high and low performance. Thus, we further examine the same issue by using high-performing and low-performing banks sample next in section 4.2.2.

4.2.2 Regression analyses for high-performing and low-performing banks

We further examine the same issue by using median value of bank performance to further separate sample into high-performing and low-performing banks. Table 4.4, 4.5 and 4.6 show the results for sample of high-performing banks, Table 4.7 to 4.9 for sample of low-performing banks. Table 4.4 presents performance results of both basic models and models with interactions between board characteristics and crisis year. Similarly, Table 4.5 gives the results of adjusted performances and Table 4.6 shows the results of bank risks. As shown in Table 4.4 and Table 4.5, we find the CEO duality has significantly negative effects on stock returns at high-performing banks, but, it becomes insignificant after adjusting the risk factor. The interaction term between CEO duality (DUAL) and crisis year (Yeardum) has a significantly negative effect on stock returns, adjusted ROA and adjusted ROE, that is, during financial crisis, high-performing banks with CEO duality would have significantly lower performances than those without CEO duality.

Table 4.7 shows the results of bank risks for high-performing banks. The results indicate that high-performing banks with CEO duality have relatively lower stock volatility than those without CEO duality. During financial tsunami, CEO duality would intensify bank's volatility of ROE; high-performing banks with higher ratio of independent director and larger board have relatively lower bank risks in terms of ROA measure.

In summary of results in high-performing banks, we find the CEO duality does play certain role on bank performance and risks. When bank CEO also serving as the president of the board will reduce bank market performance in favor of H_{2a} and also decrease market volatility in favor of H_{5a}. During crisis period, high-performing banks with CEO duality will reduce bank's accounting performance in terms of ROA and ROE after adjusting risk factor. Besides, higher independent board in terms of independent director ratio and higher board size will also help control bank risks during financial tsunami in favor of in favor of H_{4b} and H_{6b}.

Table 4.7 to 4.9 show the results for sample of low-performing banks. We do find the significant influence of board structure on low-performing bank's performance and risks. Banks with CEO duality have a consistently and significantly positive impact on bank accounting performance in terms of ROA and ROE while this significant effect on performance disappears after considering the risk factor. Although CEO duality does not have significant effects on market performance of stock return, it reduces market volatility of low-performing banks in favor of H_{5a} and also helps improve risk-adjusted bank market performance during crisis period, confirming H_{2b}. Those results indicate that CEO duality helps efficient decision making to improve firm performance in financial crisis, thus, the positive relationship between CEO duality and firm performance exists during financial distress period which result is consistent with findings in Boyd (1995).

Except for CEO duality, board independence is also supported to have a significantly positive effect on low-performing bank's performance and negative effects on bank risks. Table 4.7 shows that bank performance in terms of ROA is improved by the higher ratio of independent directors on the board regardless of ROA or risk-adjusted ROA, confirming H_{3a}. We also find that higher independence of the board helps mitigate the low-performing bank's risks in terms of VOLROA and VOLRET, in favor of H_{6a}. Independent board could mitigate the potential opportunism of CEO though monitoring of independent board, thus, improve bank performance and reduce bank risk-taking behavior. However, above positive relation between independent board and bank performance, hypothesis H_{3b}, is not supported during financial distress period.

Taking a look at the effect of board size on low-performing bank's performance and risks, we find significantly positive relation between board size and market performance in terms of RET1YR and ADJRET (confirming H_{1a}), and significantly negative relation between board size and bank risks in terms of VOLRET and VOLROE, confirming H_{4a}. During financial tsunami, larger board will enhance low-performing bank's risk adjusted accounting performance (ADJROA) in favor of H_{1b}, and also help control market volatility (VOLRET) in favor of H_{4b}.

Overall, we conclude that using the whole sample to test research hypotheses, board structure seems unrelated to bank performance and bank risks in terms of inconsistent results. However, dividing bank performance to high-performing and low-performing banks based on median of performance, we find different results for high- and low-performing banks. For high-performing banks, CEO duality would decrease bank's market performance either in crisis or non-crisis period, and it would also decrease market volatility. For low-performing banks, except for CEO duality, independent board and board size also play significant role in bank performance and bank risks. We find that independent board, CEO duality and board size have positive effects on bank performance, but only CEO duality stays its influence in bank performance during financial tsunami. As to the effect of board structure on bank risks at low-performing banks, we find board size, CEO duality and independent board have negative effects on bank risks and only board size stay its significant influence in bank risks during financial tsunami.

5. Conclusion

This study investigates the role of board structure on US bank performance and risks during crisis and non-crisis period by using 59 commercial banks during 2000 to 2013. We find that board structure does affect bank performance and their risk-taking behavior at different performing banks. For high-performing banks, CEO duality would decrease bank's market performance either in crisis or non-crisis period, and it would also decrease market volatility. For low-performing banks, board structure even plays more significant effect on bank performance and bank risks either financial tsunami or non-crisis period than it does on high-performing banks. We find that independent board, CEO duality and board size have significantly positive effects on bank performance, but only CEO duality stays its influence in bank performance during financial tsunami. Moreover, board size, CEO duality and independent board have significantly negative effects on low-performing bank risks and only board size stay its significant influence in bank risks during financial tsunami.

Overall, our results show that board structure presents to play more important role on low-performing banks than on high-performing banks. During financial crisis, CEO duality would deteriorate bank's risk-adjusted performance. These results suggest that corporate governance during crisis period in banking industry still remains room to be improved, especially in board independence. Sound bank governance system definitely helps banks risk management and safely experience through financial crisis.

OVERVIEW THE RELATIVE EFFECTIVENESS OF EMERGING COUNTRIES POLICY MEASURES DURING AND AFTER FINANCIAL CRISIS

Dr. Tumpak Silalahi
University of Padjadjaran,
Bandung Indonesia
silalahi@bi.go.id

The objective of this research is to overview the impact of crisis and policy measures taken during the crisis, evaluate the effectiveness of those measures and analyze the exit strategy in Indonesia. To achieve those objectives, this paper will review some policy measures in monetary, fiscal and financial sectors that had been taken to deal with the 2008 global financial crisis using descriptive and statistical analysis. Based on finding, we could conclude that Indonesia had clearly demonstrated the effective and timely response of monetary, fiscal and financial sector policies which helped Indonesia to recover from global economic crisis.

Additionally, the econometric model was used to evaluate the impact of monetary and fiscal policy to economic output using quarterly data from 1990 - 2010. The result shows that monetary and fiscal policies have significant impact to economic output. In the short run the changes in real GDP is significantly affected by changes in real monetary supply in the previous three quarter and real fiscal expenditures. The lesson learned from this research among other are that cooperation and coordination among the policy makers and the timely responses are very important in tackling the crisis; an effective conventional monetary policy in normal times may become less effective in a crisis thus unconventional monetary policy indeed necessary as timely policy response and the improvement for more timely disbursement of government expenditure is important to increase the effectiveness of this policy to stimulate economic output. Moreover, several Indonesian exit strategy and policies to face future challenges are very important to reach the ultimate objective of sustainable economic growth while maintaining macroeconomic stability.

Keywords: monetary policy, fiscal policy, financial sector policy, global financial crisis

JEL Classification: E52, E62, E63

Introduction

The global financial crisis in 2008 had an impact on Indonesian economy as can be explored by assessing Indonesian macroeconomic and financial institution indicators. As a small open economy, Indonesia could not be immune from impact of external shocks. The integration in financial sector has left many countries particularly for open economy to contagion risk. The pressures in the global liquidity had caused a massive short term portfolio capital outflow followed by a decline of Indonesia's financial market performances. In the real sectors, reflecting the input of global slowdown, exports declined and it had an indirect impact on household and private sector's income, leading to a decline in Indonesia's consumption and investment.

All over the globe, at the period the crisis, The Government and The Central Bank implemented policy measure in monetary, fiscal and financial sectors to deal with the global financial crisis. Bank Indonesia had implemented an accommodative monetary policy in order to keep a moderate growth achieve at least by maintaining financial markets liquid which was facilitated by relatively low inflation. The policy rate was brought down in December 2008 with the intention to decrease banks' lending rates. Some unconventional monetary policy measures such as narrowing the interest rate corridor for standing deposit and lending facility had also been taken to address liquidity issues. On the fiscal side, the government provides policy response to keep domestic demand by several fiscal stimulus and trade policies. There were also coordination between Ministry of Finance, Central bank and other institutions in order to maintain financial and macroeconomic stability.

With this background, this paper is aimed to review the policy measures taken during the crisis, evaluating their effectiveness and analyzing the exit strategy to reach the ultimate objective of sustainable economic growth while maintaining macroeconomic stability in Indonesia. In turn this is expected to make a contribution to a comprehensive evaluation of the effectiveness of the policy measures in SEACEN Economies. To handle the broad issues in the paper, two methodologies are adopted: firstly, by descriptive analysis using simple statistics and graphics; and secondly, by econometric model to analyze the relative effectiveness of policy choices. However, it is difficult to analyze the effectiveness of policy choices exclusively during the crisis with an econometric model, since then we have only limited period of data. Therefore, we will analyze relative effectiveness of policies from 1990 – 2010 using Error Correction Model.

The Hyphothesis

There are two arguments between economist about the policy measure to respond the turbulence during the economic crises. The first argument who support the idea that monetary policy is the first line of defense during the turbulance while the second opinion believe that fiscal policy has a more important role particularly when conventional monetary policy measures are not sufficient enought in addresing losses in output due to weakening of economy. As it has stated before, the objective of this paper is to identify and evaluate policy measures during the global financial crisis 2008's so the next sections will explore and review the effectiveness of those policy measures..

The policy choices available during the global financial crisis to maintain economic stability consist of Monetary Policy, Fiscal Policy and Financial Sector Reforms. In examining the relative effectiveness of both monetary and fiscal policies on economic growth, we use the Engle and Granger two step estimating procedure which allows an explicit testing of co-integration and specification of the Error Correction Model (ECM).

The relationship between monetary policy and economic growth was derived from the general theoretical framework formed by Quantity Theory of Money with the following identity:

$$MV = PY \qquad (1)$$

M refers to money stock, V velocity of circulation, P price level and Y income. If V is constant then there is a relationship between changes in the stock of money and changes in the value of national income.

$$M = kPY \qquad (2)$$

The relationship between fiscal policy and economic growth could be explained through the national income identity.

$$Y = C + I + G + (X - M) \qquad (3)$$

Model Specification, Data sources and Limitations

Empirical model in this paper is aimed at testing the relationship of economic growth with monetary policy, fiscal policy and other control variables.

$$Yt = f(MP_t, FP_t, Z_t) \qquad (4)$$

Where Y is a measure of economic activity, MP, a measure of monetary policy, FP measure of fiscal policy and Z is other control variables that may affect economic activity.

In the end, the general form of the Error Correction Model (ECM) specification in this paper is:

$$\Delta Y_t = \sum_{j=1}\sum_{k=0}\beta_{1jk}\Delta X_{jt-k} + \sum_{k=0}\beta_{2k}\Delta Y_{t-k-1} + \lambda ECM_{t-1} + C + e_t \tag{5}$$

Where:

Y = dependent variables (economic output)

X = independent variables, consists of monetary variables, fiscal variables, and other control variables

ECM = residuals from long run relationship between variable

n = number of explanatory variable in the model

p = number of lags used to represent the short run dynamics in the model

There are several variables which could be used as proxies for of economic activity, fiscal policy, monetary policy and control variables as outlined in the table below. We use quarterly data from 1990 Q1 to 2010 Q2. Some of variables were adjusted for seasonality using Census X12 method.

Table 1: List of Variables

Indicator	Variable	Sources	Notes
Growth	GDP Real	IFS, staff estimated	
	GDP Nominal	IFS	
Fiscal	Fiscal Balance	BI	
	Government Revenue	BI	
	Government Expenditure	BI	
	Primary Expenditure		Government Expenditure – Interest Payment
	Primary Balance	BI	
Monetary	M1	IFS	
	M2	IFS	
	Policy Rate	BI	Prior to Q3 2005, we use SBI 1 month as proxy for policy rate
Inflationary Effect	GDP Deflator	IFS, staff estimated	
	CPI	BI	
External Sector	Exchange Rate	IFS	
	Current Account Balance	IFS	
Dummy Recession	1997/1998 Recession	Estimated	Q1 1997 – Q4 1998
	2008/2009 Recession	Estimated	Q4 2008 – Q2 2009

Notes: all variable are in logarithm, except Fiscal balance, primary balance, current account balance (because they contains negative values) and dummy recession (binary 1/0)

The data collection consist of monetary policy, fiscal policy and financial sector reform gathered from the data of Bank Indonesia as an authority of monetary policy and bank supervision and regulation in Indonesia. For the fiscal policy and non bank financial supervision data collected from the Ministry of Finance. The data was colected with data series since January 2008 before the global crisis until 2010.

The Result

To characterize the time series property of the variables, instead of using the Augmented Dickey-Fuller (ADF) tests, it used Phillips Perron (PP) methods. This PP approach is more appropriate than ADF since the data shows a structural break as effect of 1997/1998 crisis. Both of the ADF and PP test indicate that most of the series are non-stationary when the variables are defined in levels, except Fiscal Balance, Primary Balance, Policy Rate and Current Account Balance. But first-differencing the series removes the non-stationary components in all cases and the null hypothesis of non stationary is clearly rejected at the 5% significance level suggesting that all variables are integrated of I(1). Thus, the next step of testing for possible cointegration relationship will be done only with the I(1) variables.

Table 2 Unit Root Test for Variables

Variables	Abbreviation	ADF Test Result					Phillips Perron Test Result				
		Level		1st difference		Level of integration	Level		1st difference		Level of integration
		t-stat	p-values	t-stat	p-values		t-stat	p-values	t-stat	p-values

GDP US	USGDP	-0.215	0.992	-2.199	0.028	I(1)	-0.249	0.991	-3.144	0.002	I(1)
GDP Japan	JPGDP	1.014	0.917	-3.321	0.001	I(1)	1.351	0.955	-16.482	0.000	I(1)

Following the Engle and Granger two step-method, in the next step we estimate the long run equilibrium relationship among variables by OLS and test for stationary of the residuals, in the form:

$$y_t = \alpha_0 + \alpha_1 x_t + e_t \tag{6}$$

To identify the unit root in the residuals, it used critical values for the Engle - Granger Cointegration Test provided in Enders (2004). After estimating several alternatives model based on the variables, so the best long run cointegration equations as follow:[1]

[1] RM1_SA defined as real seasonally adjusted M1 which equal to nominal M1/GDP Deflator. RGE_SA defined as real seasonally adjusted government expenditure which equal to nominal government expenditure/GDP Deflator. *value in ( ) shows standard error.* **** significant at $\alpha = 1\%$, ** significant at $\alpha = 5\%$, * significant at $\alpha = 10\%$*. We realize that there might be endogenity relationship between RM1_SA and GDP_SA, but to be

$$\underset{}{RGDP\_SA} = \underset{(0.05)^{***}}{5.13} + \underset{(0.03)^{***}}{0.88\,RM1\_SA} + \underset{(0.25)^{***}}{0.20\,RGE\_SA} \tag{7}$$

$R2 = 0.94$

The critical value of residual unit root test from this equation is -6.61, and given the critical value of Engle - Granger Cointegration Test for 2 variables which is -4.123 for significance at 1%, then variables real GDP, real M1 and real government expenditures are said to be cointegrated.

Next step is to switch to a short run model with an error correction mechanism in the form:

$$\Delta RGDP\_SA_t = \sum_{j=1}\sum_{k=0}\beta_{1jk}\Delta X_{jt-k} + \sum_{k=0}\beta_{2k}\Delta RGDP\_SA_{t-k-1} + \lambda ECM_{t-1} + crisis + C + e_t \quad (8)$$

Where X consists of real M1, real government expenditure and other control variables, meanwhile ECM is residuals from equation (7). To address the impact of crisis, it also used dummy recession variables CR97 and CR08. With general to specific approach to several combinations of cointegrated variables and lags, the best models found as follows:

Table 3: Error Correction Models

Variables	Dependent : Real GDP		
	Coefficient	t-stat	
Real M1(-3)	0.07	2.17	**
Real Gov_Exp	0.03	3.92	***
ECM(-1)	-0.06	-1.91	*
Exchange Rate (-1)	-0.04	-2.95	***
Inflation (-1)	-0.29	-5.63	***
Crisis 97	-0.01	-2.06	**
Constant	0.02	11.36	***
R2	0.66		
DW-Stat	2.00		
SIC	-5.76		

**** significant at $\alpha = 1\%$, ** significant at $\alpha = 5\%$, * significant at $\alpha = 10\%$*

Analysis of results

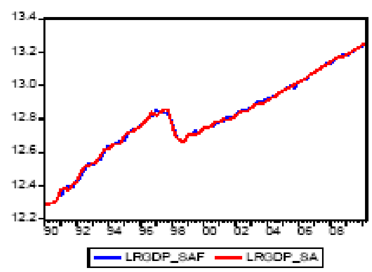
The empirical results show that Real GDP cointegrated with real M1 and real fiscal expenditure. On the basis of this information, an error correction model was developed which was shown to be well-specified relative to its own information set and capable of parsimoniously representing the data set.

---

inline with the agreed methodology we assume the one-way relationship between them and use ECM. For robustness, we also use VECM and found the long run relationship between those variables (in appendix).

From the error correction models, it could be concluded that in the short run the changes in real GDP is significantly affected by changes in real fiscal expenditures and real monetary changes. The previous real GDP changes are not significant to affect real GDP changes. The crisis 1997 decrease the real GDP significantly, meanwhile the crisis 2008/2009 effect is not significant. The result also shows a well-defined error correction term, and indicates a feedback of 6% of the previous quarter's disequilibrium from the long run money supply, and fiscal expenditure to economic activity. To evaluate the goodness of the model, I did some in sample forecasting and compared the result with the actual data. The result was quite good as shown in Graph 1. The root mean square error (RMSE) of the forecast was only 0.01.

Graph 1 Evaluation of Model



The lag in the effect of monetary changes relative to fiscal policy as shown in table 4 indicates that the impact of fiscal policy on GDP is relatively faster than monetary policy. This result is in line with the Elmendorf and Furman (2008) which consider that a key potential advantage of fiscal stimulus relative to monetary stimulus was that it could boost economic activity more quickly, and true fiscal stimulus implemented promptly can provide a larger near-term impetus to economic activity than monetary policy.

Table 4 Evaluation of the Effective Fiscal Stimulus Principles

Principles	Explanation	Measure for Indonesia's Fiscal Stimulus	Explanation
Timely	FS should not be enacted prematurely, delayed too long, or consist of tax cuts or spending increases that would take too long to be implemented or to boost output	1 2 3 4 5 Less Effective	Although government immediately giving instruction for FS, but there were problems that delaying the implementation or disbursement of the fund. The government expenditure is mostly disbursed in Q-4 (Graph 26)
Targeted	Tax cuts and spending increases should be directed so	1 2 3 4 5	▪ Although the biggest proportion of the FS is tax

Principles	Explanation	Measure for Indonesia's Fiscal Stimulus	Explanation
	that they provide the greatest benefit to people who are affected most adversely by an economic slowdown	Effective	reduction, but this could stimulate economic output from investment and indirectly would increase employment and wages. Then, these will increase consumption and economic output. ▪ Moreover, the big spending in infrastructure is good because it will boost a sustainable growth in longer term instead of only short term
Temporary	The FS should not increase the budget deficit in the long run	1 2 3 4 5 Quite effective	The source of fund for fiscal stimulus is come from the excess of budget utilization (SILPA) in 2008 and debt. Fund from excess of budget utilization won't affect the next government budget but the usage of debt, in the long term could impact the budget deficit. Additionally, the budget deficit plan in 2010 still relatively high (1.6% GDP) (Table 15)

Note: The 1 – 5 interval scale is based on authors' opinion, which number 1 indicate the policies are ineffective and number 5 indicate the policies are very effective.

Conclusion and Policy Recommendation.

This paper finds that the effect of global financial crises on Indonesian economy caused by sudden stop of capital inflow to emerging market indicate by declining of the economic growth for three quarter during the quarter III 2008 until first semester of 2009. Evidence shows that Indonesia impacted by the global financial crisis resulted from sudden stop capital inflow into emerging market countries and declining global economy growth. Hence, the impact on macroeconomic indicators can be identified by the first and second round effects. The first lesson from the recent crisis is that Indonesia as part of emerging country clearly demonstrated the effectiveness of timely monetary, fiscal and financial sector policy which helping Indonesia to recover from economic crisis. Indonesia and mostly Asian country had experienced the financial crisis during the last ten years. The first Asian crisis episode occurred in 1997 had significant reformation in the financial sector both in policy reform and institutional reform. However, in the second crisis ten years later known as global financial crisis occurred in 2008, the reform, can be categorized as soft reform relatively compare to the first Asian crisis.

The second lesson is that the closer cooperation and coordination among the policy maker is very important in identifying and tackling a global crisis. During the crisis period, some policy measures in monetary, fiscal and financial sectors had been taken to deal with the global financial crisis. On the Central Bank authority, Bank Indonesia had implemented an accommodative monetary policy in order to keep a moderate growth and relative low inflation. The policy rate started to decline on December 2008 with the intention to decrease bank's lending rates. Some unconventional monetary policy had also taken to address liquidity issues. On the fiscal side, the government gives responses to keep domestic demand by several fiscal stimulus and trade policies. There were also coordination between Ministry of Finance, Central bank and other institutions in order to maintain financial market and macroeconomic stability.

The policy measures had been taken during the crisis formulated in a timely manner with the ultimate objective of sustainable economic growth while maintaining macroeconomic stability in Indonesia. Based on error correction models, we could conclude that in the short run the changes in real GDP is significantly affected by changes in fiscal expenditures and inflation. Meanwhile the monetary policy changes and the previous real GDP changes are not significant to affect real GDP changes. Hence, since the conventional monetary policy is not enough during the high degree of uncertainty particularly pressure from external circumstances, thus unconventional monetary policy will enrich the monetary instrument.

By employing and adopting the measures from the studies of Han, Park et al. (2013) and Valentine and Fleischman (2008), the present study aims to examine students' awareness of professional ethics. Students with different majors are the studied subject. Reviewing literature and conducting the empirical survey show some noteworthy points. Firstly, not much can be found on professional ethics in Vietnam, in terms of academic studies and instructions (i.e. codes of conduct) for occupations. Secondly, from students' perspectives, individual ethical standards do not play any role in their awareness of professional ethics. As a consequence, a systematic educational program professional ethics requires a priority significantly.

1. Introduction

Professionals are playing important roles in organizations and in the society, as they are ones who have specialized knowledge and skills which are necessary for organizational and societal development. They are powerful to affect others by such knowledge and skills (Robinson and Dixon 2007). Moreover, with such specialized knowledge and skills, professionals can practice and have a huge control over this knowledge and skills; and benefits the society as well (Brien 1998). In another words, professional ethics can be referred to identifiable, complementary role rights and duties of clients, customers and professional peers (Brinkmann and Henriksen 2008). Therefore, whether society and its members can get benefits from professionals, it depends on the way professionals practice their professional actions (Jamal and Bowie 1995; Brien 1998). In the other words, professional ethics can be seen as individual ethical responsibility from occupational perspective (Beikzad, Abdolapoor et al. 2012)

According to the study of Trevino (1986), personal values (such as personal ethical standards) are considerable factors which have an important influence on the way individuals making ethical decisions. Moreover, professionals perform their professional activities only in the occupational contexts which are promoted by organizations, on the one hand. A socially responsible organization, which has more opportunities to succeed than others do, will create an appropriate environment for ethical decisions of individuals (Han, Park et al. 2013). Professional activities likely impact company's ethical development and CSR practice (Valentine and Fleischman 2008), on the other hand. Moreover, they are also an pivotal element of a company value assets (Hoivik 2002). Thereby, organizational context can be considered as important factor affecting professional ethics.

In this regard, this study aims to examine students' awareness of professional ethics. To address this purpose, the following questions are proposed: (1) how individual and organizational factors impact professional ethics? (2) what are differences in students' perspectives of professional ethics regarding to demographic indicators? And (3) what are managerial implications from the research findings?

2. RESEARCH BACKGROUND

2.1. *Individual factors*

In the light of the literature on professional ethics, ethical decisions are influenced by individual factors (Trevino 1986; Treviño, Weaver et al. 2006). These individual factors are clarified by many studies as personal values, which include knowledge, attitudes, and intention (Douglas, Davidson et al. 2001; Hoivik 2002). In their study, Beikzad, Abdolapoor et al. (2012) reviewed two components of knowledge, including knowledge of society culture and sufficient knowledge of occupation. Personal values are classified by the beliefs that individual have consciously or unconsciously about the world (Rokeach, 1972 cited in Douglas, Davidson et al. 2001). These beliefs are different between individuals. Moreover, Hunt and Vitell (1986, cited in Douglas, Davidson et al. 2001) include personal values as personal experiences. Similarly, Karassavidou and Glaveli (2006) also confirmed that personal values have important impact on attitudes and behaviours which directly affect the way individuals make decisions. Therefore, it can be concluded that personal values is closely connected with professional ethics (Valentine and Fleischman 2008). Therefore, this study, firstly, is to answer the question “What is the relationship between individual factors and PE?”.

2.2. *Organization factors*

In organizational context, personal values are interacted by organizational factors. Furthermore, Longenecker, Moore et al.(2006) also pointed out that ethical framework formed by organization constrains individual ethical behaviors in decision making. It means, individuals’ responses to ethical issues on their profession are framed and determined by the interactions between individual and organizational factors (Han, Park et al. 2013). This point is also confirmed by the study of Douglas, Davidson et al. (2001), even though these factors affect individuals differently. In a study of reviewing professional ethics literature, Treviño, Weaver et al. (2006) categorized factors in organizational context, including: language, rewards/punishment, ethical infrastructure, ethical climate/culture, and leadership. Adapting these organizational factors, many researchers conducted their investigated the impacts of rewards/punishment, peers, and leader on professional ethics.

Punishment and rewards are factors having strong impacts on ethical behavior of an individual (Ball and Trevino 1992). An individual will be strongly impacted in his/her professional behaviors, if he/she observes co-worker punished or rewarded. From such an observation, rules and regulations are accustomed (Ball and Trevino 1992; Han, Park et al. 2013). In particular, none of us want to suffer from any of unethical behavior. Therefore, unethical behaviors in profession will be limited if the management board apply appropriate punishment. Similarly, ethical behaviors are encouraged and reinforced if they are treated in a certain way of rewarding.

From the observation whether (un)ethical behaviors of peers are punished or rewarded, individual are also affected by these behaviors. The more interaction with peers, the stronger impact from them an individual is on (Treviño, Weaver et al. 2006). This point is also confirmed by many research findings (Patterson 2001; Deshpande and Joseph 2009; Elango, Paul et al. 2010; Han, Park et al. 2013; Fu 2014). These studies points out, the way in which an individual respond to in a situation (ethically or not) depends much on the moral approval from a peer. Therefore, individual’s professional ethics are likely to be impacted by ethical behaviours of his or her peers.

One crucial factor in the context of organization affecting professional ethics is manager. This factor is the influential factor impacting others (e.g. rewards/punishments, peer’s ethical behaviors). In fact, from management perspective, managers are figurehead of their organization (Bateman and Scott 2011), and they create the ethical environment through their ethical/unethical behaviors/activities. Managers show their disagreements about unethical behaviors by setting types of punishments; or they can encourage ethical ones by rewarding employees having ethical attitudes. Therefore, employees observe, pay attention, and imitate managers’ ethical behaviours as a model of norms and expectations for appropriate conduct (Mulki, Jaramillo et al. 2009).

2.3. *PE and studies on PE in Vietnam*

Even though research on professional ethics issues is not new, exploring ethical perceptions, understanding, and awareness of Vietnamese employees have been meager to depict a comprehensive overview on this issue. According to the review of literature, the researchers cannot find any studies on professional ethics conducted in Vietnamese context, except a conceptual paper of Trang, Khoa et al. (2014). The paper aims to figure an overview of professional ethics literature. The result shows that there are six dimensions, including laws and rules; personal ethics; knowledge of society culture; professional competence; professional standards/norms; and corporate ethics. Among these six factors, professional competence and corporate ethics can be quantitatively measured. These researchers then investigated students' perceptions of these two factors.

Except Trang, Khoa et al.'s study, which can be considered as an academic view, professional ethics in practice in Vietnam is fragmentary and unguided. Assessing the internet to find instructions on professional ethics, the researchers find some points that need to be concerned. Firstly, there are some professions/sectors having instructions or issued codes of conduct, like lawyers, accountants-auditors, medical professions, stock agencies. The codes of conduct for these occupations are issued by professional associations (like Vietnam Lawyer association, Vietnam Association of Certified Public Accountants); or related ministries (like Ministry of Health). The other professions do not have a clear instruction and the term 'professional ethics' is understood differently in different sectors. Secondly, there are some large corporations (like FPT, Holcim, Vinamilk,Vietcapital, …) issuing codes of conduct for their employees. It means, the professions in these sectors are not shared similar norms/standards in performing occupations and firms/organizations do not pursue and force their workforce in applying these codes. These points might be the reasons leading PE to being a 'hot' issue which is usually mentioned in Vietnam due to many scandals in different sectors.

From the background of PE in literature and in practice in Vietnam, this study employs the method conducted in the study of Han, Park et al.(2013) to examine the influences of individual and organizational factors on PE. Based on the research background, we propose the following hypotheses to explore the relations between organizational factors and PE:

H1: Punishment and an individual's PE have a positive relation.

H2: Rewards and individual's PE have a positive relation.

H3: Perception of peer's ethical behaviors and individual's PE have a positive relation.

H4: Perception of leaders' unethical behaviors and individual's PE have a positive relation.

3. METHODOLOGY

The main purpose of the present study is to empirically examine the level of students' awareness of professional ethics. Therefore, quantitative approach to gather a large number of participants is chosen. The participants involve in a survey using questionnaire to collect data. The study focuses on students as its main sampling because students are potential workforce provided by colleges and universities to practical business. The awareness of students is crucial to reflect their attitudes and behaviors in later occupations.

Data were collected in two steps. The purpose of the first step is to refine the contents and measurement scales before conducting final survey based on convenient sampling. Potential respondents were students in both majors engineering (e.g. civil engineering, chemical engineering, and environmental engineering) and business administration, who are over 20. Two hundred and fifty questionnaires were sent to reach the sample, and 230 questionnaires were returned and only 220 questionnaires were valid.

The questionnaire is adapted from Han, Park et al. (2013) and Valentine and Fleischman (2008). It includes 30 items to measure. For individual and organizational factors, we adopt the measurements and scales from Han, Park et al. (2013). The scale of individual standards of ethical values is with 9 items. There are 4 factors with 16 items in organizational factors, namely: punishment; reward; peers' ethical behaviors; and the ethical integrity of boss. Five items to measure professional ethics are adopted from Valentine and Fleischman (2008). According to Valentine and Fleischman, professional ethics standards are based on the content of similar 'company ethics'; and higher scores indicated a belief that a profession was ethical.

All the items are adjusted to suit the context of the study. Finally, the questionnaire with 6 factors is presented as follow:

Factor 1: Individual standards of ethical values

1. IEV1_I shouldn't harm others psychologically
2. IEV2_For my own interest, I should not harm others
3. IEV3_One shouldn't harm others no matter how small it may be
4. IEV4_Any behavior harming others' dignity and peace shouldn't be allowed
5. IEV5_I shouldn't harm others physically
6. IEV6_I shouldn't pursue my own interest at the expense of others' welfare
7. IEV7_Everybody has different moral standards
8. IEV8_Something that is moral for one may be immoral for another
9. IEV9_Each situation or society requires different ethical standards

Factor 2: Reward for ethical behaviors

1. REB10_My ethical behavior is reflected in my annual performance evaluation
2. REB11_Ethical behavior is recognized and rewarded by our company
3. REB12_Our company gives incentives for ethical behavior

Factor 3: Punishment for unethical behaviors

1. PUB13_If I behave unethically, my annual incentives will be reduced
2. PUB14_If I behave unethically, my annual performance assessment will be negatively affected

Factor 4: Peers' ethical behaviors

1. PEB15_I think my colleagues generally behave ethically
2. PEB16_My colleagues work as ethically as possible
3. PEB17_My colleagues try to abide by the ethical principles of the profession

Factors 5: The ethical integrity of boss

1. EIC18R_My boss tends to intentionally exaggerate my mistakes and convey unfavorable information on me to my direct supervisor
2. EIC19R_My boss may dismiss an employee just because he/she doesn't like the employee
3. EIC20R_My boss intentionally undermines employees' rapport with one another

4. EIC21R_My boss occasionally attempts to intentionally distort what I said
5. EIC22R_My boss may take advantage of my idea
6. EIC23R_My boss hesitates to have employees trained and educated
7. EIC24R_My boss tends to attribute his/her mistakes to me
8. EIC25R_My boss intentionally turns down my requests
9. EIC26R_My boss tends to dwell on my mistakes instead of being forgiving

Factor 6: Professional ethics

1. PE27_I believe that my profession is guided by high ethical standards
2. PE28_My profession reprimands individuals and companies that behave unethically
3. PE29_Individual and organizational ethical standards are supported in my profession
4. PE30_My profession encourages continued ethical development and training
5. PE31_I believe that people in my profession conduct business in an ethical manner

The data is cleaned and processed by using exploratory factor analysis (EFA technique) in SPSS software. Before applying the EFA method, the reliability of the scales has been tested by using Cronbach's alpha criteria, it should be at least 0.6 to be accepted (Nunnanly và Burnstein, 1994). Then, EFA technique is applied with data exploration and variable reduction steps. The EFA process is accepted with the threshold of KMO measure higher than 0.5 and significant at 5%, Eigen values must be larger than 1, Factor loadings of each variable should be at least 0.5, it is no any cross-loading above 0.35 into more than one factors (Hair et al., 2006). Besides, the difference between students' awareness of professional ethics distinguished by demographic variables are considered by ANOVA analysis.

4. DATA ANALYSIS

Input the respondents' information and their choice into the SPSS database that is further used for the related analysis. The characteristics of the sample include gender and majors. In the valid sample, the percentages of male and female students are 59 and 41, respectively. Regarding major categories, 50.5% respondents are studying engineering and 49.5% are in major of business administration.

Most of items are dispersed in the Likert 5 scales with mean is from neutral to agree (See Table 1). That means the student's perceptions on Professional Ethics described by these variables not high. It could be due to the fact that all participants are students, not yet joining labor force; therefore they

Table 1: Descriptive Statistics

	N	Minimum	Maximum	Mean	Std. Deviation
IEV1	220	1	5	3.94	.845
IEV2	220	1	5	4.27	.859
IEV3	220	1	5	3.56	.897

IEV4	220	1	5	4.16	.871

PUB13	220	1	5	3.42	.969
PUB14	220	1	5	3.62	.926
PEB15	220	1	5	3.58	.770
PEB16	220	1	5	3.45	.772
PEB17	220	1	5	3.45	.742
EIC18R	220	1	5	3.46	.913
EIC19R	220	1	5	3.68	1.102
EIC20R	220	1	5	3.72	.989
EIC21R	220	1	5	3.87	.957
EIC22R	220	1	5	3.46	1.140
EIC23R	220	1	5	3.47	.924
EIC24R	220	1	5	3.59	1.032
EIC25R	220	1	5	3.51	.958
EIC26R	220	1	5	3.48	.938
PE27	220	1	5	3.70	.772
PE28	220	1	5	3.46	.923
PE29	220	1	5	3.46	.867
PE30	220	1	5	3.82	.790
PE31	220	1	5	3.50	.819
Valid N (listwise)	220				

Based on the results of the EFA, we classified Individual ethical values into two factors: Idealism (IEV1 to IEV6) and Relativism (IEV7 to IEV9) (see Table 2). Cronbach's alpha for Idealism and Relativism were 0.809 and 0.581, respectively. When excluded item IEV7, Crobach's alpha of this factor increases in 0.601. All remaining items loaded on each factor as the research model and receive the Cronbach's alpha from 0.644 (for REB) to 0.909 (for EIC), satisfy the condition mentioned above. Therefore, all of these indicators will be used in the EFA steps.

Table 2: Factor analysis of Individual Ethical Values

Items	Factor 1 Idealism	Factor 2 Relativism
IEV1	.585	
IEV2	.711	
IEV3	.770	
IEV4	.601	
IEV5	.528	
IEV6	.665	
IEV7		.384
IEV8		.681
IEV9		.637
KMO	0.852	0.600
Bartllett's test (sig)	0.000	0.000
Eigen value	3.081	1.635
Variance explained (%)	51.355	54.507
Cummulative Variance explained (%)	51.355	54.507

Mean	3.9871	3.9803
Standard deviaion	0.618	0.686
Cronbach's alpha	0.809	0.581

As showed at Table 3, both factors Reward for ethical behaviors and Punishment for unethical behaviors group in one component when compared to theory model. Under respondents' opinion, two constructs have closed relation together, cannot separate them, especially in organization. Therefore, this new factor is formed and named company's policy for ethical behavior. Other factors remain their names.

Following EFA analysis, the regression analysis is conducted for new related factors by Enter method. Results of regression showed that VIF<2 and Tolerance was greater than 0.5, that means there was no multi-collinearity (see Table 4).

Table 4: Regression analysis

Model		Unstandardized Coefficients		Standardized Coefficients	t	Sig.	Collinearity Statistics	
		B	Std. Error	Beta			Tolerance	VIF
1	(Constant)	-1,068E-16	.055		.000	1.000		
	The ethical integrity of boss	.136	.058	.146	2.333	.021	.970	1.031
	Company's policy for ethical behaviors	.163	.074	.161	2.202	.029	.706	1.417
	Peers' ethical behaviors	.256	.072	.262	3.561	.000	.702	1.424

a. Dependent Variable: REGR factor score 3 for analysis 3

Results of regression analysis showed that only 3 factors, including: the ethical integrity of the boss, company's policy for ethical behaviours and peers' ethical behaviours, have positive relations with Professional ethics. In the present study, there is no relation between Individual standards of ethical values and Professional ethics. It means that students are not aware of the role of individual in Professional ethics. This might be explained by the reasons that students are not provided/trained Professional ethics in a systematic way. It might lead them to think individual values have no impact on Professional ethics.

Lastly, ANOVA analysis helps to examine the differences in students' awareness of Professional ethics in term of demographic indicators, such as gender and majors with a significance level of 5%. The results showed that there is a significant difference in male and female students. This difference is on two items PE28 and PE30. In both two items, female students have higher score than their counterpart do (See table 5). Similarly, with a significance level of 5%, the results of analysis ANOVA showed no differences in ethics awareness among business administration and engineering students.

Table 5: ANOVA analysis results between male students and its counterpart

		Sum of Squares	df	Mean Square	F	Sig.
PE27	Between Groups	.055	1	.055	.092	.762
	Within Groups	130.540	218	.599		
	Total	130.595	219			
PE28	Between Groups	3.574	1	3.574	4.254	.040
	Within Groups	183.135	218	.840		
	Total	186.709	219			
PE29	Between Groups	.511	1	.511	.679	.411
	Within Groups	164.121	218	.753		
	Total	164.632	219			
PE30	Between Groups	3.439	1	3.439	5.624	.019
	Within Groups	133.289	218	.611		
	Total	136.727	219			
PE31	Between Groups	1.225	1	1.225	1.833	.177
	Within Groups	145.770	218	.669		
	Total	146.995	219			

5. DISCUSSION AND CONCLUSION

The present study is to examine students' awareness of professional ethics by employing and adapting the scales from the studies of Han, Park et al. (2013) and that of Valentine and Fleischman (2008). The analysis has shown that, in students' perspectives, individual ethical values do not have significant impact on their awareness of professional ethics. Meanwhile, 17 variables in organizational factors are divided into 3 factors, namely: policy for ethical behaviors, peers' ethical behaviors, and the ethical integrity of boss.

To analyze the difference in students' perspectives of professional ethics, a comparison is conducted regarding demographic indicators. The result has shown that there is a difference between male and female students' awareness of professional ethics; meanwhile, participants' majors do not make any.

The research findings show some noteworthy points to discuss. As mentioned in the research background, there are not many studies on professional ethics. Therefore, this study can be considered as one of pioneer ones conducted in Vietnam. According to Trang, Khoa et al. (2014), professional ethics is not paid enough attention in university and vocational education. There is no course relating to this topic. This fact helps much in explaining why students do not think individual values having impacts on professional ethics. Moreover, it might be also useful to understand there is no difference between perspectives of students in different majors.

The second point is that, when conducting the survey, students expressed their confusion in understanding the term professional ethics. One of the reasons is that they are not only taught as to professional ethics in their curriculum, but they even cannot find easily what is (are) code(s) of conduct in their professions. This can also support in understanding research in professional ethics is still meager.

The last point needs to be concerned is that there are not common/shared norms/standards in performing occupations in many sectors. Accompanying with no course provided in university/vocational education, this fact has been creating more barriers for professionals in approaching and behaving ethically in their professions.

6. IMPLICATIONS AND LIMITATIONS

One pivotal implication from these research findings is that education sector, especially Ministry of Education and Training and universities, need to supplement a course Professional ethics to University and vocational education programs. On the one hand, a course Professional ethics needs to be added to curriculum to provide students with an overview of knowledge and general understanding of how to behave ethically in performing occupations. On the other hand, all courses in majors need to provide a chapter or a part on Professional ethics to provide student systematic information on code of conduct their occupations. Such doing will help to increase students' awareness of individual values on professional ethics. This implication can be supported by the contribution from the study of Karassavidou and Glaveli (2006).

The research finding points out students do not aware of the impacts of individual ethical values on Professional ethics. From this fact, it is necessary to develop an educational/training objective which can encourage and integrate individual ethical standards into program. This point echoes with the suggestions of Brinkmann and Henriksen (2008). A(n) educational/training program on professional ethics would be the first step for developing shared standards/codes of conduct in occupations.

Like other studies, the present research faces some limitations. Firstly, the approached participants are students in two majors, business administration and engineering, rather than many other ones, like medicine, law, and pedagogue. For this reason, this study cannot represent for awareness of students in general. The further research should extend the sampling to many majors in universities to depict more comprehensive understanding of professional ethics. Secondly, as explained in the study of Valentine and Fleischman (2008), the scale of Professional ethics is borrowed from Corporate ethics. Hence, the measures might be not as exact as its real meaning is for this specific research context. Moreover, the research finding of Trang, Khoa et al. (2014) also points out that there is necessary to undertake a qualitative research to develop the measure for Professional ethics. This point is also suggested in the study of Karassavidou and Glaveli (2006). Further research should focus on developing a scale for professional ethics.

The purpose of this paper is to examine the effects of Financial Market Development on capital structure of manufacturing sector in Vietnam.
Keywords: HOSE, Capital structure, Financial market development, Z-score model, Stock market, Credit market, Banking sector.

1. Introduction

Capital structure has a long history since Modigliani and Miller (1958)built the first modern thinking of capital structure. Academics have dedicated much endeavor to understand financing choices of firms. Recent researches try to quantify financing decisions guidance while early studies employed qualitative method. However, the schools of capital structure literature shows extensive researches examining only internal factors influence on capital structure and a little attention on the effect of macroeconomic environment on corporate financing decisions (Hackbarth et al., 2006). It is relatively amazing as intuitively the macroeconomic conditions should have impact on important firm decisions and financing decision is not an exemption. Cognizant of this limitation, this study attempts to contribute to the literature by directly examining the nexus between financial market development in a transitional economy like Vietnam and capital structure decisions among manufacturing firms.

The paper follows the thought that the development of financial market would have large impact on the economy growth and consequently is perceived to have influence onfirms' financing policies. The crucial effects of financial market on the development of economy have been proven by a lot of researches and empirical studies (Bagehot, 1873; Hicks, 1969;Schumpeter, 1911; and Levine, 1997). They proposed that financial development help encourage the industrialization in England, stimulate technological progress and more liquid financial markets do create investment and hence economic growth. From the above argument, it is supposed that financial market development is the key factor affecting financing choices of firms as its function help allocate and channel capital more effectively as well as distribute investment funds and diversify risks, giving more financing sources for firms. Furthermore, it is worth having deep understanding how fast-changing macro-environment especially financial market development influence financing choices of firms under transitional economy such as Vietnam.

The content of this paper comprises five sections. In the section 2, literature related to financing choices of firms is introduced as hypothetical foundation for the whole study. Next, the description about sample as well as key determinants related to financial market development and the steps involved is provided in the Methodology section. The section 4 discusses the results and finally, the conclusion is presented in the last part of this paper.

2. LITERATURE REVIEWS

2.1. *Capital structure theories*

Modigliani and Miller (1958) built the first brick for thought of capital structure literature proposing that firm value does not rely on capital structure under perfect market condition without the effect of tax, inflation and transactional costs. The theory started a long history of debates on capital structure school as many academics doing research in economic field argued that no firm actually works in such a perfect market condition. Consequently, they have put much efforts in determine how capital structure could be used as tool to increase firm value.
Jensen and Meckling (1976) and Jensen (1986) proposed that all firms try to keep the tax benefits from debt always balance with the cost of bankruptcy.Myers (2001) confirmedthat

there is a tax advantage firms can enjoy when they finance by debt and hence, the firm should seek more debt financing opportunities to maximize tax benefit and eventually increase profitability. However, the climbing level of debt is also followed by the insolvency probability. Therefore, capital structure is considered to be the trade-off between tax benefits of debt and insolvency costs.

As regards capital structure of a firm, pecking order theory created by Myers and Majluf (1984) and Myers (1984) is considered as an alternative to trade-off theory and one of the most influential theories about leverage in corporations. This theory isanticipated that the firm enjoy using internal source of fund when available and prefer debt over equity when external financing is required.Myers (1984) explained that it is due to the adverse selection, firms will choose internal instead of external finance

In the agency cost theory proposed by Jensen and Meckling (1976), they said that optimal capital structure will help the firms to reduce the costs associated with the conflicts between the stakeholders. Jensen (1986) also recommended the ability of debt in moderating the conflicts between manager and shareholders. This argument is explained by the fact that debts force the firms to pay out cash for creditors thus reducing the amount of money that managers can use to pursue their own interest.

The information asymmetry theory of capital structure (Ross, 1977) proposed that firm managers have more information about thefuture prospects of the firm than the market. Therefore, the financial decision made by managers provides the market with the information about the firm’s future prospects. Increasing the level of leverage shows that the managers are really confident about the success of the firm in the future thus increasing the firm value by attracting the investments from the market.

Since the very first works of Lintner (1956), Hirshleifer (1958) and the well-known study of Modigliani and Miller (1958), researches and studies day by day have had more and more steps in the perfection of model development on capital structure.

2.2. *Financial Market Development and Capital Structure*

The study carried out by Jong et al. (2007) support the view that macroeconomic factors can have significant impacts on firm leverage in two ways. More specifically, these variables can affect capital structure directly. For instance, the utilization of debt will be improved in a more developed bond market and it is the same case for new stock issuance when the firm decides to finance their business from equity. Furthermore, the indirect effect of macroeconomic factors can influence debt structure through their effect on firm-particular variables. For example, the fact remains that in nations with a better legal system and more developed economy, it is more likely for the firms to take more debt but also the impacts of some firm characteristics on capital structure such as profitability, liquidity, growth opportunity and so on are also strengthened.

The relationship between economic development and debt-equity financing choices has been mentioned by some studies in recent years. They have found that the capital structure decision of a firm not only depends on internal factors but also bears the influence of macroeconomic variables:Total Money Supply (Olorunfemi and Adeleke, 2012); Change In The Interest Rate (Rayan, 2008; Bokpin, 2009; Joseph, Titman and Twite, 2012; Claessens and Klapper, 2002);

Inflation (Bokpin, 2008; Lemma and Negash, 2012; Baltaci and Ayaydin, 2014;Kim and Wu, 1988); Bond Market Development(Sergey, 2009;Agarwal and Mohtadi, 2004; Maksimovic et al., 1995); Stock Market Development (Olorunfemi et al., 2012;Chekanskiy, 2009;Jonget al., 2007; Agarwalet al., 2004; Maksimovic et al., 1995; Bokpin and Isshaq, 2008; Adeyemi, Babatunde and Oboh, 2011); and GDP Growth Rate (Bokpin,2009; Claessens and Klapper,2002; Lemma and Negash, 2012;Baltaci and Ayaydin, 2014; Chekanskiy, 2009; Jong, et al.,2007).

One study worth taking into account is the work of Maksimovic and Demirgiiq-Kunt (1995) exploring the effect of stock market development on the financing choices of firmsin 30 countries for a period of 11 years from 1980 to 1991. It seems to be not enough because the financial market includes more, not only stock market. In this paper, not only the stock market but banking sector development, interest rate and one of the most remarkable event financial crises in 2008 is put into concern. The advantages of this research can be proved by the use of different sources including the macroeconomic factors as well as the internal factors like firm size and firms' financial quality which is calculated by eight separating variables.The impact of financial market development on financing choices of firms is hypothesized as below.

Hypothesis 1:Credit Growth Rate has positive relationship with leverage

Credit is one of the most important sources of fund for the growth of national economy especially developing countries like Vietnam. The growth of credit market is the fundamental requirement for any enterprises to expand production, raise productivity thus encourages the whole economy to develop(Richard Duncan, 2011). He explained that in the period of credit expansion, it is easier for consumers and businesses to borrow and invest. This is the reason for the increase in consumptions and jobs thus improvement in national income and economic growth.In contrast, the decline of credit market associated with bad debt is a sign of an economic depression.The study about bank loan supply, lender choice and corporate capital structure of Mark T. Leary (2005) proposed that the credit market development is one of important factors affecting the corporate capital structure. More specifically, he observed that leverage level of bank-dependent firms increased in the period of expanded bank credit while this level decreased in the period of credit crunch in which investment capital is difficult to obtain. He also postulated that considering credit market movements helps improve the understanding about corporate finance. JianfuShen and Michael Firth and Winnie P.H. Poon (2014) brought out new evidences about the credit supply to the firms' financing choice in China. It is found that the leverage level of large and state-owned firms in China moves with the same direction with the credit supply. With more available credit fund compared to small and private firms, large and stage-owned firms are less likely to use internal funds as well as fund from new stock issuance but rely more on debts. On the contrary, firms having limited access to the bank loans are supposed to depend on the availability of their own earnings and less likely to change their source of fund even when the credit expansion occurs.

Hypothesis 2:Interest Rate has negative relationship with leverage

Evidence reveals that one of the most closely observed variables in the economy all over the world is interest rate. The effects of interest rate spread from the individual choices such as whether to purchase a house or buy securities to the financing decisions of firms such as whether to utilize their funds contributing to the industrial facilities or to put their money into saving account. The fact remains that capital structure of a firm is not entirely free from the influence of interest rate.

A lot of researches studying about the relationship between interest rate and firm leverage choice have been proposed. Goldstein, Ju and Leland (2001) demonstrated that ideal capital structure is affected by the interest rate's changes. They also assert that interest rate is a significant factor contributing to the formation of firms' capital structure. Furthermore, their study show that an optimal level of leverage is the trade-off between tax advantage and insolvency cost associated with debt. Hyde (2007) proposes that interest rate's adjustment will lead to the changes in a firm's financial expense correlated with debt thus affecting the firm's cash flows.However, in the study of Rayan (2008) about financial leverage and firm value shows that there is no significant relationship existing between interest rate and firms' financing choices.

Hypothesis 3: Stock market development has negative relationship with leverage

It is recommended that the development of stock market supports the equity financing over debt financing while the banking development creates more motivations for the firms to finance by debt (Agarwal and Mohtadi, 2004).The stone corner of studying about the relationship between firm capital structure and the development of financial market is conducted by Maksimovic et al. (1995) in 30 countries for a period of 11 years from 1980 to 1991. The results indicated that there existed a significant negative correlation between stock market development and the firm level of leverage ratio. However, when the whole sample was broken down, some findings appeared. More specifically, the further development of developed stock markets causes the equity to substitute debt in financing choice. In contrast, as regards the developing stock markets, large firms engage more in leverage but this market development pattern does not significantly affect the small firms.

Studying about the stock market development and financing choices of firms, another research conducted by Bokpin and Isshaq (2008) about Ghana from 1991 to 2005 proposed some different results. According to their results, stock market development was found not to affect the substitution of equity for debt in financing choice. Furthermore, the study showed that the stock market liquidity is negatively related to the short-term debt ratio.

Hypothesis 4: Banking sector development has positive relationship with leverage

It is proposed by the financial intermediation theory that transaction costs and asymmetric information can be reduced through financial intermediaries as banks. Moreover, banks also create more opportunities for the firms seeking external financing. Evidence reveals that a lot of empirical and theoretical studies have existed studying about the relationship between firms' leverage and banking sector development.

Utilizing panel data from 21 developing countries in 18-year period, SumitAgarwal and Mohtadi (2004) found that stock market development is negatively related to level of leverage while banking sector development increases this variable. Moreover, they also asserted that the development of banking sector and stock market is more significant in the long-run compared to the short-run.

Hypothesis 5: Financial crisis has negative impact on leverage

In recession, a limited amount of funds provided by financial institution would intuitively make firms face more difficulties in achieving financing sources for their business. Evident by the financial crisis occurring in 2008 and 2009 caused a deep downturn in economic activity in the

US and many other nations (Deesomsak, et al., 2004).More specifically, many banks and financial firms went bankrupt when a large number of borrowers refused to repay their debt due to the sharp fall in house price. With the shock in banking and financial sector, a large number of individuals and firms decided to withdraw all of their deposits from the banks leading to a more serious situation. Consequently, banks and financial institutions started to sell out their own assets and limit the new lending which caused a credit crunch in the following period.

From the summary about financial crisis in 2008 and 2009, it is easy to see how this shocking event destroyed the economy in the US and other nations. One of the main purposes of this study is to examine the effect of financial crisis on the capital structure of listed manufacturing firms in Vietnam.

2.3. *Firm specific factors for control variables*

Firm Size

Many studies figured out that firm size has significant relationship with leverage. A study conducted by Deesomsak, et al. (2004) about the determinants of capital structure and the effect of Financial Crisis in 1997 to the Asia Pacific region asserted that larger firm have lower bankruptcy cost as well as stable cash flows and easier access to credit market therefore usually utilize debt to take full advantage of tax shield. In other words, firm size is positively related to leverage. Also studying about the determinants of capital structure, Huang, G. & Song, F.M. (2006) and Dragotă, I.M. &Semenscu, A. (2008) found a positive relationship between capital structure variables and firm size in China and Romani, respectively. They argued that large firms with good reputation and less asymmetric information usually prefer financing by debt over equity. On the other hand, Mazur (2007) discovered a negative relationship between level of leverage and firm size in the Polish companies. As significant impact of firm size on capital structure, this paper employs firm size as control variable.

Firm Financial Quality

Financial quality of a firm is one of the important indicators banks consider to reduce default risk when making lending decision, therefore the financial health of a firm is perceived to have impact on firm capital structure. This is proved by many credit rating agencies have developed their own model to measure the risk of default. Financial quality is supposed to have negative relationship with leverage (Donaldson, 1961).

The stone corner of credit risk measurement model was established by Altman (1968).A study about the relationship between leverage and firm value under the influence of financial quality was conducted by Cheng et al. (2011). The result indicated that the positive impact of leverage on firm value is stronger under the influence of better firm financial quality which is measured by Z-score.The paper uses financial quality model built by Altman (1968) for control variable as following reasons. The first, the model takes into account five financial ratios then provide a distinct score that can give more comprehensive picture of firm financial health than using single financial ratio. The model as following:

$Z = 0.012\ X1 + 0.014\ X2 + 0.033\ X3 + 0.006\ X4 + 0.999\ X5$

X1: Working Capital/Total Assets is a measure of the net liquid assets of the firm. Working capital is the difference between current assets and current liabilities. According to the study of Deesomsak, Paudyal, and Pescetto (2004), liquidity is expected to maintain a negative relationship with level of debt. This result is consistent with the pecking order theory saying that high liquidity often makes firms less willing to engage with debt. Another analysis made by Mazur (2007) also proposed that firms with high liquidity ratios prefer equity for their financing purpose.
X2: Retained Earnings/Total Assets is a measure of profitability. This measure is used as a part of financial quality.
X3: Earnings Before Interest and Taxes/Total Assets is a measure of the true productivity of the firm's assets, abstracting from any tax or leverage factors. It was postulated by Altman (1968) that this ratio is very suitable for the evaluation of firms' financial quality due to their ability to represent the earning power of firms' assets which deciding the existence of any firms.
X4: Market Value of Equity/Book Value of Total Debt
X5: Sales/Total Assets represents the ability of firms' management in using assets to push sales in order to revenue for the companies. This measure also helps firms to evaluate the efficiency of managers in dealing with challenges in the competitive environment.
The second, by using financial quality found by Altman (1968), we can rank all firms from the best to the worst financial quality. Firms have a Z score of greater than 2.99 clearly are regarded as non-bankrupt. Firms having a Z below 1.81 are all bankrupt. Firms having Z score ranging from 1.81 to 2.99 are considered as the "zone of ignorance" or "gray area".

3. METHODOLOGY

3.1. *Data and sample*

Being one of the most important sectors due to its remarkable contribution to country's GDP, manufacturing sector is chosen to target in this study. In manufacturing sectors, all the listed firms in Hochiminh Stock Exchange (HOSE) having available annual data during the period of 2006 to 2013 will be obtained. The companies with gap between years are removed from the dataset in order to get the best efficient observations to analyze. Moreover, the companies with no total debt are also excluded from the sample to ensure the precision of calculation method (the fifth ratio of Z score containing total debt as denominator so the number cannot be zero). Because the number of manufacturing firms listed in HOSE is not the same over time, the data utilized is unbalanced. The sample consisting different number of observations over 8 year-period generates a 492-observation panel data.

3.2. *Model development*

It is postulated by Alfred (2007) that capital structure of a company represents the percentage of debt and equity used to financing their business. Another definition coming from Kennon (2010) defines capital structure as the percentage of money in a business by type including equity capital and debt capital. Each type of these capitals has its own advantages as well as disadvantages. Capital structure is also mentioned by Firer, Ross, Westerfield and Jordan (2004) as the relative amount of debt and equity used to enhance their operation.

As regards the measure of capital structure, there is no universal agreement about this issue. Some researchers prefer a more comprehensive measure of debt which is total debt while some others utilize long-term debt; short-term debt is not widely used (Mazur, 2007). It is reported that the results achieved by using narrow and broad concepts are very similar or even better with the broader concept. Total debt over total asset has proved its efficiency in business research area through numerous studies conducted before by Alonso (2008), Chen (2002), and Chenget al. (2011) since it does not take into account the long-term or short-term behavior of any firms but only their total borrowings during the year. In another aspect, the use of book value of debt seems more reasonable compared to the market value of debt due to the difficulties in obtaining data (Graham and Harvey, 2001). In consistent with the above arguments, the measure of capital structure in this study is the total debt over total assets calculated with book values.

To analyze the impact of Financial Market Development on firms' capital structure, we use leverage model including one dependent variable and five explanatory variables (Credit Growth Rate, Interest Lending Rate, Stock Market Development, Banking Sector Development and Financial Crises) and two control variables (Firm Size and Financial Quality).

$$LEV_{it} = \beta_0 + \beta_1 SIZE_{it} + \beta_2 Z_{it} + \beta_3 CRE_{it} + \beta_4 BANK_t + \beta_5 INT_t + \beta_6 FC_t + \beta_7 STOCK_t + \varepsilon_{it}$$

Where:

LEV: Total debt/Total Assets

β_i: Coefficient for each of the independent variables

SIZE: Firm size

Z: Firms' financial quality

CRE: Credit Growth Rate

INT: Interest Lending Rate

FC: Financial Crisis Dummy Variable

STOCK: Stock Market Size

BANK: Bank Size

Table 1: independent Measurement

Variables	Measurement
LEV	Total debt/Total assets
SIZE	Natutal logarithm of Total assets
Z	Financial quality
CRE	Domestic Credit/GDP
STOCK	Stock market capitalization/GDP
BANK	Total banking assets/GDP
FC	Dummy variable (1 for 2008 and 2009; 0 for the other years)
INT	Interest lending rate

4. RESULTS AND DISCUSSIONS

4.1 Diagnostic test for Multicollinearity

One of the most popular problems in dealing with data in any researches is multicollinearity in which two or more explanatory variables of the model have linear relationships. Multicollinearity can lead to strange results when we want to determine how the exogenous variables independently contribute to the endogenous variable. Therefore, testing multicollinearity among independent variables help the research models avoid biased and unreliable results. The simplest testing strategy for multicolinearity is examining the correlation coefficient among pairs of separate variables. High correlation coefficient of equal to or exceeds 0.8 explains that these variables are highly correlated, causing serious multicolinearity problem. The correlation matrix shows that all the variables in this model can satisfy the multicollinearity testing which contribute to a reliable and unbiased model following (Appendices Table 2)

In addition, to have strong reliability indicating the absence of multicolinearity, variance inflation factor (VIF) is employed to examine the multicolinearity problem between regressors. It was proposed by Besley, Kuh and Welsch (1980) that the tolerance should be greater than 0.2 or at least 0.1, equivalents to VIF ≤ 10. The variance inflation factor (VIF) and the tolerance are both widely used as measures of the degree of multicollinearity. Several rules of thumb – most commonly the rule of 10 – associated with the VIF– are regarded by many practitioners as a sign of severe or serious multicollinearity but this rule has no scientific justification (Uriel,2013). With the mean VIF of 3.27 and no index exceeding 10, the result illustrates that there is nomulticolinearity problem in this dataset (Appendices table 3).

4.2 Fixed and random effects

There are two common assumptions made about the individual specific effect, the random effects assumption and the fixed effects assumption. Every company has its own characteristics (type of management, board of directors, ownership, age, reputation etc.) which may or may not affect the variable variation across entity. Random effects assume that the entity's error terms are random and uncorrelated with the independent variables which allows for time-invariant variables to play a role as explanatory variables. The fixed effect assumption is that the individual specific effect is correlated with the independent variables. From the fixed and random effect testing, the results indicate that there exist both effects in the model (Appendices Table 5).

To determine Random or Fixed effect model is appropriate, Hausman Test that has long been widely used will be conducted. The null hypothesis of Hausman test is that the random effect model is true so the coefficients are equal throughout the population. On the other hand, the alternative hypothesis proposes fixed effect model is more appropriate and reliable in which at least one coefficient distinct from others. The result of Hausman test is presented in Table 6. The Hausman test statistic comparing the random-effects estimators to the fixed effects estimators reports a value of 20.46 with the probability of 0.0043 which is less than 0.05. This implies a rejection of the null hypothesis indicating that fixed effect is appropriate in Model I.In addition, in order to receive the best results without biased and distortion, we have to conduct some tests before running the regression including Autocorrelation and Heteroscedascity.

Test for Heteroscedasticity

```
. xttest3

Modified Wald test for groupwise heteroskedasticity
in fixed effect regression model

H0: sigma(i)^2 = sigma^2 for all i

chi2 (91)  =    2.1e+07
Prob>chi2 =      0.0000
```

Homogeneity of variance of the residuals (constant variance) is one of the main assumptions of OLS regression. If the variances of residuals are not equal across observations, this model suffers heteroscedascity. With the presence of heteroscedascity, the OLS estimates are no longer BLUE which means OLS does not provide the estimate with the smallest variance. It is suggested by Greene (2000, p. 598) that heteroscedasticity within a fixed-effect regression could be detected by implementing the modified Wald test. The result indicates that there is the problem of heteroscedascity in the model.

Test for Autocorrelation

```
. xtserial LEV SIZE Z CRE STOCK BANK FC INT

Wooldridge test for autocorrelation in panel data
H0: no first order autocorrelation
    F(  1,       88) =    186.022
           Prob > F =      0.0000
```

Assumption three of the Classical Linear Regression Model is that the covariance between the error terms over time is zero which means that the errors are uncorrelated with one another. If the errors are not uncorrelated with one another, the autocorrelation problem occurs which may cause distortions to the efficiency of a regression model. Autocorrelation causes the standard errors of the coefficients to be smaller than they actually are and higher R-squared. The test shows that the existence of the autocorrelation problem exists. However, according to Oscar Torres-Reyna (2007) and Maryam Asghari (2013), serial correlation test is applied to panel data with a long period of time (20-30 years) and it is not a problem in a dataset with very few years.

In conclusion, with the existence of heteroscedasticity in prior fixed-effect regression model, it is crucial to have some robustness to this model to limit the biasness created by this friction. For that reason, fixed effect regression with robust option was carried out to provide robust coefficients restraining the distortions in the regression. The table of results is represented below:

LEV	Coef.	Robust Std. Err.	t	P>|t|	[95% Conf.	Interval]
SIZE	.1460776	.033641	4.34	0.000	.0792438	.2129114
Z	-.0334077	.0101904	-3.28	0.001	-.0536528	-.0131626
CRE	-.0619959	.0488426	-1.27	0.208	-.1590302	.0350385
STOCK	-.4833173	.1485899	-3.25	0.002	-.7785172	-.1881175
BANK	-.0361956	.0458324	-0.79	0.432	-.1272497	.0548585
FC	-.073942	.0247936	-2.98	0.004	-.1231988	-.0246852
INT	-1.114438	.4071806	-2.74	0.007	-1.923373	-.3055025
_cons	-1.241906	.4397291	-2.82	0.006	-2.115505	-.3683078

(Full table result is presented in Appendices Table 7)

4.3 Credit Growth Rate

Credit is one of the most important sources of fund for the growth of national economy especially developing countries like Vietnam. The growth of credit market is the fundamental requirement for any enterprises to expand production, raise productivity thus encourages the whole economy to develop. However, the result shows that credit growth rate has no statistical significant effect on capital structure of manufacturing sector on HOSE. The fact remains in Vietnam that when the credit market starts to grow, the money is pumped into the other economic sectors instead of manufacturing. More specifically, the fund is mainly distributed into real estate sector or some other services like personal loan due to the rising credit demand of Vietnamese people nowadays. This result is not consistent with the study of Leary (2005) as well as Shen et al. (2014) which considered the credit growth rate as an important factor affecting the corporate capital structure.

4.4 Stock market development

Stock market development is represented by the total stock market capitalization over GDP. This variable enters the regression with a negative size which shows an adverse relationship between stock market development and firm leverage level. The fact remains that a growing stock market creates conditions for the firms to take advantage of equity financing thus reducing the use of debt. The result proving the negative relationship between stock market development and debt ratio has received a lot of support from many researches and studies over time such as the study about financing choices conducted by Bokpin and ZanginaIsshaq (2008) in Ghana as well as the study of SumitAgarwal and Mohtadi (2004) over 11 developing countries. Furthermore, the study carried out by Jong (2007) also pointed out the indirect effect of country-specific factors including Stock market development substituting the financing choices of firms from debt towards equity. In the study of Demirgfic-Kunt and Maksimovic (1995), they also said that banks are really fearful of stock market development since this can lead to the decline in the volume of their business. The regression conducted in this study has shown that the fear of banks has come true when the debt ratio of firms tend to decrease associated with the development of stock market.

4.5 Banking sector development

The purpose of this study is try to prove that financing choice of firms is not only rely on their own characteristics, but also on their surrounding environment such as the growth of the economy, the stock market development as well as the size of banking sector. However, the result points out that there no significant correlation between banking sector and firms financing choices. This result is not consistent with the study of Sumit Agarwal and Mohtadi (2004) who found that banking sector development increases the level of leverage in the long run. The fact remains that regardless of the increase in banks' total assets; the change in total assets of manufacturing companies is a different matter and does not rely on the aforementioned phenomena.

4.5.1Financial Crises

The results for the impact of Financial Crises on Firms' financing choices provide evidence that a relationship does exist. The finding reveals that there is a negative correlation between financial crises and manufacturing firms' level of leverage. This result can be clearly explained by the failures of banks and financial institution activities in the economic depression. To be more detail, the firms found it very hard to finance their operation by debt provided by banks and financial institutions because of their lack of fund due to the huge withdraw by a large number of clients. Almost all countries around the world had to suffer the consequences of financial crises and Vietnam is not an exception.

4.5.1 Interest lending Rate

From the macro point of view, interest rate is an effective tool for the central bank to implement monetary policy thus regulates the relationship between saving, investment, inflation as well as economic growth. In other words, interest rate always has a great influence on the economy. As regard the micro perspective, interest rate plays a very important role affecting personal and corporate decision-making between saving and spending on production, lending or depositing money into the banks. Like many other researches and studies conducted before by Goldstein et al. (2001); Rayan (2008) and Hyde (2007), this variable is proven to have significant relationship with the dependent variable. The result indicates that there exists a negative relationship between interest lending rate and level of debt. As a matter of fact, when the interest rate climbs higher, firms will cut off financing by debt in order to reduce the financial expense as well as increase the overall profit.

4.6 Control variables

4.6.1 Firm size

Size effect is proved to have significant positive relationship with leverage. This result supports the trade-off hypothesis as one of the main reasons is that the stable cash flows of the big companies would help them to reduce the costs of financial distress caused by debt. Moreover, larger companies often have better access to the capital market and prefer to use debt financing over equity. The positive relationship between firm size and level of leverage is pointed out by a lot of prior research about capital structure. Hsiao, Jung-Lieh; Hsu, Ching-Yu; Hsu, Kuang-Hua (2009) argued that large firms with good reputation and less asymmetric information usually prefer financing by debt over equity. Furthermore, a research conducted by Deesomsak, Paudyal, and Pescetto (2004) about the determinants of capital structure and the effect of Financial Crisis in 1997 to the Asia Pacific region asserted that larger firms have lower bankruptcy cost as well as stable cash flows and easier access to credit market, therefore usually utilize debt to take full advantage of tax shield. Dragotă, I.M. and Semenscu (2008) and Huang, G. & Song, F.M. (2006) also discovered a positive relationship between level of leverage and firm size. Last but not least, Information signaling theoryalso supports the use of debt in the business sector.

4.6.2 Financial quality

Including the largest information to calculate, financial quality is one of the most important parts contributing to this paper. The result indicates that in Vietnam, firms with better financial quality would avoid financing by debt to take advantage of retained earnings as the first source of funds following to the pecking order theory or maybe they would issue more equity to penetrate into the growing stock market in Vietnam over years. It is supported by Donaldson (1961) that the more profitable firms tend to borrow less thanks to the internal finance they got from their business. Likewise, in the test conducted by Fama and French (2002), they found that the more profit firms can get the less leverage will they use which is in line with pecking order theory. Furthermore, the significant effect of this variable to firms' financing choices also shows that the Z-score model proposed by Altman (1968) can be applied in the case of Vietnamese Industrial Sector helping the management make better decision about capital structure based on the firms' financial quality.

5. CONCLUSION

In conclusion, there have been a lot of studies and researches about firms' financing choices for a long period of time since the first work of Modigliani and Miller in 1958. However, the consideration about macroeconomic factors' effects on firms' financing choices has just started in recent years and this topic seems to be very new in Vietnam. In recognition of this gap, this paper aim to examine the effects of financial market development on financing choices of firms from manufacturing sector listed in Ho Chi Minh Stock Exchange. This study collect data from 91 manufacturing companies listed in HOSE during the period of 8 years from 2006 to 2013 to catch up with the pace of financial market development including the most shocking event to all countries around the world – Financial Crises in 2008.

Three over five factors reflecting the financial market environment were shown to have considerable impacts on Firms' financing choices including Interest Lending Rate, Stock Market Development, and Financial crises. The remaining factor Banking Sector Development and Credit Growth Rate does not show its significant effect on financing choices of firms. Furthermore, firm specific factors consisting of firm size and financial quality also have significant relationship with firm capital structure.

In general, financing choices of firms from manufacturing sectors seem to be relatively sensitive to shifts in financial market environment over the period of 8 years from 2006 to

2013. Three factors related to the development of financial market within this study have been proven to have significant effects on financing choices of firms. However, there are still some limitations in this paper. At first, the research only investigatesthe impact of financial market development on manufacturing sector in Vietnam. Due to data availability, study period is just from 2006 to 2013 and this is not really convincing for the long term effect measurement. For further research, it is worth examining how financial market development impact on firm financing decisions when ownership structure of firms are put into consider as state – owned companies is the most unique forms of enterprises commonly existing in transitional economy like Vietnam. Furthermore, it is interesting to explore other macroeconomic factors beyond financial market such as inflation or the economy growth rate that may influence firm financing choices.

As capital market liberalization spreads internationally, the influences of foreign portfolio flows on local equity markets are worth being examined. The paper provides a quantitative assessment on the impacts of daily foreign flows on Vietnamese stock market returns (VN-index) in two different up and down trend periods from the end of 2005 to 2011. By combining three widely-used econometric tools which are Vector Autoregressive Models, Granger Causality Tests and Impulse Response Functions, we find several interesting facts. Firstly, almost significant relationships between foreign flows and market returns are very short-term, just in one or two days. Secondly, daily foreign gross purchases and gross sales are demonstrated to have a link with returns and to Granger cause them. On the contrary, foreign net purchases show no relation with market returns. Besides, among three measures of foreign flows, gross sales are demonstrated to have more significant correlation coefficients which spread over three samples (full sample, up and downtrend periods) with market returns. As a result, it could be argued that Vietnamese stock market returns are most sensitive to selling information of foreign investors. Finally, it is shown that market returns response positively (10-day accumulated response) to a random shock to both gross purchases and gross sales even though there are individually negative reactions in some days.
Keywords: Investment, Foreign Portfolio, Stock Market, Vietnam.

1. Introduction

Under waves of capital liberalization spreading globally, it is worth investigating the impact of the foreign portfolio flows on local equity markets. That is even highly justifiable in developing countries such as Vietnam where stock markets are usually small and illiquid, compared with wealthy foreign portfolio flows which account for a noticeable portion in Vietnamese stock market. Actually, there have been many rumors around the possible impacts of foreign flows on Vietnamese stock market returns, which somehow affects investors' psychology and trading strategy. However, not many academic studies about this issue have been conducted yet. It is, therefore, important to examine the relationship between foreign flows and equity market returns in Vietnam. As a result, this study aims to investigate whether foreign portfolio flows affect Vietnamese stock market returns or not and then figure out how they impact on the returns.

Evidences of foreign portfolio flows' impacts on emerging equity markets have been found by a number of researchers. Surprisingly, most of them come up with a fairly similar result which is a positive link between foreign flows and returns. Foot et al. (2001), after conducting a research on 44 different markets, conclude that foreign inflows predict equity returns positively in emerging markets (both short-term and long-term). Furthermore, they figure out that one-basis-point shock of foreign flows causes a 40 basis point increase in returns and the most increases are in the first 30 days or so. Bohn and Tesar (1996) also report the same finding. They use low frequency monthly and quarterly data and find out the positive relationship in emerging markets.

Besides, there have been detailed studies on a particular emerging stock market. Pavabutr (2004) conducts a comprehensive study about the impacts of foreign flows on Thailand stock market before, during and after Asian crisis in 1997, and on 2 different segments (most favorite and least favorite companies by foreign investors). Using a structural VAR to examine the dynamic relation between foreign flows and market returns, he then concludes that there is a strong contemporaneous link (positive) between flows and returns on daily and weekly basis but weakening as time passes (as an aggregate market scale). Clark and Berko (1996) also discover a statistically significant correlation between monthly foreign inflows and market returns in Mexico. They regress Mexican stock returns (Bolsa index) on foreign net purchases and find that "foreign purchases of 1% of market capitalization are associated with a 6 % rise in Bolsa index". On the other hand, Chakraborty (2007) just finds a slight cause running from foreign portfolio flows to market returns when studying foreign indirect investment (FII) flows in India equity market during the period from April 1997 to March 2005. Chakraborty tests a hypothesis that "monthly net FII flows as a proportion of previous month's BSE market capitalization does not Granger-cause monthly BSE National Index return" and only rejects that null hypothesis at 5 % level of significance.

This paper contributes to the literature by yielding a number of new findings on the relation between past foreign flows and aggregate stock market returns in Vietnam. Besides, such discoveries will provide domestic investors with more accurate information of possible impacts of foreigners' trading on market returns, which is helpful for them in making investment decisions.

The rest of the paper is organized as follows. Section 2 describes data and methodology employed. Section 3 presents results and discussion about the impacts of foreign portfolio flows on stock market returns. Results summary and conclusion are offered in section 4.

2. Data Description and Methodology

2.1. *Data*

Raw data consists of market index (VN-index), foreign gross purchases and gross sales of stocks, investment certificates both through dealing and put-through on a daily basis (on Hochiminh Stock Exchange only). The full dataset covers from October 26, 2005 to March 16, 2011. The study period starts from October, 26th, 2005 as this was the time the Decision No. 238/2005/QĐ-TTG of The Prime Minister Phan Van Khai become effective. This policy open more opportunities for foreign investors since it allows foreign investors to hold up to 49% (except banking industry: 30%) of the total listed shares of a firm on Vietnamese stock market compare with before only 30%. The policy started to be effective (effective on Sunday, October 23rd, 2005). The study breaks up such data into two sub-samples: the first is from October 26, 2005 to October 15, 2007 and the second is from October 16, 2007 to March 16, 2011 since the paper aims to explore the impact of foreign flows in different up and down trend period in stock market with relatively balanced observed window. The market index (VN-index) experienced a dramatic uptrend (bull market) during the first period and a downtrend (bear market) in the remaining time, in general. Those data are then processed properly to be employed in the proposed models.

- Daily aggregate gross purchases on day t (in VND billions) = foreign gross purchases (stocks and investment certificates) by dealings on day t + foreign gross purchases (stocks and investment certificates) by put-through on day t
- Daily aggregate gross sales on day t (in VND billions) = foreign gross sales (stocks and investment certificates) by dealings on day t + foreign gross sales (stocks and investment certificates) by put-through on day t
- Daily aggregate net purchases (in VND billions) = Daily aggregate gross purchases - Daily aggregate gross sales
- Daily market return is calculated as follows:

$$R_{mt}(\%) = \frac{VNindex_t - VNindex_{t-1}}{VNindex_{t-1}} * 100\%$$

Where

Rmt: Daily market return on day t

VNindext: VN-index on day t

VNindext-1: VN-index on day t-1

2.2. *Methodology*

The study follows these main steps: dynamic relation with unrestricted Bi-variate Vector Autoregressive Models (VAR), "Granger" causation with Granger Causality Tests, and shock response with generalized Impulse Response Functions (IRF).

The first step is to test variables to see whether they satisfy requirements of Vector Autoregressive Model which is the thesis's main model. VAR requires all its variables to be stationary. Therefore, stationary testing must be conducted first. Two popular unit root tests: Augmented Dickey-Fuller (ADF) and Phillips-Perron (PP) are employed to examine whether time series are stationary or not. If all variables are stationary at levels, i.e. I(0), then VAR models are able to be used. If not, i.e. integrated of order d>0: I(d), additional Johansen Co-integration Tests are needed. Co-integration tests are used to determine if there exists a long-run relationship between variables (Gurajati, 2004). If two variables (one is stationary and another is non-stationary at levels) are co-integrated then VAR will be still applicable. However, if two time series are both non-stationary at levels and co-integrated then Vector Error Correction Models (VECM) will be employed instead. In case of no co-integration found, such pairs of variables will not be included in the analysis.

Next, Bi-variate Vector Autoregressive Models (unrestricted versions) are employed to examine the dynamic relation between each of three flows measures (foreign gross purchases, foreign gross sales and foreign net purchases) and market returns on a daily basis. The focus of this study is the link between

past foreign flows and current market returns. While running the models, a caution should be taken in choosing lag-length to which the results are very sensitive. Akaike Information Criteria (AIC) is applied to choose appropriate lag-length. Specifically, the lag-length which has the smallest value of AIC is applied. In VAR models, correlation coefficients are estimated easily (by Ordinary Least Squared method) and such parameters help to explain the relation or correlation between lagged values of foreign flows and local market return. F-statistic (to test the null hypothesis that all coefficients in one equation are jointly equal to zero) is also examined to see whether the model is fit or not. Nevertheless, it should be noted that even in the case F-statistic is greater than F-critical value (null hypothesis is rejected), it does not necessarily mean that there is a relationship between past foreign flows and market returns. The fact that is that in one equation, there are two kinds of coefficients: those of past flows and those of past returns (see estimated VAR models below). Therefore, it can fall to the case that no coefficient of lagged values of foreign flows is significant, which indicates no relation, but at least one coefficient of past returns is statistically significant, which confirms past returns relate to itself. That is the reason why Granger Causality Tests are employed next to clarify the link.

The estimated VAR model for the analysis of foreign flows and market return is as follows:

$$F_t = a + \sum_{j=1}^{k} \beta_j F_{t-j} + \sum_{j=1}^{k} \gamma_j R_{m\,t-j} + u_{1t}$$

$$R_{mt} = a' + \sum_{j=1}^{k} \delta_j F_{t-j} + \sum_{j=1}^{k} \varepsilon_j R_{m\,t-j} + u_{2t}$$

Where

Ft: Aggregate foreign flows (gross purchases, gross sales or net purchases) on day t

Rmt: Daily market returns (VN-index)
a,a': Constant
$\beta,\gamma,\delta,\varepsilon$: Correlation coefficients
k: maximum number of lags
u1t, u2t: Zero-mean white noise disturbances

Thirdly, Granger causality tests are used to figure out the causal relationship (in Granger sense) between variables. Generally speaking, the main purpose of this test is to examine if past foreign flows "Granger" cause market returns by testing the joint hypothesis of equal-to-zero coefficients of lagged foreign flows. VARs' coefficients are argued to be interpreted more deeply by using Granger causality test. X is said to Granger cause Y if X helps in the prediction of Y, or put another way, if the coefficients on the lagged X are statistically significant. It should be noted that the statement X "Granger" causes Y does not imply Y is the result of X. Four possibilities are raised by Gurajati (2004): unidirectional causality from Y to X, unidirectional causality from X to Y, bilateral causality and independence.

Fourthly, Generalized Impulse Response Function will be employed to trace the effect of a one-time shock to one of the innovations on current and future values of the endogenous variables in VAR, that is, to investigate how market returns react to shock to foreign flows. In VAR models, a shock to ith variable does not only affect itself but also is transmitted to all other endogenous variables through the dynamic structure of VAR. There are different types of impulse in which Cholesky and generalized impulses are widely used. Each of them has its own characteristics. Cholesky impulse requires an advanced specification of variables' order and its results are sensitive to that order. On the other hand, generalized impulse has an advantage in that it is independent of the ordering of variables in VAR. Therefore, this thesis employs generalized impulse functions. In addition, IRF will not be carried out for all pairs of variables but just for those which are demonstrated to have causal relationship (from Granger Causality Tests).

Finally, so as to dip further into the relation, the same testing process is carried out for weekly data to see if there is any long-term link (Only important results of weekly data tests are to be presented and compared with daily ones). Weekly data are processed from daily dataset. Weekly variables such as weekly foreign gross purchases, foreign gross sales are computed as the same manner as daily ones but they are sum of five consecutive trading days. The procedure is applied for the full sample and two sub-periods on a weekly basis.

3. Impacts of Foreign Portfolio Flows on Vietnamese Stock Market Returns

3.1. *Dynamic Relation between Foreign Flows and Market Returns*

3.1.1 Foreign Gross Purchases and Market Returns

As can be seen from Table 1, past foreign gross purchases just have significant relation with market returns in the down trend period and full sample, not in the up trend period. No correlation coefficients (of specified lags) are statistically significant from 26/10/2005 to 15/10/2007 when VN-index experienced a dramatic uptrend, even though the joint hypothesis of equal-to-zero coefficients is rejected. Whereas, there is a positive link between past foreign gross purchases (lag 1) and daily market returns from 16/10/2007 to 16/03/2011. Coefficient of foreign gross purchases lag 1 is also positive in full sample but even greater and more significant than in the downward period. That is justifiable since the number of observations in the second period accounts for up to 63.23 % of the full period.

One striking point is that the relationship is very short-term and temporary in those samples (full and bearish period): only between yesterday foreign gross purchases (lag 1) and today return of VN-index. The following lags of foreign gross purchases (e.g. lag 2, 3, 4, etc.) do not have any significant correlation with market returns (except foreign gross purchases lag 8 which is in negative relationship with market returns).

Table 1: Bi-variate VAR of Daily Returns with Daily Foreign Gross Purchases (Partly)

3.1.2 Foreign Gross Sales and Market Returns

On the other hand, foreign gross sales seem to have stronger connection with market returns than the gross purchases. Compared to foreign gross purchases, all significant coefficients are higher.

As can be seen in Table 2, there is a positive relation between yesterday foreign gross sales (lag 1) and today market return in both up trend and down trend period and the whole period in which the most significant one is of full sample and the least is that of the second sub-period. However, the correlation is also short-term, mostly in day 1 and day 2.

Table 2: Bi-variate VAR of Daily Returns with Daily Foreign Gross Sales (Partly)

	FULL SAMPLE	1ST PERIOD 26/10/05 - 15/10/07	2ND PERIOD 16/10/07- 16/03/11
	DAILY_RETURN	**DAILY_RETURN**	**DAILY_RETURN**

t-statistic	[-3.06241]	[-1.01295]	[-2.71819]
DAILY_GS(-3)	0.00069	-0.00041	0.00133
t-statistic	[0.85130]	[-0.25945]	[1.38471]
DAILY_GS(-4)	-0.00033	-0.00081	0.00003
t-statistic	[-0.41226]	[-0.51310]	[0.02655]
DAILY_GS(-5)	0.00029	0.00157	-0.00007
t-statistic	[0.35382]	[0.99199]	[-0.06920]
DAILY_GS(-6)	-0.00119	**-0.00280***	-0.00053
t-statistic	[-1.54248]	[-1.87784]	[-0.58063]
F-statistic	**13.72128**	**4.59360**	**9.41555**
***, **, *** significance at 10%, 5% and 1%**			

Interestingly, there is a significant reversal (at 1% level of significance) in the relation between lag 2 of foreign gross sales and market returns in the second and full sample, which does not take place in the case of gross purchases. The reversal happens in lag 6 in the first period, however. This may indicate temporary price pressure effect. The price pressure hypothesis states that stock temporary changes in demand influence stock prices but when that change weakens, prices will come back to their previous levels.

3.1.3 Foreign Net Purchases and Market Returns

Table 3 illustrates VAR results of foreign net purchases and market returns which are totally different from what have been shown in the first two measures of foreign flows. No significant relation is found between past foreign net purchases and VN-index returns in all bull and bear period.

Table 3: Bi-variate VAR of Daily Returns with Daily Foreign Net Purchases (Partly)

	FULL SAMPLE	1ST PERIOD 26/10/05 - 15/10/07	2ND PERIOD 16/10/07- 16/03/11
	DAILY_RETURN	DAILY_RETURN	DAILY_RETURN
DAILY_NP(-1)	0.00022	-0.00017	0.00059
t-statistic	[0.38081]	[-0.15922]	[0.82132]
DAILY_NP(-2)	0.00056	0.00138	0.00027
t-statistic	[0.91706]	[1.13605]	[0.37569]
DAILY_NP(-3)	0.00058	0.00092	0.00029
t-statistic	[0.94326]	[0.75071]	[0.39227]
DAILY_NP(-4)	-0.00069	-0.00032	-0.00071
t-statistic	[-1.12279]	[-0.25323]	[-1.00314]
DAILY_NP(-5)	0.00035	-0.00086	
t-statistic	[0.57811]	[-0.70433]	
DAILY_NP(-6)	-0.00066	-0.00048	
t-statistic	[-1.08085]	[-0.39482]	
DAILY_NP(-7)	0.00038	-0.00039	
t-statistic	[0.66372]	[-0.38527]	
F-statistic	**10.80816**	**3.80288**	**13.02938**

***, **, *** significance at 10%, 5% and 1%**

In sum, three measures of foreign flows (foreign gross purchases, gross sales, and net purchases) have different relation with market returns. Only gross purchases and gross sales have positive link with returns but it is just temporary relation, just at lag 1. There is, however, a price reversal at lag 2 of foreign gross sales. In addition, almost correlation coefficients of past weekly foreign flows and weekly returns are insignificant, which strongly confirms the short-term relationship between past foreign flows and market returns. The inconsistency between the paper's findings and those of Foot et al. (2001), Clark and Berko (1996) could be explained partly by the fact that most investors in Vietnamese equity market are individuals who often follow short-term strategy in trading stocks. According to the Vietnam Association of Financial Investors, transactions carried out by individual investors account for up to 85 % of the total daily trading values, which is opposite to common situation in other countries. On the other hand, net purchases (specified lagged values), the real foreign cash inflows, do not associate with market returns. It is also worth noting that among three measures of foreign flows, gross sales are demonstrated to have more significant correlation coefficients which spread over three samples with market returns. As a result, it could be argued that Vietnamese stock market returns are most sensitive to selling information of foreign investors. Besides, two sub-samples give worthy results. It is shown from the tables that foreign flows (especially, gross purchases) correlate stronger with market returns in the second period when the general market went down and then partly recovered (there are more statistically significant coefficients and the F-statistic is also more significant in the second one).

3.2. *Granger Causality between Foreign Flows and Market Returns*

By analyzing correlation coefficients in unrestricted VAR models, the results can just come up with the relation between past foreign flows and market returns (correlation does not necessarily imply causation). In order to investigate the causality, Granger Causality Tests (pair wise versions) are employed for all measures of flows and in three samples. Actually, Granger Causality Tests are one of the helpful techniques to interpret VAR results. They also require users to specify lag-length. Consequently, the same lag-length used in VAR models is applied. Table 4 shows Granger Causality Tests for three types of foreign flows in the full sample. Theoretically, there are four possible results from Granger Tests: unidirectional cause from X to Y, unidirectional cause from Y to X, bilateral cause and independence, however, the causation running from past foreign flows to market returns is the paper's primary focus. Daily foreign gross purchases and gross sales are found to "Granger" cause market return (at 5 % level of significance) while there is not enough evidence for reject the null hypothesis that "Daily Net Purchases does not Granger cause Daily Return" in the full sample. Furthermore, it is found that the causality between foreign gross sales and market returns is unidirectional, that is, only gross sales "Granger" cause returns. Go back to what has been mentioned in the previous part, about price pressure effects. Since it is proven that changes in foreign gross sales are a source for changes in market returns in full sample, the price pressure effect shown by the reversal of VN-index returns in the previous part is confirmed more strongly. The finding is consistent with that of Pavabutr (2004) in Thai Stock Market.

Table 4: Granger Causality Tests of Foreign Gross Purchases, Gross Sales, Net Purchases and Market return (Full Sample-Daily)

Pair wise Granger Causality Tests
Sample: FULL SAMPLE_DAILY

Null Hypothesis:	F-Statistic	Probability
DAILY_GP does not Granger Cause DAILY_RETURN	2.17350	**0.02701**
DAILY_GS does not Granger Cause DAILY_RETURN	2.79847	**0.01041**
DAILY_NP does not Granger Cause DAILY_RETURN	0.70011	0.67205

As a result of Granger Causality Tests in full sample, it can be argued that changes in lagged foreign gross sales and gross purchases help explain changes in current market returns and therefore such flows can be used to help predict market returns in some stages in future.

On the other hand, there is no significant causation between three measures of foreign flows and VN-index returns in the case of two sub-periods (Table 5, 6).

Table 5: Granger Causality Tests of Foreign Gross Purchases, Gross Sales, Net Purchases and Market return (First Period-Daily)

Pairwise Granger Causality Tests
Sample: FIRST PERIOD

Null Hypothesis:	F-Statistic	Probability
DAILY_GP does not Granger Cause DAILY_RETURN	1.16815	0.31957
DAILY_GS does not Granger Cause DAILY_RETURN	1.61253	0.14169
DAILY_NP does not Granger Cause DAILY_RETURN	0.68219	0.68722

Table 6: Granger Causality Tests of Foreign Gross Purchases, Gross Sales, Net Purchases and Market return (First Period-Daily)

Pairwise Granger Causality Tests
Sample: SECOND PERIOD

Null Hypothesis:	F-Statistic	Probability
DAILY_GP does not Granger Cause DAILY_RETURN	1.35390	0.23957
DAILY_GS does not Granger Cause DAILY_RETURN	1.68732	0.12105
DAILY_NP does not Granger Cause DAILY_RETURN	0.47818	0.75179

Like the case of dynamic relation shown by VAR models, NO "Granger" causality running from net purchases to market returns is discovered, which could mean that Vietnamese equity market's returns are affected by foreign gross purchases and gross sales more strongly than the "true" cash inflows: foreign net purchases. That is inconsistent with some previous studies whose measures of foreign flows are net purchases scaled by market capitalization (Pavabutr, 2004, Foot et al., 2001). They all find the relation between net purchases and market returns in their samples.

3.3 Impulse Response Functions: How Does Market Returns Response to Shock to Foreign Flows?

After carrying out Granger Causality Tests and figuring out that foreign gross purchases and foreign gross sales "Granger" cause market returns, Impulse Response Function, another useful technique in VAR analysis, is used to investigate how VN-index returns react to shocks to foreign gross purchases and gross sales individually in the full sample.

Figure 1 shows visual illustration of the response and accumulated response in the whole period.

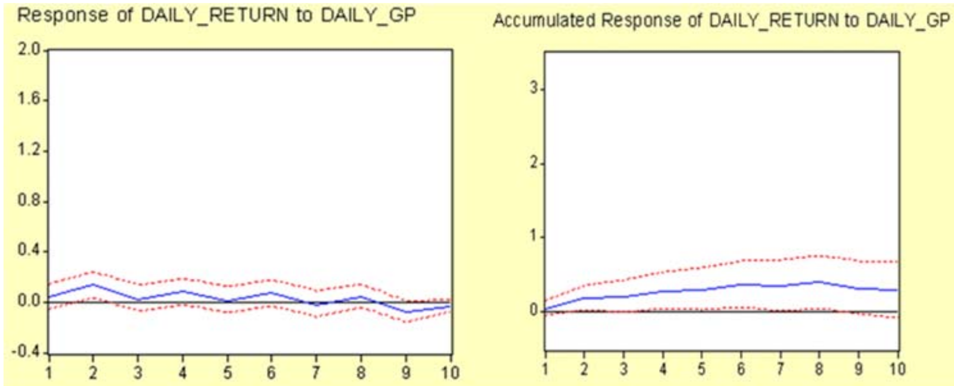

Figure 1: Response and Accumulated Response of Daily Market returns to Shocks in Daily Foreign Gross Purchases (Full Sample)

In general, the reaction of market returns to foreign gross purchases shocks is fluctuated over a 10-day period. Specifically, one standard deviation increase in gross purchases residual makes the current market returns (period 1 in IRF represents for contemporaneous response) go up by 0.043 units or 0.043 %, day 2's market returns will increase by 0.138 % which is the highest, the response of market returns on day 3 is down to 0.023 %, even though it is still positive, and then peaks to 0.08 % on the next day, etc., which indicates that the daily reaction is short-term and unstable. Actually, in VAR result Table 1, the correlation coefficients also experience the same thing but none of them (except lag 1 and 8) are statistically significant. The accumulated effect of the first 6 days is 0.37 %. The reaction is, however, negative on day 7, day 9 and day 10. The accumulated response after 10 days, therefore, is only 0.286 %.

As shown Figure 2 which describes responses of market returns to foreign gross sales shocks, there are some interesting points to be noted.

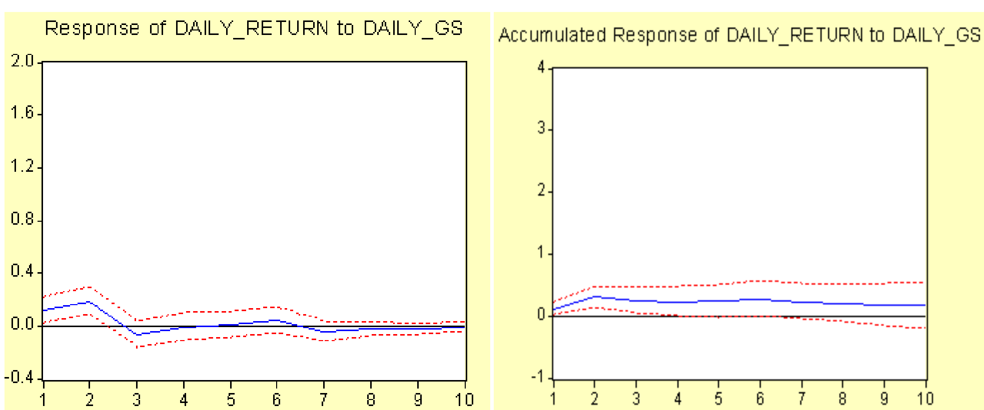

Figure 2: Response and Accumulated Response of Daily Market return to Shocks in Daily Foreign Gross Sales (Full Sample)

First of all, daily market returns react to foreign gross sales more strongly than to gross purchases on day 1 (contemporaneous response): increase by 0.1185 units (or %) compared with only 0.04 units. However, the figure is not as fluctuated as that of gross purchases. There is usually a reversal after 2 days.

In addition, the daily reaction weakens as time passes and not significant from day 4 on, which shows the short-term reaction of market returns. The strongest responses are on day 1 and day 2 with positive reaction at approximately 0.12 % and 0.18 % increase in daily market returns. However, returns on day 3 and 4 react negatively to a rise in foreign gross sales: reduce slightly by 0.066 % and 0.007%. Positive reaction is then found on the next two days and then market returns will go down for a rise in foreign gross sales in the remaining period (day 7 to day 10). The accumulated response after 10 days is 0.166 %, just over half of the accumulated reaction of market return to shock to foreign gross purchases.

4. Conclusion

As demonstrated in the paper, past foreign flows do have specific relationship and impacts on Vietnamese stock market returns. Both past values of daily foreign gross purchases and gross sales are demonstrated to have significant relationship with daily market returns. However, such relation is short-lived, mostly just in 1 or 2 days. Generally speaking, there is a positive link between yesterday foreign gross purchases as well as yesterday foreign gross sales and today market returns (except gross purchases in the first period). Moreover, a strong negative relationship is found between lag 2 of foreign gross sales and market returns in second and whole sample. Surprisingly, past foreign net purchases do not show any connection with stock market returns, demonstrating that Vietnamese equity market returns are affected by gross flows more strongly than by net flows which are the "true" cash inflows of foreign investors. Furthermore, among three measures of foreign flows, gross sales are found to have more significant correlation coefficients which spread over three samples with market returns. As a result, it could be argued that Vietnamese stock market returns are most sensitive to selling information of foreign investors. When it comes to Granger Cause then only gross purchases and gross sales in full sample are found to cause returns. Consequently, those two flows are applied in Impulse Response Functions and the results indicate that market returns response positively (10-day accumulated response) to a random shock to both flows even though there are individually negative reactions in some days.

It is found that both lagged values of daily foreign gross purchases and gross sales have a significant relationship with daily market returns. However, such relationship is short-lived and temporary, mostly just at lag 1 and 2. In addition, when running tests with weekly dataset, almost correlation coefficients of past weekly foreign flows and weekly returns are insignificant. This is inconsistent with those of Foot et al. (2001): "The majority of price increases do not occur over a short period of time, such as a few days. Prices seem to rise subsequent to inflows for a month or two" and Clark and Berko (1996) who find a statistically significant correlation between monthly foreign flows and market return in Mexico. Particularly, there is a POSITIVE link between yesterday foreign gross purchases, yesterday foreign gross sales and today return of VN-index (except gross purchases in the bull market from 26/10/05 to 15/10/07 when the positive connection is proved to be insignificant). On the other hand, there is a significant price reversal

(NEGATIVE) at lag 2 (the day before yesterday) of foreign gross sales which may indicate temporary price pressure effect like in Thai stock Market (Pavabutr, 2004). Surprisingly, no significant relation between past foreign net purchases and market return is discovered , which is not in line with some previous studies whose measures of foreign flows are net purchases scaled by market capitalization (Pavabutr, 2004, Foot et al., 2001). In addition, both past foreign gross purchases and gross sales are found to "Granger" cause market return in the full sample (from 26/10/05 to 16/03/11) and those two flows have a 10-day POSITIVE accumulated impact on return of VN-index.

quan_vdh@yahoo.com
This study aims to examine the effectiveness of gold hedging against inflation in long-run in Vietnam over the period of January 1995 to July 2014. By applying a new and innovative technique – threshold co-integration test instead of linear co-integration test – to the relationship between Vietnam's gold price and consumer price index (CPI), the research figures out that gold does provide a complete hedge against inflation in long-run. However, the gold inflation relationship in long term is unstable. The linkage between gold and inflation is found to be non-linear co-integration. The results could benefit both Vietnamese monetary policy makers and investors who hold Gold in their portfolios. Moreover, in order to have a broader view on inflation- hedge of gold across SEA countries, the research also conducts studies on Thailand since the country has quite similar economic backgrounds with Vietnam.

1. Introduction

Investors now become more and more aware of excessive risks due to the unstable market caused by recent financial crises. As a result, they try to look for financial assets which not only can act as profitable investment assets but also are able to preserve themselves from unexpected events. Many popular financial assets such as real estate, government bond, oil, etc. no longer protect fully investors because of the unprecedented crises that the world is facing now. That brings back the interest in Gold, which was a financial asset that received little attention despite its historical role of being a standard of value in many countries' economy. Gold proved itself as a foundation stone of the international monetary system through the popular of the Gold Standard in the 19th century and the Bretton Woods system in the 20th century. Since the Bretton Woods system collapsed in 1971, Gold's role has diminished but still remained an important asset in the reserve holdings of many developed countries and now become an investment asset that attracts a lot of attentions from not only investors and authorities but also from researches. Many in depth studies have been done on the dynamics of gold price. Among them, the researches on the ability to hedge against inflation become the most controversial topic.

Indeed, almost studies on gold price have doing researches mainly on the U.S. During the 20th century, it is shown that there is the economic power shifts from U.S. toward fast growing emerging economies, especially in Asia. Furthermore, in these countries, the traditional mindset of gold as a store of value has existed for decades. Indeed, India, China, Indonesia, Thailand, Vietnam are always in top of gold consumer or producer countries according to World Gold Council. Hence, there is still a need to study this field in Asian countries.

In the case of Vietnam, the role of gold overall monetary policies and in stabilizing the economy is debatable. Vietnamese people consider gold as second currency and a safe haven of wealth for decades. The reasons for this can be explained by the history of Vietnam's economy that has changed from closed to open. In addition, the economic chaos in the 1980s has caused hyperinflation and prevalent distrust of the local currency. As a result, gold, U.S. dollar and other strong currencies have been used parallel to store wealth and conduct major transactions. The series of economic reforms named "DoiMoi", enforced in the second half of the 1980s, the faith of the Vietnam Dong was rebuilt to some extent but the usage of U.S. dollar gold still remains common until today (Siregar & Nguyen, 2013).

In summary, there seems to be a strong belief that gold can provide protection as a hedge or a safe haven against high Inflation. However, to the author's knowledge, hardly any studies has been done on these issues in Asian countries. While inflation has been the focus of many recent works, only one of them have explored the role of gold in hedging against inflation in the country (Le Long, De Ceuster, Annaert, and Amonhaemanon, 2013). On the other hand, this previous research applies the conventional technique which is regression model. Therefore, adopting the innovative technique of co-integration – threshold co-integration approach, this paper aims to examine the relationship between gold price and inflation in Vietnam. Strictly speaking, the research's framework allows for non-linearity, providing a useful measure of the effectiveness of inflation-hedging of gold. Moreover, in order to have a broader view on inflation-hedge of gold across SEA countries, the research also conducts studies on Thailand since the country has quite similar economic backgrounds with Vietnam. Besides, Thailand is also one of the major gold consumer country in the world.

2. Literature Review

In 1930, the theoretical study on the relationship between gold price and inflation was established by Fisher (1930). Fisher's hypothesis, generalized to other investment assets, implies that the expected nominal return on any investment asset expected to be equal to its real return plus the expected inflation rate. Shortly after, Fama and Schwert (1977) had carried out a study to examine the historical return on a numerous assets over the period 1933 to 1971 to explore which asset could have been used to protect investors' wealth against both expected and unexpected inflation. Their results confirmed only residential real estate was a perfect hedge against inflation but their works had inspired and opened a new field of research with plenty of techniques for following researchers.

Literature on the relationship between gold price and inflation has been through three stages of development.

(1) In the early stage, many empirical studies had attempted to justify the value of gold as an inflation-hedging asset through traditional techniques such as regression model, linear co-integration test or error correction models. The study conducted by Chua and Woodward (1982) is the first one testing gold's effectiveness as inflation hedge. By regressing nominal gold returns on both the expected and unexpected inflation, they conclude that gold can effectively hedge against inflation for the U.S., but not for the others. Mahdavi and Zhou (1997) apply co-integration and vector error-correction models (VECM) to the relationship and find no evidence of co-integration between gold price and CPI. Ghosh, Levin, Macmillan, and Wright (2004) take a more intricate technique by including endogenously determined structural breaks into model. The results indicate that there is a co-integrated relationship between gold and inflation for both post war period and since the 1970s. Later, by using the same technique, Levin, Montagnoli, and Wright (2006)expand the previous research to many countries and come to two critical findings. First, there is a stable long-run relationship between the gold price and the price level. Second, in the major gold consuming countries such as Turkey, India, Indonesia, Saudi Arabia, and China, gold acts effectively as a long-term hedge against inflation. In an effort to provide more significant evidence across countries, Tkacz (2007) discovers that gold price contains significant information for future inflation in several countries, especially in those that have adopted formal inflation targets.

(2) After those prior literature on the significant of this relation, it is debatable that conventional co-integration techniques are unable to prove the existence of a stable long-run relationship between gold and inflation since they ignore the noteworthy structural changes associated with the transition of gold from being the basis of the global monetary system to be treated as a commodity. Furthermore, except two major structural changes in gold price since the early 17th consist of the breakdown of Bretton Woods in 1973, oil price shocks in 1973 and 1979/1980, the relationship between consumer prices and gold prices also undergone several serious crises comprise the collapse of Soviet Union in 1991, the burst of the 'dot-com bubble' in 2001 and the recent financial and economic crises started in 2007. For those reasons, the traditional co-integration and VECM methodology seems to be too restrictive. As a result, in the beginning of 20th century, researchers around the world tried to compare and contrast these two techniques in their paper and argued which is the suitable one. Kyrtsou and Labys (2006) use cross-validation of the non-linear co-integration test (bivariate noisy Mackey-Glass Model) with linear co-integration test (VAR) on the U.S inflation and commodity prices. Worthington and Pahlavani (2007) provide evidence in favor of a co-integrating relationship between the price of gold and inflation and help to conclude that a gold investment can serve as an effective inflationary hedge. By applying three tests at the same time

(Johansen co-integration, Single equation error-correction model, Co-integration with structural breaks), Batten, Ciner, and Lucey (2014) show there is no co-integration between gold and inflation if the volatile period of the early 1980s was excluded from the data. Even though their research is not actually examining directly the relation between Gold price and Inflation, they contribute to the argument that linear test cannot provide an adequate result. Generally speaking, these above studies confirmed that ignoring such substantial changes in the relationship between variables could yield to the inability of proving the existence of a stable long-run relationship. Therefore, recent researches have developed a new advance testing method that focus on the possibility of existence of non-linear co-integration between two variables.

(3) The first study that seriously considers the possibility of non-linearity in the inflation hedging relation is provided by Wang, Lee, and Thi (2011). They argue that the existence of transaction costs and the business cycle dependence of the gold demand possibly result in a nonlinear relationship between consumer prices and gold prices. For that reason, they account for nonlinearity based on the threshold co-integration framework. In detail, they analyze the short-run and long-run inflation hedging effectiveness of gold in the USA and Japan for a sample period ranging from January 1971 to January 2010 by conducting two co-integration test: linear test proposed by Engle and Granger (1987)as well as the nonlinear threshold co-integration test suggested byEnders and Siklos (2001). The evidence demonstrate that a gold investment was able to hedge against inflation in the USA, and partially hedged against inflation in Japan. Due to their significant findings and innovative techniques, this research will mainly adopt their procedure to test the relationship in the context of Vietnam and Thailand. In addition, there is one research regarding non-linear co-integration test also need to added into the literature, which is the “Gold as an inflation hedge in a time-varying coefficient framework” of Beckmann and Czudaj (2013). Even though their research does not completely turned into non-linear co-integration test, they already applied the Bi-variation co-integration test and Markov switching vector error correction model (MS-VECM) approach. They conclude that gold is partially able to hedge future inflation in the long-run and this ability is stronger for the USA and the UK compared to Japan and the Euro Area. The advantage of using the non-linear model also is found in describing the dynamic of other connections, for instance, Gold and Dollar (Capie, Mills, & Wood, 2005), Purchasing Power Parity (Heimonen, 2006), Stock Price and Dividends (Esteve & Prats, 2010), Gold and The Yen (Wang & Lee, 2011).

In conclusion, the empirical evidence of the relationship between gold and inflation worldwide is still controversial. Theoretically, most of previous studies supported this relationship. That is, the price of gold tends to move in the same direction and positive correlation with CPI. When inflation occurs, gold will become "safe haven" for investors. However, recent empirical evidence also suggests that this relationship is not clear and sustainable; gold is not completely hedge against inflation. This relation depends very much on place and time the study surveyed. Thus, the questions here are not only on does gold act as an inflation hedge, but also on how well it is. Besides, the previous approaches of authors are varied and different. Recent researches have put efforts on discovering new techniques in attempting to reflect more accurately the nature of this relationship. For that reason, this paper wants to adopt the new testing method of Wang et al. (2011) to present further asymmetric impact on the relationship between CPI and gold prices in long term in Vietnam.

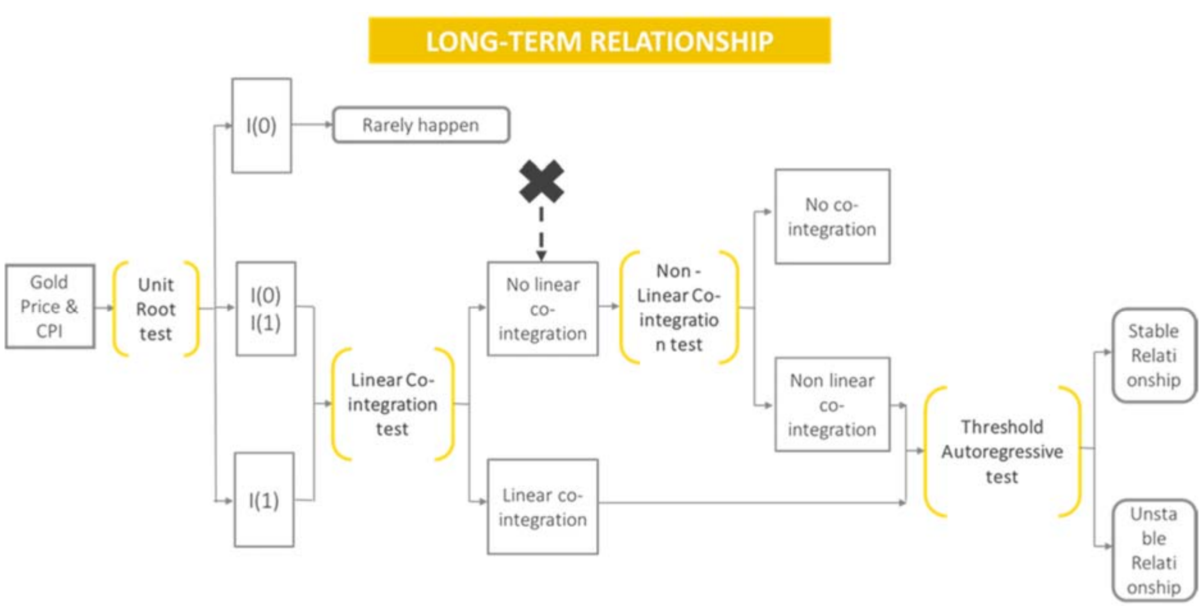
3. Data & Methodology

3.1. *Data collection*

To understand the inflation hedge ability of gold in Vietnam, monthly data of gold price from World Gold Council (per ounce denominated in Vietnam Dong) and CPI from International Monetary Fund (IMF) over the period of January 1995 to July 2014 are used for analysis. The monthly data of Gold Price published in the newest report called World Gold Council Value Research & Statistics Database on 22nd September, 2014 are used. It presented the price of gold per ounce denominated in Vietnamese Dong based on the London PM Fix. The source for CPI is monthly Vietnam CPI from International Financial Statistics of International Monetary Fund (IMF). From the report, the year 2010 was chosen as the index year. The sample period is also from January 1995 to July 2014, which yields 245 observations. Raw data from above sources will be processed appropriately depends on the applied models. First of all, they all will be transformed into natural logarithms.

3.2. *Methodology*

The paper examines long-term relationship between two variables by using both linear and non-linear techniques. The conclusion will be on the ability of gold in hedging against inflation in the long-run. The unit root test is applied first to the log of gold prices and CPIs. When the variables meet the precondition of integrated at the same level, the Engle and Granger linear co-integration test is applied next. Then, to allow for asymmetric adjustment, Enders and Siklos non-linear co-integration test is used to check for stable non-linear relation.



3.2.1 Unit root test:

In applied econometric, most statistical testing method are under assumption of the stationary series.

Because with the properties (means, variances and co-variances) that did not change over time, the data would be easy to predict, and hence, can be modeled and forecasted. On the other hand, the outcomes achieved from the non-stationary series can be spurious since they may indicate a relationship between two variables that does not exist.

As a result, there are a lot of tests which is called unit root test to check whether these variables are stationary or non-stationary. The most common and basic unit root test is the Dickey – Fuller test (Dickey & Fuller, 1979). However, comparing different results from different tests is always a good idea to avoid any bias from the tests and also takes advantages of all kinds of them. Therefore, four testing methods will be applied in this research to identify whether the series is I(1) – integrated in first order – which is most economic data should be or I(0) – stationary. They are Augmented Dickey-Fuller (ADF) (Dickey & Fuller, 1979), Phillips-Perron test (Phillips & Perron, 1988), Dickey Fuller Generalized least squares (GLS) test (Elliott, Rothenberg, & Stock, 1992) and NP-MZ_α(Ng & Perron, 2001).

The tests applied to the natural log of gold price and CPI. The null hypothesis H0 of all tests is having unit root (non-stationary) against the alternatives of stationary series. The equation contains both constant and time trend. The optimal lags are selected according to Akaike information criterion (AIC).

Nevertheless, it is noticed that most economic and business data, particularly financial time series data (such as inflation, macroeconomic indicators, GDP, exchange rate, etc.) are far from stationary, especially in their original units of measurement (Nelson & Plosser, 1982). Therefore, the term "co-integration" was coined to capture the possibility of the existence of long-term relationship between economic series. Two or more variables are considered to be co-integrated when first, all of them have to be integrated in the same order (d), which means it is stationary after differenced "d-times".(Ghosh et al., 2004).

3.2.2 Engle and Granger linear co-integration test

To study the long-run relationship between gold price and CPI, the research uses the concept introduced by Engle and Granger (1987).

According to the research of Wang et al. (2011), the long-run relationship regression between Gold price and CPI is given by:

$$g_t = \theta_0 + \theta_1 p_t + e_t \qquad (1)$$

whereg_t represents for the log of gold price, $p_t$is the price; $\theta_1$is the hedging coefficient that denotes how well gold investment could hedge against inflation or the cross-price elasticity between gold price and CPI and e_t is the error term.

To perform stationary test on the residuals, Engle and Granger used ADF test on following regression with different critical value by MacKinnon (1991):

$$\Delta e_t = p e_{t-1} + \varepsilon_t \qquad (2)$$

whereε_t is the white – noise disturbance.

If the residuals is stationary, there is a linear co-integration between two variables, which means a significant long-run relationship between them. If not, we cannot found any linear co-integration between CPI and Gold Price. However, the standard co-integration framework in equation (2) is misspecified if the adjustment process is asymmetric. For that reason, Enders and Siklos (Enders & Siklos, 2001) proposed the asymmetric (nonlinear) adjustment model to capture the possibility of non-linear co-integration. These tests will be used in this research for the same purpose.

3.2.3 Non-linear co-integration Enders and Siklos test

Due to the drawbacks of linear co-integration test, Enders and Siklos (2001) extended the Engle and Granger (1987) methodology by taking into account asymmetric adjustment. The proposed adjustment models were called the threshold autoregressive (TAR) model and the momentum threshold autoregressive (MTAR) model:

TAR is given by the equation:

$$\Delta e_t = I_t p_1 e_{t-1} + (1 - I_t) p_2 e_{t-1} + \varepsilon_t \qquad (3)$$

Where I_t is the Heaviside indicator such that $I_t = \begin{cases} 1 \ if \ e_{t-1} > \tau \\ 0 \ if \ e_{t-1} \leq \tau \end{cases}$

While MTAR is given by the equation:

$$\Delta e_t = M_t p_1 e_{t-1} + (1 - M_t) p_2 e_{t-1} + \varepsilon_t \qquad (4)$$

$$M_t = \begin{cases} 1 \ if \ \Delta e_{t-1} > \tau \\ 0 \ if \ \Delta e_{t-1} \leq \tau \end{cases}$$

The coefficients p_1 and p_2 represent the different speeds of adjustment for the deviations from the long-run equilibrium. τ is the threshold value, which is unknown and estimated by a search method as proposed by Chan (1993). The TAR model imparts an abrupt non-linear behavior depending on whether the error-correction term is above or below the threshold value, while the MTAR model allows different behavior depending on whether equilibrium deviations are rising or falling. In both models, to test for threshold co-integration, the φ statistic using a non-standard F-statistic is applied first. The null hypothesis of the first test is no co-integration, H_0: $p_1 = p_2 = 0$. The critical value are tabulated in Enders and Siklos (Enders & Siklos, 2001) for both TAR and MTAR specifications. If the null hypothesis is rejected, the next test using a standard F-statisticH_0: $p_1 = p_2$ is implied to check the symmetric or asymmetric adjustment in long-term. Combining both the results of two tests, we will get the final conclusion on the non-linear relationship between gold price and CPI in long-term, which are:

- If the null hypothesis of the first test (no co-integration) is rejected and the null hypothesis of symmetric adjustment of the second test is not rejected, the long-term relationship with symmetric adjustment is recognized. The Engle and Granger model is supported.
- If both null hypothesis is rejected, the threshold co-integration is founded, meaning that the long-term relationship with asymmetric adjustment is recognized. The Threshold Vector Error Correction Model can be applied next to test for short-run.
- If the null hypothesis of the first test is accepted, there is no co-integration between two variables.

4. Empirical results

4.1 Unit Root Test

The results are presented in Table 1. In general, almost all unit root tests reveal that two series are integrated of order one (1). To avoid spurious outcome, the co-integration analysis is conducted next.

4.2 Engle and Granger linear co-integration test

[1] Note: The tests are applied to the natural log of gold price and CPI. The null hypothesis H_0 of all tests is having unit root (non-stationary) against the alternatives of stationary series. The equation contains both constant and time trend. The maximum lag applied is 17 periods as followed the previous research of Wang et al. (2011). The optimal lags are selected according to Akaike Information Criterion (AIC). Four methods include Augmented Dickey-Fuller test (ADF), Phillips-Perron test (PP), Dickey-Fuller – Generalized Least Squares test (DF-GLS), Ng and Perron (NP-MZα)

Table 2. The result of Linear Co-integration Test

Engle–Granger Co-integration test and Co-integration parameters				
Vietnam	**Dependent Variable**	**θ0**	**θ1**	**ADF Test on residuals**
	LNG	**7.896827*****	**1.929461*****	-1.855161
	P-value	0.0000	0.0000	0.6744
	R^2	0.958598		
Thailand	**LNG**	**-5.436157*****	**3.441181*****	-3.043881
	P_value	0.0000	0.0000	0.1227
	R2	0.918231		

The regression equation gives the first look at the relationship between Gold price and Inflation in long-term. θ1 = 1.929461 for Vietnam tells us that when CPI rises 1%, the gold price in Vietnam dong rises 1.929%, showing the complete inflation hedge of gold. In contrast, θ1 = 3.441181 in Thailand tells us that when CPI rises 1%, the gold price in Bath rises 3.44%, showing the complete inflation hedge of gold in both countries. However, both series are non-stationary, which might lead to spurious problem. Thus, to get the most reliable economic relationship between two variables, the co-integration will be employed by testing the stationary of residuals.

The results displayed in table 2 suggest the absence of linear co-integration between Gold price and CPI in Vietnam because we cannot reject the null hypothesis of unit root (p-value = 0.6744). The similar result is explored in Thailand. The insignificant of ADF test on residuals tells us that there is no linear co-integration between Gold price and Inflation in Thailand as well.

4.3 Non-linear co-integration Enders and Siklos test

Table 3. The result of Non-linear Co-integration Test

	Model	N of lags	$H_0: p_1 = 0$	$H_0: p_1 = p_2 = 0$	τ (tau – Threshold value)	$H_0: p_1 = p_2$
			t-Max	Φ		F-equal
Vietnam	TAR	14	-0.914066	6.319635	0.173862	8.382464
	MTAR	14	-0.962327	6.124746	0.032502	8.000346
Thailand	TAR	2	-1.49232	4.424558	0.180446	0.754726
	MTAR	2	**-1.831807****	4.464834	0.035147	0.832524

The results summarized in table 3 uncover the null hypothesis of no co-integration (H_0: p_1= p_2=0) can be rejected at 10% level of significance in TAR model. The study continues to employ the second test for null hypothesis of stable non-linear long run relationship to assess whether the adjustment to the long-run equilibrium is symmetric (H_0: p_1= p_2) or asymmetric (H_1: $p_1 \neq p_2$). The F-value equals 8.382464, significance at 5% level, suggests asymmetric adjustment for Gold price and CPI in long-term in Vietnam

To sum up, in the test of co-movement towards the long-run equilibrium between gold price and CPI, the outcomes suggest non-linear co-integration or asymmetric adjustment between two variables. In the case of Thailand, the results from the similar testing procedure is inconsistent with the results from Vietnam. The non-linear relationship is significantly only in one test t-Max ($H_0 : p_i = 0$) in MTAR model. Consequently, there is no significant evidence of the presence of the non-linear co-integration between gold return and inflation in Thailand.

5. Discussion

As found in the previous section, the results seem to support the assumption that gold should be effective in hedging against inflation. However, a deeper look into the gold price and data of Vietnam during the last ten years will probably request us to be more prudent before jumping into the conclusion that gold's effectiveness in hedging against inflation should be the same in different time-frames: short-term vs. long-term consideration.

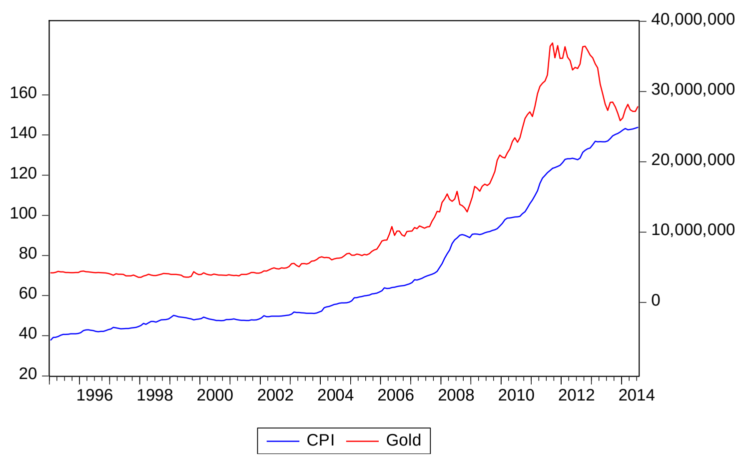

Figure1.The trend of Gold Price and CPI in Vietnam from 1995 – 2014

Figure 1 illustrates that both gold price and CPI are on an upward trend, especially during the 2007 financial crisis, both increase significantly, indicating the possibility of inflation hedging of gold in Vietnam. However, gold price experiences more fluctuation than CPI over the period. While gold price reached to its highest peak at around 36 million VND in September 2011 before decline in 2012 and 2013 due to government's controlling action, CPI kept on increasing steadily. This might affects the hedging ability of gold, especially in short-term.

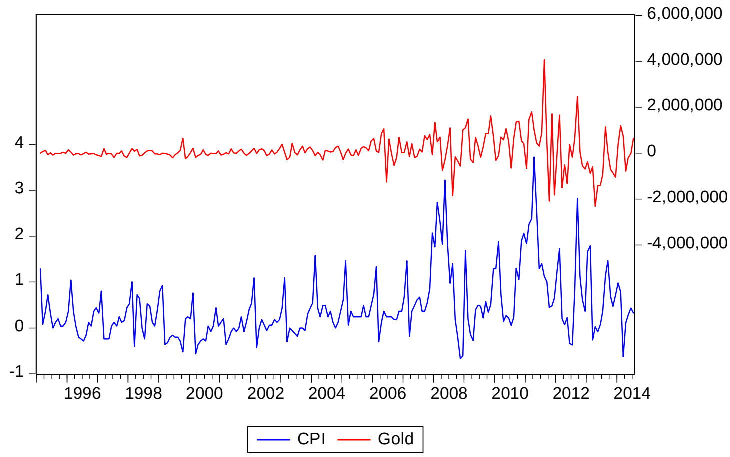

Figure 2: **The volatility of Gold Price and CPI in Vietnam from 1995 – 2014**

Figure 2 shows that there is a wide gap between the movement of CPI and gold price, which implying the possibility of different short-run adjustment between gold price and CPI.

In short, Fig.1 exhibits that the relation between gold price and CPI in Vietnam might exist the long-run trends. Meanwhile, fig.2 illustrates the presence of price rigidity in short-run. Hence, the analysis process should go further by composing two sections to verify separately long-term and short-term relationship.

6. Conclusion

In general, the findings of this research support the argument that gold is an effective tool for hedging inflation in long run from developed countries such as United State or Japan, to developing countries such as Thailand or Vietnam. However, the relationship can vary from country to country and usually be unstable. For instance, the relationship between gold price and inflation in Vietnam is found to be stronger than that in Thailand, implicitly showing the gold investment behaviors in Vietnam is more crucial than that of neighboring country.

This study contributes to the existing literature in a number of ways. Firstly, most previous studies took a developed countries perspective like the U.S or Japan. By investigating the inflation hedge capacity of gold investment for a developing country, where financial market is much less developed and other inflation hedge assets are less available, the study provides valuable international evidence. Additionally, although Ghosh, Levin, Macmillan, and Wright (2004) claimed that holding gold as an inflation hedge is more adequate for investors in developed countries, Vietnam raises a special case study since gold is used publicly and to the same extent as the national currency (VND) for the aims of saving, payment and transactions. In additions, regarding to the reaction of the government and citizens before and during the plunge of economy from 2005 till now, the gold price in Vietnam fluctuates in a unique way, making the complicated but interesting literature for other countries, especially in Asia.

Secondly, gold return – inflation relation reflects the extent to which gold is popular in the economy relative to the fiat money and other investment assets. Thus, the study may partially help Vietnam's authorities in formulating and implementing effective monetary policies and also other macro policies to utilize the capital resource accumulated in gold. Finally, it is expected that the result of this research is to be of interest to investors as well. The findings of the study suggest an up-to-now strategy for investors who are considered to include gold in their portfolio. The evidence of inflation hedge ability of gold allows investors have a better asset portfolio and reduce the loss caused by inflation.

However, this study also has some limitations. Firstly, available monthly data of 19 years does not actually bring enough convincible to the results. This will be an evitable limitation of this research. However, it covers almost the up and down period of Vietnam’s economic. Hence, the empirical results hopefully still have practical meaning. Secondly, the outcome might not reflect fully the fluctuation of Gold Price due to the complexity of the economy. Many economic variables effect on each other while the research focus only on two variables Gold Price and Inflation. For further research, it is worth investigating how efectiveness of gold hedging against inflation changes in short-run as the relationship between Gold price and CPI in Vietnam is not stable, proposing some interesting outcomes when investing the linkage between gold price and inflation in short run. Morever, it is interesting to have more comprehensive comparision the ability of gold in hedging against inflation between developed and developing countries.

URBAN DEVELOPMENT THROUGH LAND-BASED INFRASTRUCTURE FINANCING: CASES IN HO CHIMINH CITY

Du Huynh

Lecturer at Fulbright School

duhtvn@gmail.com

Alex Ngo

MPA/MBA Dual Degree Candidate, 2012 John F. Kennedy School of Government, Harvard University and the Wharton School, University of Pennsylvania

We identify several varieties of land-based financing for infrastructure projects that would be relevant for Ho Chi Minh City, Vietnam. In our typology we compare several international projects and three cases in Ho Chi Minh City to highlight lessons based on project completion and the financial burden to the city government. We find that the city can apply different models based on several factors such as: its ability to manage land clearance, alignment of incentives between investment partners, and revenue collection related to infrastructure development.

Introduction

Ho Chi Minh City (HCMC), Vietnam is undergoing rapid transformation in its urban design and infrastructure. A large amount of capital is required for urban development in coming years. The city government, however, is facing difficulties in mobilizing capital for such high demand. The irony is that while the city has significant land holdings and with values that have been appreciated strongly thanks to infrastructure improvement for the last two decades, land-based infrastructure financing is still uncommon. This is surprising considering that many other developing cities around the world have used some sort of land-based financing. Internationally, land-based financing techniques have been used most heavily during periods of rapid urban growth and large leaps in the scale of urban development. For example, the massive municipal infrastructure investment in China over last 15 years has been financed in large part by converting land assets into infrastructure.[1] However, land-based financing is often but not always the case. If the investment is poorly designed and generates few benefits then the land value appreciation will fall short of the investment cost.

Basically, there are two categories of land-based financing for infrastructure including: (1) Land acquisition-based financing and (2) non-land acquisition-based financing. In the former, land (areas are usually bigger than the need of infrastructures) will essentially be recalled, then infrastructure will be built on it and the surrounding land will be sold, leased or exploited to cover the investment costs. This strategy based on land price appreciation has its disadvantages. It is captive to real estate market fluctuations, and it is limited by the availability of land. It raises opposition from residents of land to be acquired, making the process of resettlement and compensation very expensive for the government. In the latter model, governments will build infrastructure on land and impose some types of taxes or fees to capture portion of land or property appreciation thanks to infrastructure improvement to cover investment costs. This model can solve land acquisition problems prevalent with the previous model, and it may work for cases extremely difficult in recalling land. However, even non-land acquisition-based financing of infrastructure is can be vulnerable to a hostile legal or political environment. It is not easy to have a right level of tax or fee, and opposition to taxation may be difficult to surmount. Increases in taxes and fees to serve new development usually are not in favor with voters.[2] Moreover, this technique requires a well organized administrative system that includes accurate information on land uses and effective tax collection.[3]

[1] Peterson (2009, p. 23&83)
[2] Altshuler and Gomez-Ibanez (1993, p.3)
[3] Peterson (2009, p.19)

This paper discusses options by using the land-based financing model for HCMC in raising necessary funds and implementing infrastructure development. In the first section, we review the experiences in other countries and highlight several lessons. In the second section, we examine three prominent cases in HCMC including: the Phu My Hung new urban area project, the Thu Thiem Peninsula urban development project, and the Tan Son Nhat – Binh Loi – outer ring road project. Hereafter, we abbreviate these projects as Phu My Hung or the PMH project, the Thu Thiem project and the TSN-BL project, respectively. We apply several questions: "What are key factors that made some cases successful while others not?" and "What are the implications for HCMC (in particular) and other places in applying land-based financing?" The final section will address implications and related issues in applying the land-based financing techniques.

Section 1. Financing Modes from International Experience

In principle, governments have the responsibility in creating infrastructure for public use. In many cases governments simply build infrastructures through their general budget. However, especially in rapid expansion periods when the demand of infrastructure is very high, public money may be not sufficient. Other solutions need to be considered.

One solution, value capture financing, relies on the relationship between increased property values and local improvements in infrastructure. Allowing governments to capture just some of the value of in property appreciation could help pay for infrastructure such as transportation network improvements.[4] For these reasons, land-based infrastructure financing has become a popular model around the world. Even though landowning regimes differ between countries (as well as between municipalities), governments have been able to tap land-based financing techniques to support rapid urban growth. In China and Vietnam, for example, land belongs to the state while in Columbia significant amounts of land are held by private interests. Given these differences, particular strategies have helped jurisdictions raise funds where their general revenues are not sufficient or feasible.

In the land acquisition-based model, the public sector usually takes ownership of land and associated use rights and then sells, leases, or trades some of the land to finance capital projects. The public sector may construct infrastructure improvements itself and thereafter exploit the value of the surrounding improved land, or it may engage private entities to build such projects in exchange for land upfront. In the non-acquisition based model, governments build infrastructure and impose taxes or fees on beneficiaries to cover investment costs. The underlying theory for policies that impose taxes on land improvement is to recapture some of the "unearned increments" in land value that private landholders enjoy from public investment in infrastructure services.[5]In addition to tax and fee, user charges, in many cases, are another suitable financial tool to recover costs for infrastructure services like electricity, telecommunications and water where it is relatively inexpensive to meter use and send bills accordingly. Characteristics of each technique will be discussed more specifically in the following discussion and many of the concepts are heavily borrowed from Peterson (2009).

Land Acquisition Based Financing

Selling land to pay for infrastructure is enticing because of its advantage in raising huge resources in a relatively short period of time. However, a major requirement for the government is that it must take control of land before it can monetize or transfer it to private developers. Moreover, determining the

[4]Walder (2003)
[5] Peterson (2009, p.71)

value of land to be transferred for private developers as well as the allocation of ownership in the joint venture mode is a challenge for this model. We discuss types of the acquisition-based model below.

Transfer land to private developers in exchange for infrastructure

Transferring land to developers, through swaps, sales, or leases has been a common method for infrastructure development. The intercontinental railroad system in the US was mainly built through this model more than a century ago. In exchange for each mile of track laid, the US federal government granted railroad companies 20 square miles of surrounding land.[6] In this case, railroad companies made huge profits from land in addition to operating the railroad systems and the longest and costliest railroad system was built without any financial burden for the US government.

A similar ongoing story in Alexandria, Egypt involves the transfer of 3,360 hectares in 2005 to a private developer by the Alexandria Company for Urban Development in return for the developer's provision of basic infrastructure. The private company will install internal infrastructure and some external infrastructure and as part of the deal, the investment company also will supply the New Urban Communities Authority with housing for low-income households, equal to 7 percent of total development costs. The investment cost of this project was \$1.45 billion, more than 50 times total urban property tax collection and equal about 5 percent of total national government revenue.[7] However, the project has currently run into trouble because the land was directly given to the company by the Ministry of Housing instead of through a competitive bidding process.[8]

In these schemes, transfers to private developers usually involve land that is directly improved by the infrastructure project. The enhancement in nearby property values becomes an important incentive for private investors to provide external infrastructure. This is in addition to the value that comes from internal infrastructure to a development area, which is commonly supplied by private developers. Meanwhile, from the public perspective, the positive benefits for the wider community from improved external infrastructure comprise a major justification for land transfers to private parties.

The main benefit of this model is that governments may receive a large amount of up-front resources for other projects or purposes while necessary infrastructure is still built. Moreover, they does not have to bear the financial burdens and risk as it does in engaging in joint ventures to build the infrastructure or by building infrastructure itself and then sell surrounding improved land.

However, this mode presents a couple caveats especially for developing countries. First, it is not

---

[6] Terry Cox (2003)
[7] Peterson (2009, pp.60&104) and World Bank (2006, vol.2, p.60)
[8] https://www.zawya.com/story.cfm/sidZW20100623000134/Court%20Ruling%20Does%20Not%20Cancel%20TMG%27s%20Madinaty%20Deal-Egypt%20Minister

always easy to have competitive and transparent bidding, and it is not easy to decide a reasonable price or volume of land that developers would get in exchange of a certain infrastructure. Second, land clearance may face considerable trouble from either of two situations. If the land clearance process is conducted by the government before land is handed over to private developers, there may be a lack of incentives to implement the process quickly and decisively. Otherwise, if the land clearance process is conducted by the private investor, there may be a lack of experience and expertise in dealing with local citizens and authorities. In the two cases in the US and Egypt mentioned above, the process was workable because the land clearance was simple. Third, public skepticism may haunt such projects when private developers (especially foreign investors) rake in huge profits. Moreover, enforcements for private investors or developers to build committed infrastructure instead of mainly or even merely focusing on exploiting given land is one of critical issues. Some of these problems are illustrated more clearly in the second section with the TSB-BL case of HCMC, Vietnam.

Engage in joint ventures to build the infrastructure

Forming a joint venture to build infrastructure is one way to invite private participation in infrastructure without totally relinquishing ownership of land use rights. This model is popular in many countries. Experiences from China and India are mentioned below.

In China, because all urban land is owned by municipal governments, selling land for value capture in improved properties has been a dominant strategy for infrastructure development. The Chinese government has engaged the private sector to build and to finance infrastructure in exchange for land use rights. In the case of the construction of the six-lane outer ring road around Changsha the Hunan Provincial government used a joint venture -- the Ring Road Corporation-- to build the highway. With the projected cost at $730 million, the government paid nothing out of pocket for the highway, and instead transferred development and land use rights to 3,300 hectares of land to the joint venture.[9]

The developer's revenue from selling leasing rights from this land was enough to cover half of the investment cost for the highway, and the rest was borrowed from the China Development Bank and commercial banks with the informal guarantee of the municipal government through "comfort letters." The underlying implication was that the government would transfer additional land to the Ring Road Corporation in the event that it could not meet its debts. The result was that the highway was built and financed as planned.

Another case of a joint venture to build and operate a new airport is Bangalore International Airport in India. To build a green field airport with $490 million investment cost, the government represented by the Karnataka State Industrial Investment and Development Corporation ventured with domestic

[9]Peterson (2009, p.67)

private partners and a consortium led by Siemens and Unique Zurich. The government contributed 3,850 acres of land, in which 2,000 acres were devoted to the airport, and $87.5 million and in return it received a 26 percent interest of the joint venture. The result was that the airport was built on time and on budget.[10]

In building big infrastructure projects, there are usually two main issues: (1) dealing with local residents in the land clearance process and administrative procedures with local authorities; and (2) financing. The advantage of the joint venture model is that it utilizes the different strengths of public and private parties. Private partners have: the incentive and motivation to manage projects so that they are on time and on budget; the ability to mobilize huge amounts of capital in short periods of time; and access to creative means for resettling residents, sometimes through informal methods. The advantage of public, local partners is their extensive knowledge of and skills in dealing with local politics and administrative issues. This solves the second problem of the first mode mentioned above.

However, similar to the exchange of land for infrastructure above, the joint venture still faces problems of identifying the value of land and the appropriate allocation of shares to partners. Just as in the land transfer mode, public opposition or anger may arise when private partners, especially foreign investors, earn huge profits. In addition, as relatively long-term instruments for land financing, joint ventures face a chronic problem of contract incompleteness.[11] Ambiguity in the contract terms can deter the joint venture mode. Moreover, this mode may be subject to moral hazard in the case that the government guarantees (formally or informally) the borrowing of the joint venture.

Pros and cons of the joint venture model will be illustrated more concretely in the Phu My Hung new urban case that will be described in the second section.

Build infrastructure and sell surrounding improved land

A traditional mode of infrastructure development for urban growth is for the public sector to install needed infrastructure and then to sell serviced land to developers. This is an old procedure used to finance infrastructure investment. Baron Haussmann in 19th century Paris had already used public confiscation of property to build new roads and to sell the resulting higher-valued, improved surrounding land to pay back city debts. However, due to protest of landowners this model was abolished when the courts ruled that excess land acquired by the city for road construction, but not used for actual public works, had to be returned to the original private owners—not at its increased land value after public improvements had been completed, but at its original acquisition price. Around the same time as Haussmann's Paris project, New York City purchased large tracts of land in the path of city expansion and then sold the land at great profit when water mains, sewers, and transportation

[10] Peterson (2009, pp. 69&70)
[11] Milgrom and Robert (1992)

improvements were installed. To finance these activities, both Paris and New York borrowed huge amounts of money and adopted the associated borrowing risks for their municipal governments. As shown in these examples, the build-sell mode has been popular for a long time, and today it is still popular in many countries.[12] Modern implementations can be seen in Egypt and India.

In Egypt, for example, the government legally owns all rural desert land while the private sector owns much of the developed urban land. As cities have grown, the government has installed the infrastructure to support new developments and sold this serviced land to help repay the costs. The New Urban Communities Authority (NUCA), the agency responsible for making these investments, made huge outlays in Egypt's program to expand new cities, spending US$12.7 billion for infrastructure over 435 square km of land. The problem with this strategy, however, is that the government had not been able to recover its costs through land sales after installing the supporting infrastructure. The price for serviced land had been set by an administrative formula that did not reflect market prices. As a result, the NUCA's New Cities program had not reached its growth targets by 2005, partially because infrastructure development had been poorly targeted and concentrated in areas of low demand.[13]

In the Bangalore International Airport case, there were two main components. First, the investment on 3,850 acres of land was undertaken by joint venture to build the new airport. Second, the government also retained 400 acres near the airport site and intended to sell this land at auction, and in the process capture the land value increases from the airport. The proceeds from the land sale were intended to finance a new highway connecting Bangalore with the new airport.

However, the public land-sale component of the project has broken down. Due to resistance and legal challenges from landowners, the government could not proceed with its full plan for land sale. Instead, some land may be given to government agencies for office space development and other facilities may be built to lease to private operators instead of selling the land outright. Moreover, opposition from farmers over the land acquisition process has led the state government to say that it "will return an eighth of an acre of airport land to farmers for each acre of land that was originally acquired."[14]This has ended up as an in-kind betterment tax, details of which will be discussed later.

The land acquisition process for the airport land was fairly smooth because all land belonging to the joint venture had been cleared before the construction and land price went up. In contrast, 400 acres have not been cleared yet due to disputed and bureaucratic land acquisition procedures, and a lack of responsibility and public capital. The lack of clear rules and transparency in land acquisition became

[12]Peterson (2009, pp. 17&18)
[13] World Bank (2006)
[14]Peterson (2009, pp.69-71)

a detriment to public accountability. Landowners became resistant to compensation rates that were backed by compulsory enforcement and untied to market prices.

A variation of the build-sell strategy is possible where municipal governments have high value or "golden land" in urban areas. It is easy to sell such land in order to raise large amounts of funds. For example, in Mumbai, India the Mumbai Metropolitan Redevelopment Authority, for 13 hectares of land "in just two land auctions, in January 2006 and November 2007, [it] was able to generate Rs50.8 billion (approximately US$1.2 billion) from the sale of small land parcels in Bandra-Kurla."[15] Similarly, in four years (2001-2004), HCMC received about $400 million or 15% of the city budget through selling land and building in the city downtown.[16]

The advantage of this technique is its simplicity for the government when it builds infrastructure by itself. It does not have to engage private partners to invest in the land until after construction is completed. Therefore, the process of initial land valuations and structuring agreements may be simpler than other modes. However, it faces other serious problems. First, the public financial burden can be a big issue. Government budgets usually do not have enough funds for such investments. Either formally or informally they must borrow money to finance projects and rely on land value appreciation. This, of course, creates huge risk for municipal budgets. Second, the compensation process can take a long time while land prices continue to rise, causing dispute and unrest by landholders. The political implications for such projects can be huge, making the government reluctant and extremely careful in the land clearance process. Furthermore, the incentives and motivations for public servants to clear land swiftly are limited compared to the joint venture scenario where performance incentives and resources from private investors may expedite land clearance. As we discuss below, this is one of main problems of the Thu Thiem project in HCMC.

Non-land Acquisition Based Financing

In most cases, building infrastructure is a mandate. However, in many cases it is too costly or impossible for governments to take land to finance necessary infrastructure. In these cases governments can still build or manage infrastructure construction through private contractors and raise the required funds through imposing several types of taxes or fees to recover investment costs. Exactions may be in-kind or financial.[17] These models include: betterment levies, sale of development rights, developer exaction and impact fees.

---

[15]Peterson (2009, p.91)
[16]Rosengard et al (2006, p.26)
[17]Altshuler and Gomez-Ibanez (1993, p.3)

Betterment levies

A betterment levy captures part of the land-value gain attributable to infrastructure investment by imposing a one-time tax or charge on the land-value gain.[18] The conceptual justification behind the levy is that the appreciation in property value that results from infrastructure development is an unearned increment, at least some of which should be allocated to the provider of the infrastructure. The argument for a betterment levy also rests on the phenomenon that some landholders benefit more than others from improved infrastructure. For example with public transit systems in Washington, DC or Newcastle in the UK properties near transit appreciate faster than properties farther away.[19]

Two types of betterment levies have been applied in Columbia. First, valorización (the particular term for this tax in Columbia) required the government to recover 140% of estimated infrastructure costs through the levy. This also includes 30% added for administrative costs. However, this model failed because it was expensive and difficult to implement and leading to numerous legal disputes over land value gains. Aftermath Columbia's capital, Bogota, has used a special version of valorización with some flexibility. Additional factors have been used to adjust the tax. Different tax rates have been set for industrial and residential use; high-income and medium-income use; relative proximity to infrastructure improvements; and a 5-year repayments period. The result is that 217 public works projects were financed using this method from 1997 to 2007 amounted to US$1 billion.[20]

Bogota's experience has been quite successful against legal challenges because the city does not claim to have a strict formula. Additionally, the tax is spread over the whole city, so public resistance has been minimal. However, the troubles of Poland and Australia in implementing betterment levies also warn of the difficulties that come with this type of taxation. The main problems of administration in assessing the rise in property value and the political conflict that emerges from applying such new taxes were enough to cause Szczecin and Sydney to cancel their betterment levies.[21]

The disadvantage of common betterment levies is that landowners have to pay taxes in cash, moreover. This may get trouble when an economy is in downturn. For example, during the Great Depression of the 1930s, a large number of homeowners in the US were unable to pay their special betterment levies.[22]Payment in-kind can help resolve this issue. Private owners can contribute their land to the public to build infrastructure, receiving back a certain proportion of their land once improvements are completed. The betterment levy in-kind has been common in both developed and developing countries such as the US, Japan, South Korea, Egypt and India.[23]

[23]Altshuler and Gomez-Ibanez (1993, p.8) and Peterson (2009, p.59)

Sale of development rights

A strategy used in São Paulo, Brazil for financing infrastructure development has been the sale of development rights. São Paulo has been able to sell the right to add floor space beyond normal densities in order to finance public works as approved by law. "Solo criado," as these development rights are referred to, requires developers to pay for additional floor space above the normal limit. There is a pre-determined fee for each unit of floor space added, and moneys that are raised are held in a special fund with investment uses restricted by law.[24]

The Faria Lima Urban Operation was one such campaign to utilize development rights to finance improvements to infrastructure, including streets, drainage, open space, and social housing. Since the project began, reported land values rose from $300/sq m to $7,000/sq m after public investments. Rather than charging a betterment levy on land-value gains, the government sold development rights for 2.25 million sq m of floor space with the 410 ha development area. Over implementation, development rights have been sold for as much as $630 per sq m of allowed floor space. As of 2005, this has raised a total of $190 million from development rights.[25]

One factor needed to be carefully considered is that the base development allowed is not too expensive to service and that the amount charged for increases in development covers the incremental cost of serving that added development.

Developer exactions and impact fees

Impact fees are designed to charge developers the market cost of the infrastructure expansion their development projects will necessitate. This concept has the economically desirable quality of charging users based on the marginal cost of development, or the value of the negative impact on infrastructure as well as externalities that comes with a development project.

Chile is one country that has demonstrated use of impact fees. As in many other countries, municipalities in Chile are not allowed to take on debt. In the 1990s, two municipalities in the Santiago metropolitan region turned to impact fees to finance and to build external road infrastructure for new land developments. As this method was successful for these two municipalities, impact fees were also used to support Chacabuco Province to the north.

Chacabuco needed to add housing for 40,000 new households to be built on agricultural land without existing urban infrastructure. In its case, the impact of new housing developments on the roads (62 km of planned radial highway and other roadways) was estimated to be $106 million. The national government became the responsible party for collecting the fees from developers for two reasons: the

[24] Froes and Robelo (2006)
[25] Peterson (2009, pp. 76-7)

municipal governments did not have enough capacity; and the developments spanned across multiple municipal jurisdictions.

In its original vision, the formula derived the impact fee from several factors: location relative to the existing road network, project size, socioeconomic status, and estimated travel demands. Flexibility was introduced into the program by allowing lower income households to be exempt from the development impact fee. Of the money collected, US$25 million would be paid to the concessionaire and the rest to the government. For the average housing unit, this amount collected was about $1,600. The government agreed to finance 39% of infrastructure development costs while the impact fee would cover the rest.

According to Peterson, this worked in Chile because: planning capacity in these municipalities was advanced compared to other developing countries; regulatory controls over land-use were effective; and market principles were incorporated into infrastructure (e.g. toll roads). However, this mode of impact fees has not spread widely throughout Chile, probably because the national government is not as financially constrained as the local governments, and therefore there is less need to implement development impact fees.

Institutional issues with impact fees may also be the cause for their limited implementation. Developers resist the fees (as organized groups) because they cannot always recover the fees from customers. Furthermore, the benefits of these fees are distributed across the communities with no single party to defend them. Politically, these policies are also difficult to implement because they essentially raise costs to landowners while the uses of raised funds may not be transparent.

All these types of taxes and fees including the betterment levy, development fee, and impact fee are more common in developed countries, partially because of the administrative capacity to record land values and to implement tax collection.

In short, the advantage of non-land acquisition-based techniques is that they avoid troubles of land acquisition. However, it is very difficult to value improvements for each parcel of land in monetary terms. To implement this model, a transparent and competent administrative system is required. In addition, the taxes or fees that are imposed from infrastructure development projects may find resistance from the public or organized groups of developers. From that point of view, it is important to allow some flexibility as in the case of Bogota's betterment levies and Chacabuco's impact fee.

Section 2. Land-based financing cases in Ho Chi Minh City

Land-based financing has been applied in Vietnam in general and HCMC in particular for a long time. However, most of the cases are the land acquisition-based financing. For non-land acquisition mode, though several techniques have been introduced and applied, the result is still modest. There are at least two reasons causing this problem: (1) impractical (or at least unreasonable) regulation such as the fee for land conversion from agriculture land to commercial or industrial land is based on productivities of agriculture products instead of appreciation of land value or investment costs; and (2) the complication of these techniques. Due to the lack of information and uncommon of non-land acquisition-based financing model, this section only analyzes the land acquisition-based through all three modes: transferring land to developers for infrastructure; joint venture with developers; and government-led building of infrastructure and sale of improved land with three cases including Phu My Hung, Thu Thiem and TSN–BL projects.

Phu My Hung New Urban Area

Twenty years ago, PMH was only a swamp area seven kilometers from the downtown of HCMC to the south and one of the poorest regions of the city, but it now becomes one of the most coveted residential areas in Vietnam, and is used as a national model for urban development.[26]From almost nothing, the price of a square meter of land is about US$4,000. The price of a 100 square-meter apartment is roughly $150,000 and equivalent to 150 times of Vietnam's GDP per capita or 60 times of HCMC's GDP per capita in 2009. While private developers are almost wholly responsible for the planning and construction of PMH, the city benefited from its development by receiving a ten-lane roadway (as well as other infrastructure) as part of the development. Interestingly, this is a rare case which was built successfully through land-based financing in Vietnam.

The process

PMH is one of the first examples of land-based financing projects since Vietnam's reunification in 1975. It was part of a larger scheme by HCMC to develop an area to the south of the city (Saigon South) including three main projects: Tan Thuan export processing zone (EPZ), PMH area and Hiep Phuoc industrial park in which Tan Thuan EPZ was built first.

The concept of developing the Saigon South was not yet completed from the beginning. It was started from the initiative to build EPZs and has been evolved over time. In the late 1980s, when Vietnam was only beginning its transition to the market economy, the market economy was a new and strange

[26]http://www.forbes.com/global/2008/0929/024a.html

concept for many people. The political environment had barely begun the policy of stimulating foreign investment into Vietnam. Considered as the cradle of the market economy in Vietnam, HCMC was at the forefront of the liberalization process. Due to the unique context that might cause high potential of risk, the HCMC government hesitated to lure foreign business enthusiastically and foreign investors were wary of the idea of investment in Vietnam, however. The initiative to build EPZs to attract foreign investors and promote exports was originated from intellectuals belonging to a group of high ranking officials and closely watched individuals related to the former Saigon government led by Phan Chanh Duong.[27] In 05/1988, this group conducted *the study of building EPZ in HCMC* and it was put in the list of *the pilot programs to develop foreign economic development in the period of 1989-1995 of HCMC*.[28] On 10/24/1989, the Tan Thuan EPZ program, a quasi-government agency and state-owned enterprise without capital was established and Mr. Phan was appointed the director of the program. The main constraint was that due to the duplication of programs, this program only got implicit support of some municipal leaders including the top one instead of an official program of the city.

After painstaking efforts with many memorandums as well as rejections, Mr. Phan finally found a group of investors from Taiwan seeking oversea investment opportunities.[29] In the early 1950s, these investors had seen the Taiwanese economy encounter a situation similar to Vietnam's situation in the 1990s. Taiwan was among the first countries having EPZs. Using their experience with EPZs, these investors recognized the opportunities for Vietnam to grow through its export sector.[30]

The result of the negotiation between the two partners, the HCMC government and the Taiwanese investors, was to establish a joint venture to build a 300 ha EPZ at Tan Thuan, a site along a peninsula toward the South of Saigon's core. The scheme was in fact bigger than an EPZ because it would also include a 17.8 km road to connect the EPZ to the National Highway 1 (the backbone transportation route of Vietnam).[31] In addition, the idea for PMH was conceived during the negotiation process between the government and the Taiwanese partners.[32] Due to the circumstances, two projects, the Tan Thuan EPZ and the PMH urban area project have been built sequentially through land-based financing by which the city government contributed land and Taiwanese partners contributed material, equipment, cash and expertise. Investment costs would be covered from leasing land in the EPZ and exploiting (sales of leasing rights or building apartments to sell) land surrounding the road.

[27] Vo (2005, p.32), Nguyen, et al (2006, vol.1, pp.65-6, and IPC (2001, p.2).
[28] See the announcement No 30/TB-UB dated 03/07/1989
[29] Interviewed Mr. Phan
[30] Interviewed Albert K. Ting, a son of Lawrence S. Ting
[31] See the Tan Thuan joint venture contract and the proposal numbered 4712/UB-ĐN, dated 09/30/1992 of HCMC's people committee
[32] According Mr. Vo Tran Tri, the city's secretary or top leader at that time, the initiative to build Tan Thuan EPZ was originated from Viet Nam and Taiwanese partners echoed it while the initiative to build Nguyen Van Linh Road and PMH was the initiative of Mr. Lawrence S. Ting and Phan Chanh Duong (see Vo, 2005).

To build the EPZ, the city government established Industrial Promotion Corporation (IPC) as the Vietnamese company to venture with its foreign counterparts[33] that were led by the Central Trading and Development Corporation (CT&D), a Taiwanese company in which the Kuomintang (KMT) initially held a 75 percent stake.[34] The Tan Thuan Corporation was thus formed as a joint venture in which IPC, on behalf of the city government, contributed 300 ha of land to own a 30 percent interest and CT&D contributed financing and expertise to own 70 percent. The investment license of the Tan Thuan EPZ was officially issued by Vietnam's government in July 1991. This joint venture was successful in building and operating the EPZ. From 1993 to 2009, manufacturers had invested more than US$1 billion and employed 60,000 people.[35] It was rated as the best industrial zone in Asia by Euromoney's Corporate Location Magazine.[36] As of 2008, its annual exports were valued at about US$1 billion.[37]In terms of size, Tan Thuan EPZ was even bigger than the aggregate area of three EPZs in Taiwan which contributed about one eighth of Taiwan's total export manufacturing product.[38]

After the EPZ was constructed, the 17.8 km road was next. To build the road (later to be named Nguyen Van Linh Road), 970 hectares of land was reserved for land acquisition-based financing: 220 ha was for the road; 600 ha was for a second joint venture to exploit to cover the investment under a 50 year lease; and the other 150 ha with complete infrastructure was to be transferred for public use. The maintenance cost of the road would be covered by road toll collection. Basically, HCMC would exchange 600 of land for a ten-land road and 150 ha of infrastructure-built land. The total investment cost of the whole project was estimated at US$242 million with $79 million for the road, and $29 million for the 150 ha of land.[39]

Table 1: Estimated Project Investment Costs at 1993

Construction	Area (ha)	Cost ($million)
17.8 km of 10 lane road	220	79
Reserved land for the joint venture	600	119
Infrastructure for HCMC government	150	29
Clearance cost	970	15
Total	*970*	*242*

To build the project, another 70-30 joint venture, the Phu My Hung Corporation, was established with $60 million equity (charter capital). IPC, on behalf of the city contributed the land to the venture, and in return it received a 30 percent interest valued at $18 million. CT&D contributed $42 million with equipment, material and foreign currency.[40]

The results

With the land for the road and about 300 ha has been handed over to the joint venture, in 2007, the 10 lane road was finished on time. This is a rare case of timely road completion in Vietnam. The road has become a key transportation route in the south of Saigon with thousands of vehicles traveling every day. Moreover, after nearly 2 decades from the initial idea, a modern urban area has been created. PMH has become one of the most desired places to live for many people in Vietnam.

Besides the road and other benefit, in terms of the city budget, the PMH project appears to be a good investment for the city government. Even in 1993, the city received a sizable share of the venture for its land contribution. Each hectare of swampland it transferred to PMH was valued at about $30,000 worth of shares.[41] This value is even higher than the land that the Karnataka government used to build the new Bangalore airport joint venture, where one hectare at the 2005 prices was around $23,000.[42] Moreover, from 1998 through 2009, the government received about half of a billion US dollars (about two-thirds of which came from VAT and income taxes, and one-third from earnings of its 30 percent share of the joint venture). The city budget has received about 60 percent of the pre-tax income from the PMH Corporation joint venture. This is not to mention the benefits of housing for thousands of residents and infrastructure improvements in roads, telecommunications, electricity, water, and sewer systems, especially the Tan Thuan EPZ, Hiep Phuoc industrial park and power plant which have played as the nucleuses of the development of the South of Saigon.

Moreover, the 970 ha of land above are actually spotted over an area of 2,600 hectares instead of just one piece of land. Therefore, the benefits of the development serve the wider South Saigon area, and not only the land within the official boundaries given to the PMH Corporation. The success of PHM has also created positive impacts for residents and businesses in HCMC and travelers on the road.

Besides successes, there have also been disputes and concerns. Even though the city received a good deal financially, public opponents still complain that foreign investors have been earning too much

---

[40] See the investment license

[41] In the joint venture contract, it was written that the land contributed to the joint venture was "clean" land. This meant that the city had to take responsibility for the land clearance by its own cost estimated at $15 million and the government would only net $3 million for the 600 ha. An important point to note, however, was that CT&D assisted the compensation for residents by providing IPC with a loan of $15 million interest free. This allowed HCMC to have a 30 percent stake in the PMH Corporation without any financial contribution.

[42] Peterson (2009, p.70)

money, and that Vietnam should have a larger share. As the result, the tax policy was changed in 2004 to retain more profits for Vietnam. Another controversy relates to the actual land given for PMH so far. According the investment license and the joint venture contract, 600 hectares of land would be transferred to the joint venture. However, up to now the joint venture has only received 300 hectares.[43] The possibility that the joint venture will receive the rest of the land is uncertain.

Risk taking

An important aspect in this case is the risk taking by key individuals and organizations in the project. On Vietnam's side, this was the first time Vietnam would give a large area of land to a foreigner, albeit an investor, after fierce wars to protect the land of Vietnam. It was a divisive controversy in terms of ideology and politics. Moreover there was no institutional experience to guide the city in its joint venture or in its regulatory role. On the foreign investors' side, it was indeed very risky to invest into such a country at the time. In fact, many investors had turned down the opportunity until CT&D came forth. The question is why HCMC's leaders agreed to support the project and why the Taiwanese investors dared to invest millions of dollars?

First, the implicit supporting system helped to alleviate the risk for Vietnam's side. As we know, Vietnam's economic reforms with Doi Moi (innovation) in the late 1980s called for market-based initiatives across government. However it had been particularly risky for civil servants and politicians to experiment with new ideas especially related to foreign investment. It was difficult to get explicit support from leaders. Moreover most government officials did not have much knowledge of the market economy. However, it was possible to get their implicit support because if an initiative became successful those informally supporting it would claim credit and could stay away unsuccessful cases.

If everybody had acted as above, nothing would have been done. To make the business worked, someone had to take risk. Fortunately, the HCMC government had such risk taking cadres. The political context in Vietnam at that time was complicated and those relating to the former regime of the Saigon government were considered suspect. However, some of the intellectuals and high ranking officials were given limited assignments in at least two groups to provide advice for the new municipal government. For these people it was a rare chance for them to use their knowledge. Therefore they had much useful advice and contribution, playing a critical role in helping Vietnam to deal with mistakes of the central planning model.[44] The plan to build an EPZ was among the recommendations of these groups. The proposal was put into pilot projects of the city and those writing this proposal were given approval by some leaders of the city to implement it as mentioned.[45]

---

[43] Interviewed Mr. Phan and Mr. Ting Jr.
[44] Dang Phong (2008 & 2009)
[45] Nguyen et. al. (2006)

Second, due to the extremely high risk, CT&D's ownership structure is a critical factor. CT&D was in fact a company established in 1989 by Taiwan's Kuomintang (KMT), the ruling party, to seek overseas development opportunities. The Central Investment Corporation (CIC- KMT) owned 75 percent of the company while the rest belonged to three private shareholders of which Chairman Lawrence S. Ting, a Columbia University graduate, a 20-year veteran of China Gulf Plastic and a son-in-law of a Finance Minister of Taiwan, owned 10 percent. One overarching reason for KMT overseas development opportunities was the uncertain international political position of Taiwan at this time especially considering its relationship with China.[46] It was, therefore, understandable for KMT to spend some money in such high risk projects because not only was it for financial purpose, but also for political and national security reasons. However, due to the political change in Taiwan, the KMT completely pulled out its investments at CT&D in late 1994 even though by then it had invested $97 million in Vietnam.[47]

Moreover, that much of CT&D's initially financing came from the KMT is also important. [48]The investment by CT&D raises the question of whether this was an example of a principal-agent problem, where the agent absorbed more risk than the principal preferred.[49]At least initially, the financial risks in these projects were counter-balanced by KMT funding. However, after some time deeper analyses of the investments were conducted. Further information about the investment and its environment reduced the risk for the project significantly. KMT funding for CT&D was eventually removed, but by that time the managers of CT&D became even further convinced of the projects' potential, investing more of their own money after some of their initial perceptions of risks had been dispelled. This is similar to the prior to and aftermath of the process that a green-field project was implemented.

Factors made the success of the project

Nguyen Van Linh Road, the new 17.8 km road, was built on schedule along with establishment of a modern urban area. Many factors made this case successful. PMH is a good example of how the joint venture works well using the strengths of private as well as public partners. In this land acquisition-based financing example, the partners came to a relatively tenable agreement written into the basic joint venture contract. The Vietnamese partner took charge of dealing with local issues such as the

[46] Interviewed Mr. Phan

[47]http://tuoitre.vn/Chinh-tri-Xa-hoi/49484/Ong-Lawrence-STing-da-chiu-ap-luc-gi.html and http://www.lawrenceting.com/

[48] There is an argument that the equity was only a small proportion of the total liabilities and equity and the customs in Taiwan that the chairman of a company traditionally takes unlimited responsibility of debt guarantee. However, this may not always be the case. Moreover, there is a dispute about this characteristics even in this case (see: http://tuoitre.vn/Chinh-tri-Xa-hoi/49484/Ong-Lawrence-STing-da-chiu-ap-luc-gi.html)

[49]Theoretically, proving that there is no principal-agent problem would require demonstrating that the same decision would be made regardless to the ownership structure of the company.

land clearance process and the administrative and paper procedures related to Vietnamese authorities from the central to local governments. The foreign partner took charge of financing and technical as well as management issues.[50] The expertise and experience of the staff who were truly knowledgeable about their localities in land clearance and other processes combined with the availability of capital financed by foreign partners created a system of strengths and incentives for the clearance process to be done quickly and decisively.[51] Each partner has executed its role well. Moreover, the road has had a significant impact on the accessibility of PMH and the quality of life of residents (and therefore its land prices). Both the government and investors have also seen competitive returns on their investments in the PMH Corporation.

Besides these features that might be more universally applied to other projects, there are some unique factors that helped the success of PMH including: the relatively low cost of resettlement; professional leadership by Mr. Phan Chanh Duong and Mr. Lawrence S. Ting; and the distribution of risk.

First, the relatively low cost of resettlement borne by the HCMC government and the resettlement process was quite favorable. Of 970 ha of land, most of land was vacant swampland, so there were not many people occupying the land. Therefore, to clear the land for PMH and related infrastructure development, the cost to the city was only $15 million, or about $1.5/sq m. Several factors allowed the resettlement costs to be this low. First, the swampland of PMH was considered unfit and risky for development when compared to other areas around HCMC. Second, private real estate development was a new concept in post-war Vietnam. Reclaiming land for private development was a new process, and there had been few, if any, precedents indicating that resettling residents from the South Saigon area should command a significantly higher cost.

The compensation price was based on a formula mainly incorporating agricultural yield, and there were not many large buildings to be cleared. For example, the rice yield of a good crop was 3 ton/ha. The value of a ton of rice was about a million VND or US$90 at 1993 price. Calculated for 30 years of production, the value of a hectare of rice land was about $8,000. Including the value of buildings and structures on the land, the average compensation price of a hectare was only about $15,000/ha.[52] This price is very cheap compared to the current cost in Thu Thiem, about $2 millions/hectare. Moreover, PMH was not recognized as a potential residential area twenty years ago. It was not in the city's master plan[53] and not many people believed that it would be successful.[54] Landholders at the time did not perceive the value of their land to be very high. Therefore it was relatively easy for the

[52]Ibid
[53]See the 1993 and 1998 master plan
[54]Interviewed Mr. Phan

city and the joint-venture to recall a large area of land.[55]

Second, the role of individuals was important. Mr. Phan Chanh Duong and Mr. Lawrence S. Ting played important roles. In the initial years, Mr. Phan and his colleagues had to deal with a wide range of issues to convince the city government to allow them to experiment with this project and to connect with the Taiwanese investors who would eventually invest in Vietnam. Since coming to Vietnam, Mr. Ting had introduced many new ideas for Vietnam. With the Tan Thuan and PMH projects, Mr. Ting prioritized job creation and ample living space. He led CT&D to develop PMH without deviating much from the award-winning master plan designed by Skidmore Owings Merrill. He resisted the urge for opportunism, for example, by avoiding building extra floors or removing green space. Furthermore, Nguyen Van Linh Road remains one of the largest (being 12-lanes in some sections) and modern corridors in Vietnam's road network. Although PMH has had its challenges, it is widely recognized as one of the best urban areas in Vietnam.

Third, the finances and incentives available to the PMH project were very favorable. It was rare for the city to receive special access to $22 million in loans with free interest from CT&D for land clearance and initial issues. As analyzed above, it was the like-venture capital and the money of an organization, so that the managers of the PMH project felt at liberty to employ the capital for more venturing uses.

While the joint venture mode of land acquisition-based financing can suffer from prolonged challenges of ambiguity and disagreement, it can also facilitate long-term incentives for commitment between partners as a remedy for contract incompleteness. In the case of PMH, the joint venture presented an investment vehicle for the principals of the government (IPC) and the foreign investor (CT&D) where there were unproven intentions of good faith. The PMH Corporation permitted the resolution of ongoing issues regarding good faith and administrative barriers in the investment climate. Therefore, when the investments were made, the partners possessed the necessary space and time to execute on their good faith. The act of the private investors led by Mr. Ting investing their own capital (after the withdrawal of the KMT from CT&D) is one such result of risk reduction from the long-term partnership with the HCMC government. On the Vietnamese side, Mr. Phan and his colleagues had strong motivations to implement the PMH project successfully because this seemed to be a rare chance to demonstrate their value. Moreover, the partnership embodied in the PMH Corporation was a motivating force behind the government's liberalization of policies regarding land use rights. For example, at the time the contract was signed between IPC and CT&D, foreign individuals were not yet allowed to own land-use rights. However, after the commitment in the PMH Corporation and persistent bargaining between CT&D and different government agencies (as well as

[55]Nguyen et al (2006, p.)

other important political actors), foreign ownership of land use rights finally became law.[56]

Troubles of the project

As with any venture, there were also problems in the PMH project. Difficulties confronting PMH were: disputes regarding appropriate shares and profits in the joint venture; opposition in the land clearance; motivation in building and maintaining the road; and the underlying ambiguity of the concession contract.

First, a major controversy with the story of PMH is with CT&D which owns 70% of PMH Company. The perception that PMH is making enormous profits has attracted lots of negative attention from the press and political interests. The government, naturally, has also tried to increase the pressure on PMH to pay more in taxes, and probably make other sacrifices, in order to satisfy its political constituency but also to the city secure a "fair share" of the returns. For example due to the ambiguity of Vietnamese regulation over a decade, in 2004 the government decided to increase the income tax rate from 10 percent to 25 percent for PMH Corp. This caused a big dispute in 2004 but PMH still has to pay at the new rate, eventually. Moreover, there is a severe dispute between the PHM corporation and its clients in paying tax of transferring the land use rights now.

In the PMH case, even though HCMC received a majority of the profits from the project and the net benefits seem to have been very positive, it has not been easy for the city and those participating in the deal to avoid criticism that city assets were sold too cheaply. Because there was no competitive and transparent bidding (in some sense CT&D was the only interested investors in the project), the PMH project becomes an easy target. This is a fundamental problem of the land acquisition-based financing mode. Land valuation, especially in an uncompetitive environment, is typically a controversial issue.

Second, politically, the land compensation and resettlement process for PMH faced its own problems. The process took many months to complete, and it required more time than originally anticipated by both the HCMC government and CT&D. Some residents also demonstrated their discontent during the early stages of the project, protesting in front of the PMH Corporation headquarters.[57] Nevertheless, the land clearance was completed within the budget, and the land was delivered to allow Nguyen Van Linh Road to be built on time.

Third, Nguyen Van Linh Road was a well executed road. The quality of the road is, however, disparate throughout its different segments. While the road sections near residential and commercial areas belonging to the PMH Corporation are well maintained and implemented the full ten-lane

[56]Interview with Khue Jacobs, former staff of CT&D.
[57]Interviewed several people

design (or even more), other parts of the road are still six-lanes and not as well maintained as the above segments. One may argue that some segments are not yet completed to the full ten-lane design because some remaining land is not yet ready, and PMH may not have the responsibility to complete the road because it has not yet received all committed land as agreed by the city. However, this is an example about incentives. Enforcement or creation of incentive for concessionaires to maintain the quality of infrastructure service is a challenge universally.

In short, PMH is a rare case successful in applying land-based financing in Vietnam. Even though it has faced some troubles throughout its development, the success has been partly due to universal advantages of the joint venture mode and partly due to some of its specific fortunate circumstances.

Thu Thiem Peninsula Project

Thu Thiem, is a 737-hectare peninsula located within HCMC's northeast growth corridor, at an extraordinary location directly across the Saigon River from the downtown.[58] It has been considered a strategic location or "golden land" of HCMC for a long time. In many respects, Thu Thiem, is a more ambitious project than Phu My Hung. The city's vision for Thu Thiem is that it will become the new center of HCMC with high-end commercial office towers in a dense, modern form, and it would also relieve pressure on the historic quarter around District 1. Since its early beginnings, Thu Thiem has been compared to Shanghai's Pudong area in terms of its potential and role in supporting urban growth. However, after 14 years from the first approval by the Prime Minister, Thu Thiem has been relatively slow to develop. An ambitious plan has been drawn, and a huge amount of money has been invested. To connect Thu Thiem with the rest of HCMC, the city has spent more than US$500 million on the Thu Thiem Tunnel and Thu Thiem Bridge. For land compensation and acquisition, more than a US$1 billion has been spent and a half billion dollars is planned to be disbursed. Chronic problems of land clearance have intensified as additional capital is committed to Thu Thiem. Currently, the price of a square-meter of land in Thu Thiem, un-serviced by infrastructure, is on average $2,000.[59] This relatively high price of land, combined with land owners expectations of future development, and the presence of powerful interests makes the implementation of the plan opaque and complex.

The plans

In the 1993 master plan of HCMC approved by the Prime Minister of Vietnam, the idea for developing the Thu Thiem Peninsula had been mentioned only briefly. However, in 1996, Vietnam's Prime Minister approved the new master plan to develop 930 ha of Thu Thiem and in the 1998 master development plan of HCMC, it was clearly announced.[60] Looking at the potential of Thu Thiem,

[58] http://www.thuthiem.hochiminhcity.gov.vn/english/managementboarddetail.php?cid=9&id=18
[59] Interviewed real estate traders and brokers
[60] See Prime Minister's decisions: 20/TTg dated 01/16/1993 and 123/1998/QĐ-TTg dated 07/10/1998

HCMC's government has decided to build this area by itself to become a modern urban area instead of handing it to private developers as in the case of PMH. A summary of the land use plan is in Table 2.

Table 2: Land Distribution plan of Thu Thiem

Used purpose	Ha
Commercial land	166*
Public and special purpose used land	82
Transportation and park	238
Water surface (i.e. streams, ponds, and Saigon River)**	300

** This number seems low. However it is likely that some commercial land is in the second and third categories due to some implicit reasons*
** The surface of the Saigon River is estimated to be 130 ha*
Source: Authors' calculation based on various sources

To implement the project, the Investment & Construction Authority for Thu Thiem new urban area was established in 2001 by HCMC's chairman,[61] and an ambitious plan was drawn. International consulting firms were invited to bid for the design of this area. The city planned to finish land acquisition by 2005 and 40-50% of investments on the plan by 2010. However, up to the writing of this paper, the land clearance is still facing a bundle of troubles and almost no construction has been completed in Thu Thiem.

Land clearance problems

The city has planned to recall all land in the Thu Thiem area. This includes the space for infrastructure and private use. The city will then sell lots to private developers. By this model the city planned to profit enormously. However, the situation has not been as simple as expected. The process has taken a long time, and land-users have recognized the value of their land as speculators have also bid up property prices in this area.

The situation in the Thu Thiem case has been complicated. The rise in prices for land has also influenced the compensation payments demanded by current residents. From 2002-2009, the city has changed the compensation payment to land-users many times. As estimated in June 2006 by *Nguoi Lao Dong* newspaper, the total amount of compensation in the 2002 decision had been US$350 million, increasing to about $550 million in the 2006 decision of HCMC.[62] However, one year later, *Tuoi Tre* newspaper estimated the compensation in the 2006 decision would be about $800 million,[63] and in the 2009 decision of HCMC the figure was raised to about $1.4 billion. Moreover, if we include resettlement costs, the total capital for the land clearance will be estimated at $2 billion.[64]

[61] See HCMC's people committee's decision 103/2001/Q Đ-UB dated 11/01/2001.
[62] http://worldcup.nld.com.vn/153700p0c1002/tien-den-bu-khu-do-thi-thu-thiem-tang-len-9000-ti-dong.htm
[63] http://vneconomy.vn/68792P0C17/khu-do-thi-moi-thu-thiem-den-dau-roi.htm
[64] Authors' estimation

However, the issue has not been resolved yet. Many land-users seem to accept the compensation price, but the most difficulty is the compensation of the rest. The problem is that compensated and uncompensated lands are mixed together. According to discussion with some property developers, Thu Thiem's land may not be ready for the construction. To compound the problem, many land-use rights have already been transacted a number of times, so that disputes remain among these property traders as to who will hold the final land-use rights. In addition to the direct problem of the land compensation, the potentially negative impacts for those who have already returned their land to the government, and suddenly received large amounts of money without jobs or land for planting is another social issue.

Financial burdens and risks for the city budget

According to the current plan, the compensation and resettlement cost is about $2 billion and the internal investment cost is about $1.2 billion (Table 3). Moreover, if the cost of main infrastructure (bridges and the tunnel) to connect Thu Thiem with other areas of the city is included, the total cost without interest of borrowing could be $4-5 billion. Taking into account the land use plan summarized in Table 2 (there is only166 ha commercial land), the city budget may encounter serious financial trouble.

We consider two possible financial scenarios for Thu Thiem where HCMC would use land sales to recover its investment in land compensation and internal infrastructure. In the case the city uses its own money interest-free, and requires a five year payback, the price of land would need to be about $2,000 per square meter (and nearly all the 166 ha of commercial land sold). This excludes any opportunity cost of forgone investment returns. If the costs for Thu Thiem are borrowed at 12% interest for five years, the price of land would need to be about $2,700 per square meter and also nearly all commercial land would need to be sold (see Table 3). In the borrowing case, for each delayed year, the cost will increase more than $300 per square meter. This is indeed real risk for the city budget because the major proportion of the compensation cost has already been borrowed.[65]

Table 3: Cost estimation

Item	City budget	Borrowing
Compensation cost ($million)	2,000	2,000
Internal infrastructure investment cost ($million)	1,200	1,200
Total cost ($million)	3,200	3,200
Interest rate	0%	12%
Numbers of payment years	5	5
Annual payment (million)	640	888
Price of commercial land ($/square meter)	2,000	2,700
Price of commercial land ($million/ha)	20	27
Required sales per year (ha)	32	33

Required sales over 5 years (ha)	160	164

Source: authors' estimation based on various sources

Troublesome factors for the Thu Thiem project

In contrast to PMH project, there are at least four causes of problems for the Thu Thiem project.

First, decisively claiming such a large area of land is perhaps outside HCMC's capacity. The land acquisition and clearance is very complicated because it impacts nearly twelve-thousand households and some land-right holders who are influential. Because the process has been so long and many pieces of land have been sold several times over, the documents of current land-holders may not even be fully legal. Legal disputes have arisen, with buyers and sellers suing each other when the compensation prices have changed significantly. This has made the land clearance process more complicated and difficult.

Second, organizational difficulties within the city government have exacerbated the lengthy planning and land clearance process. Although the clearance process is conducted by local officials who are knowledgeable about their localities and neighbors, they have minimal incentives to resolve new issues not conforming to traditional regulatory procedures. The internal culture of risk averseness perpetuates the sense that a cadre will be punished if he brings failure or damage to the organization, but if he brings success he may also not be rewarded. Furthermore, the cadre's superior would be the one to claim positive credit (while the cadre himself may still be punished for violating procedures). Therefore, it is expected that officials working within this type of organization resist trying creative solutions that are not instructed in existing regulations. A common response from public servants in such cases is to await instruction from superiors after their sending proposals.

Additional, the frequent changing of the leadership has also caused trouble for the Thu Thiem project. Commonly, one needs several years to set up an administrative system. In this case, from 2001 up to now, the head of the authority has been changed twice or on average, each person only leads this agency for three years. It is indeed short.

Third, the gap between the city's financial resources and needs of the project has dragged on the land clearance process. If the cost for resettlement is included, land clearance costs are almost equivalent to the city budget at the year the compensation prices were announced. Of course, the city budget does not have enough money. It has had to borrowed capital from state-owned financial institutions with a bundle of bureaucratic procedures. Moreover, the process to disburse capital as well as adjust cost estimation is similar to the process of state expenditure. There are many complicated procedures hindering the efforts of the public servant who wants to accelerate the land clearance process.

A problem in Thu Thiem has been that the city government has not decisively announced a rule for land compensation. Instead of limiting compensation values to an inflation or growth index while the city implements its land acquisition process, it has entered into successive, ongoing negotiations with landholders. During this time, the value expectations of landholders and the real estate market in HCMC in general have skyrocketed. This, combined with the slow process of land acquisition, has put the city government into a perverse position where it must pay twice for infrastructure in Thu Thiem. First, it must pay for the planning and outlay of infrastructure. As the plans are rolled out, the land prices have increased largely in expectation that infrastructure will built. With a slow land acquisition process, land prices have increased and given landholders the opportunity to demand more compensation. As the result, the city must pay a second time.

The experience in Thu Thiem demonstrates a perversion of the value capture concept in land acquisition-based financing. Recall that the motivation for land acquisition is to allow the government to capture some of the value increments in land from infrastructure improvements. Where increases in previously agreed "fair value" to landholders in Thu Thiem are the result of expectations of infrastructure improvement, this is "unearned increment" by private citizens. In Thu Thiem, land value that benefits from infrastructure investment by government, rather than private parties, should therefore be attributed to the government.

Although the political negotiation between interest groups and the government realistically necessitates some value sharing, it would be perverse to require the government to pay extra for land at the expense of the wider public. Take, for example, an alternative scenario where the city cannot complete the land acquisition process because renewed claims for increased compensation make it simply too expensive. Some of the infrastructure improvements may be completed, but the public ownership of infrastructure assets would be jeopardized especially if the city cannot repay debt incurred for the projects. The city would not have the land value capture necessary to cover its costs, and landholders' expectations in land appreciation from infrastructure may not be realized. Pressure would mount for the city to transfer funds (or possibly Thu Thiem's infrastructure assets) to satisfy lenders. Essentially, the wider public would be forced to bail out Thu Thiem's bad finances due to the disjuncture between landholder expectations and municipal financial resources.

Fourth, theoretically, Thu Thiem sits on land that is perceived to be more valuable and in higher need for infrastructure service than PMH. It also represents a case where limits of the government's administrative power has delayed (and possibly prevented) infrastructure from being built.

The compensation problem of Thu Thiem is, in fact, similar to the second stage of the project in Bangalore as mentioned above. The intended acquisition and sale of the 400 acres of land for the airport highway encountered major public opposition when land prices increased strongly after the airport was built.[66] Thu Thiem is in a case quite similar to Bangalore or Paris more than one and a half centuries ago.[67] The government has not been able to implement its plans to acquire land at cheap prices and sell at high prices. This is different from China where local governments have the ability to raise enormous revenues from limited market land-use rights. Some municipalities of China are especially empowered by strong administrative powers to require that farmers sell their land below market rates, allowing the government to resell the land at market rates. In some cases, the purchase price could be more than 100 times less than the resale price. After considering the costs of land improvement, net revenues may be 10 times the total cost of the land.[68]

In fact, China and Vietnam are usually successful in recalling agricultural land thanks to farmers' limited expectations and information about the property market. But in Vietnam, cases related to urban citizens are much more complicated and difficult; furthermore, they aware of their negotiating leverage on land acquisition.

In short, the Thu Thiem project is encountering significant troubles now. It may take a long time before the city recovers its investments in Thu Thiem. However, due to its strategic location, a new urban area will likely be built in the future. However, it is perhaps too costly to implement the project through the current way. While the rest of the city awaits Thu Thiem's development, the economic waste from years of delay is possibly huge. Now that a seemingly definitive decision has been made on compensation, billions of dollars are being spent on infrastructure and land clearance. The relevant question now is at which price the city will need to sell the land use rights for private developers.

Tan Son Nhat - Binh Loi – Outer Ring Road

The most serious problem of transportation infrastructure in HCMC in the last two decades is, perhaps, not infrastructure for projects like PMH or Thu Thiem. It is inner city infrastructure. The city government has made a significant effort on upgrading and building infrastructure for existing districts. However, the result is still far behind expectations, although some projects such as the Nguyen Tri Phuong bridge, the Binh Trieu bridge, the Hanoi highway and so on so forth have been built. Outside of these projects, much infrastructure remains in planning and have not reached much progress. The Tan Son Nhat – Binh Loi – Outer ring road is one such project. Within the scope of the TSN-BL project, a 14 km road will connect Tan Son Nhat, the biggest airport in Vietnam, with HCMC's major transportation routes in its northeast.

In 1997 Vietnam's Prime Minister agreed for HCMC to build this ring road through the build –

[66] Peterson (2009, p.70-1)

[68] Ding (2005)

operate and transfer (BOT) model. Multi Usage Holdings Berhad (MUH), a Malaysian company intended to build this project with $210 million estimated cost. However, the plan was canceled due to the 1997-1998 financial crisis in East Asia. The project was postponed until 2004 when LG E&C, a South Korean company now renamed GS E&C, proposed to build the project through the build and transfer (BT) model, by which the contractor would build the road and the city would give it pieces of land whose value would be the same as the investment cost. In September 2007, HCMC's government signed a contract with GS Engineering & Construction to build this project.[69]GS E&C was expected to build a 340 million road in four years, in return for five pieces of "clean" land.[70]In the agreement, the city takes responsibility for the land clearance and GS E&C takes responsibility to build the road on time.[71]

After the contract was signed, GS E&C transferred $120 million to the city for the compensation cost and the city, in exchange, gave the contractor four of the five pieces of land valued at more than $150 million.[72]The problem is that these pieces of land are unrelated to the road and do not directly benefit from the improved infrastructure in the project.

Two issues have arisen since the money and land were exchanged. First, the progress of the project is very low due to the difficulty in the land clearance. According the contract, the city was required to give clean land to GS E&C in 2008 to build the road, but as of June 2010, land clearance has not yet been finished. 390 of 3,853 households have not yet agreed to move and only some construction structures such as pillars of Binh Loi bridge are being built.[73]Second, the issue of fair value of the land for the contractor has been called into question because it was not exchanged through an open and competitive bidding process. Some reporters have argued that the officially recognized value of the land is much lower than its true market value.[74]

In terms of implementation, the project's problems are fairly predictable. Once the land has been given to the private investor, it can focus on profit driving activities related to real estate development despite any delays in land clearance for the infrastructure right-of-way. After all, the market value of land given to GS E&C does not suffer directly from the TSN-BL highway remaining un-built. Moreover, GS E&C may find itself in a position to blame the city government for delays, and demanding compensation for penalties incurred to it by its contractors and other increased costs. To be

[74] http://tintuconline.vietnamnet.vn/vn/kinhte/449367/index.html and http://www.thanhnien.com.vn/news/Pages/201025/20100616011320.aspx

certain, the highest priority of the contractor is to maximize the profitability of the land resources which it has been given. GS E&C is now selling apartments being built in two pieces of land along with requesting the Prime Minister permission to sell another piece of land to fulfill capital requirements brought on by the global financial crisis after getting the green light of the city government.[75]

In short, along with the pricing and bidding process in this case, the biggest problem is that the concessionaire has been given land totally unrelated to the infrastructure improvement project. This has not given the concessionaire any direct incentive in building the road after getting the land. Nor does the public sector feel the pressure that would otherwise come from private investors to complete the highway's land clearance. Even though the TSN-BL project exchanged land for the highway construction, it does not conform to the core principle of land-based financing in that it lacks any direct land value appreciation from its respective infrastructure improvements.

In Conclusion

Three land acquisition-based financing techniques have been applied in HCMC. However, only the PMH project has been finished. We argue that it successfully utilized advantages of the joint venture model and benefitted from other specific factors of leadership and land clearance that are more difficult to replicate. But that is not to say that the joint venture is always the preferred mode of choice. Other issues that are pervasive in the joint venture, such as contract ambiguity and the requirement for long-term coordination between partners may not be desirable in all situations.

The Thu Thiem and TSN-BL projects have faced difficulty due to other fundamental problems. The land clearance processes of the Thu Thiem and TSN-BL projects are overly complicated and draw in many interest groups. Thu Thiem has been implemented by the government agencies, so that like other public businesses, there is minimal motivation for public servants to undertake land clearance quickly and in a way that minimizes risks to the public budget. In comparing the burdens to the public, Thu Thiem is a very ambitious project that has saddled the city government with billions of dollars in debt. Meanwhile, the TSN-BL project does not face the problem of unavailable financial resource because of its relatively smaller scale and the $120 million transferred from GS E&C.

Although the land prices in Thu Thiem are quite similar those in PMH now, the two projects are very different in terms of finance. In PMH, the land is well serviced by various infrastructure services even though the city has spent little or no money its development. Furthermore, it has received nearly half a billion dollars in the last decade from PMH. Across the Saigon River in Thu Thiem, the situation is drastically different. The peninsula of Thu Thiem is effectively barren in terms of

[75] http://www.thesaigontimes.vn/Home/thoisu/sukien/29551/

infrastructure (although construction has been ongoing) while the city has been spending billions of dollars to awaken its potential. The city budget continues to bearing huge risks for this project, but the result of Thu Thiem is unclear as of yet. In addition, compared to several key contemporary transportation projects and the two projects here, Nguyen Van Linh Road was one of the few, if not the only, large-scale infrastructure project that was finished on time and on budget.[76]

[76]Rosengard et al (2006)

Section 3. Implications

In principle, there are two sets of techniques to build infrastructure through the land-based financing: land acquisition-based and non-land acquisition-based. Land acquisition-based financing may work better with situations that have low requirements for land clearance while non-land acquisition financing may work better with situations that have heavier burdens for land clearance.

Conditions to Apply Land Acquisition Based Financing

Through cases examined in this paper, there are several conditions to apply the land acquisition-based techniques. Each condition will be analyzed below.

Clearing land quickly and decisively

The prominent condition of this financing technique is to control land. Land clearance is usually the most difficult process. It is related to many complicated issues. The longer the process is, the more uncertain it is. An important issue for all land acquisition-based financing is the expediency of compensation and resettlement. Especially in market conditions where volatile jumps in property prices can jeopardize the availability of land for projects, the speed and decisiveness of land clearance becomes crucial. Balancing the need for expediency with the rights of landholders is never an easy task, but there are policy tools that have been used in other countries to allow access to land. For example, once an announcement for land clearance has been made, the government can mandate that any future increases in the compensation for land clearance will be fixed to a consumer price index. Furthermore, the section below describes several financing modes that can discourage land speculation that may result from development announcements. To some extent, it may be possible to use these in combination with the acquisition-based modes to raise funds for land acquisition.

Incentives and availability of financial resources

Land clearance is indeed complicated. To do it quickly and decisively, structuring incentives and financial resources is critical. This may help deal with newly-arisen issues quickly. For this reason, the government's land clearance programs may encounter trouble because they lack both incentives and availability of financial resources. This implies that the involvement of market forces is necessary.

With private sector's involvement, private investors can reap huge profits even through transparent bidding processes. This happens because private developers may equally bear huge risks and they may have execution capacity in managing these projects. Commonly, the sigh of foreign private investors earning large amounts of money can be unpalatable for many people, especially in countries emerging from the central planning or socialist model. Cultivating a friendly public perspective in such cases is perhaps necessary.

Determining land value

In the land acquisition-based financing mode, one of the main issues is pricing. In Vietnam, the land transfer process is rarely transparent, which can also create public anger when it is discovered that private investors earn huge profits at the expense of the government. Transparent bidding is a solution for this issue and is reflected in the case of Cairo, Egypt.

In the New Cities project around Cairo, Egypt, the auction of public land has been a successful way to raise money for infrastructure projects. In Egypt, the government owns all undeveloped desert land, and traditionally it has supported urban growth by self-financing and installing infrastructure and then selling off serviced to urban developers. However, the budget burdens associated with selling improved land through private negotiations (sales were often at prefixed, below-market prices) has pushed the government to implement auction reforms in its infrastructure development process.

Under the reforms, land has been auctioned competitively to developers and requires the buyers to install necessary infrastructure. This strategy has raised more money to cover its own costs while still providing the infrastructure needed to support rapid urban growth. For example, auctions in May 2007 alone helped Cairo raise US$3.12 billion. The government has used the proceeds to pay for the Cairo Ring Road and subsidies for low income housing.[77]

A transparent auction process is, indeed, important. Not only does this help avoid waste and corruption, it also improves efficiency of using resources because it helps to choose the right developers who have capacity to implement projects and will signal this through bidding prices.

Rules for land acquisition, uses of funding

While the decisiveness and speed of land clearance are key to land acquisition-based financing, having established rules for the process and the uses for funding may help in raising public trust in an investment program. In addition, the cases of Paris and Bangalore demonstrate the importance of public support for infrastructure investment programs dependent on land acquisition. Establishing clearer standards for government action would help to build trust and to rationalize government programs in infrastructure development. On the flip side, it may also help to limit a financially hungry government that would otherwise make economically flawed investments that drain its land resources.

[77]Peterson (2009, p.58)

Recommendations

Applying land acquisition-based financing

Each of the three land acquisition-based financing techniques including: (1) transferring land to private developers in exchange for infrastructures; (2) engaging in joint venture to build infrastructures; and (3) governments' building infrastructure and sell surrounding improved land has its own pros and cons. To use these techniques efficiently, issues related to each mode should be considered carefully.

First, transferring land to private developers in exchange for infrastructure may work for projects which have low requirement on land clearance and the appreciation of given land or property relies mainly on the infrastructures to be built. This technique has been applied in many places such as in building the railroad system across the United States 150 years ago; developing basic infrastructure for new towns in Cairo, Egypt and building the TSN-BL project in HCMC, Vietnam. The first two projects conformed to the two basic conditions of land being available and a strong link between land value and built infrastructure. The TSN-BL project, however, has run into trouble on these two conditions as well as on other fronts. First, the land clearance process has been very complicated. Second, the exchanged pieces of land are totally unrelated to the project, so that the contractor has minimal incentive to build the road. Third, the land clearance is implemented by public servants with suboptimal incentives in completing the process. Finally, the land has been given without any type of bidding or auction.

In projects like the TSN – BL highway, the build-operate-transfer (BOT) model along with a subsidy from the municipal budget may be an alternative that helps align incentives of investors with the city. In another alternative, the city can build the project itself. Land that is exchanged or sold should be auctioned through a transparent process and the money committed to accountable uses. Using the method applied in TSN-BL case is easy to get incompetent investors in both building the required infrastructures and exploiting the given lands.

Second, engaging in joint venture to build the infrastructure may be suitable for projects which have substantial requirements for land clearance but are not too complicated. This mode has been applied successfully in many countries such as the ring road project in Changsha, China; the new airport in Bangalore, India and PMH project in HCMC, Vietnam. This model is quite successful because it can usually take advantages of both the public and the private partners. The public partners usually have expertise to deal with local people in the land clearance process and related issues while private partners have motivation as well as financial availability to push the process.

The joint venture model may be good for providing incentives for public servants to work quickly for resettlement. This assumes that they have good capability to work with local conditions, and that the presence of potential earnings from land investments provides the incentive for the private partners in the joint venture to push processes to be done quickly. If this mode is applied, the articles of the joint venture contract need to be determined as clearly as possible. Moreover, similar to the first mode, the land value should be directly tied to improvements in infrastructure to align incentives of the investors with the public.

In the PMH project, besides fundamental conditions that helped the project successful, unique factors such as the motivation of Mr. Phan and his colleagues as well as Mr. Ting vision, and the public money were important. However, for the policy implication, these factors are difficult to replicate and perhaps specific to the good fortune of PMH.

Third, governments' building of infrastructure and selling of surrounding improved land has encountered difficulty in most countries. This mode may be applied in cases in which land is already available or land clearance is simple. This mode has also applied in many places such as Paris, New York, Cairo, Bangalore and Thu Thiem. The problem of this model is that the bureaucracy along with lacking incentive makes the land acquisition process very lengthy while land prices (or demands for compensation) may continue to rise thanks to completed (or expected) infrastructure investment. This creates opposition by land holders who may feel shortchanged. To avoid this, when plans to develop certain areas are revealed, governments should promulgate compensation prices that are capped and indexed to publicly known measures such as GDP plus inflation.

It is hard to know exactly where the Thu Thiem project remains because it continues to unfold. Huge amounts of money have been spent, and many people have already received their compensation. However, many have not yet agreed with the compensations. This makes the situation more complicated. According to some reports the land in Thu Thiem is available now for construction, but according to interviews with potential investors, it seems that there is not much available land due to the incomplete clearing and resettlement of residents. It is possible that the project will last much longer and will cost much more than expected.

However, HCMC's government could reassess the process. The current approach may require a long time before the revenues from land sales are enough to cover costs. Such a situation would create high risk for the city's budget; therefore, the city should focus only on recalling land necessary to build critical infrastructure. In such a scheme, remaining occupied and uncompensated land would be isolated, and the government could impose taxes or fees as mentioned in following sections.

In addition, there is a temptation for municipal governments to apply the technique that Paris and New York applied more than one and a half century ago and China has successfully applied recently to upgrade or improve infrastructure of the downtown of cities or population density areas. It is to recall a larger area of land required for the infrastructure. However, this technique is usually not feasible if governments are not strong and competent enough because dealing with a large numbers of people is extremely difficult, especially in the political perspective. This is one of main weaknesses of the public sector. Choosing approaches in which less people involving into a project is perhaps better.

Fourth, transparent land or asset auction is necessary. Peterson (2009) showed that majority of land sales are conducted off budget. There is little public accountability for these activities. Large amount of money for land sales or transfer invites corruption. This also creates social loss by choosing subpar developers and wasting public resources. A competitive bidding process may help choosing right investors and increase public revenue (usually significantly). For example, a transparent auction process in Cairo, Egypt helped increase proceeds of land sales to 10:1 factor.[78]

In short, the first and the third modes can be applied in cases in which the land clearance is not very heavy and not related to many people or interest groups. The land acquisition-based financing model may not work well for cases in which the land clearance process is complicated and involves many parties. In these cases, the non-land acquisition-based financing model may work better.

Applying non-land acquisition-based financing

Across the various modes (betterment levies, development fees, and impact fees), the biggest advantage of the non-land acquisition-based financing modes is the reduced requirement for land clearance. Beyond the amount of land needed for the infrastructure, government will not need to sell or lease additional land to cover investments. Therefore, non-land acquisition-based modes can exercise advantages in cases where land clearance is difficult and complicated. It helps reduce opposition of land acquisition because land is purely used for infrastructure.

However, for these non-land acquisition-based modes, there are difficult requirements for data and analysis to implement revenue collection. With the betterment tax, for example, the municipality will need to current and historical information on property values and also project the taxes needed to cover infrastructure costs. Often tax collection can be difficult to predict, making this mode more common in developed jurisdiction, where there is better administrative capacity to record land values and to implement tax collection. Quite frequently, land acquisition is extremely difficult in developed countries.

Another solution is to offer traditional financing like in Korea and Japan where private land holders give up their land to the public, in order to build infrastructure, and then they receive a portion back (like 40%) after the value of land has been much improved. This is, in fact, in-kind betterment levy.

[78]Peterson (2009,p. 106)

But theoretically it could also be used as an in-kind fee for development rights or impact on existing infrastructure. The benefit of the in-kind approach is that landowners do not have to pay the tax by cash which may be unavailable for payers.

Thu Thiem is, in fact, not the only case in HCMC. In the future, many more projects will rise in complexity and have greater requirements for land compensation (and therefore risk greater public opposition) if land-based financing is used. The non-land acquisition-based financing model, therefore, may be a reasonable way for the city to finance for its high demand of infrastructure. Moreover, this mode can help cities like HCMC to deal with the erecting of skyscrapers in the downtown. To avoid the overload of infrastructure, the city government can sell development rights. The price of these fees could be based on the height of structures, with each additional floor paying a certain amount. Alternatively, the municipality can use a policy that charges an impact fee on developments that stress supporting infrastructure. Through this policy, the infrastructure will be secured because increased utilization will be linked to cost recovery and allow upgrades and maintenance from these revenue streams.

Suppose that the city applied the sale of development rights to Thu Thiem. The government would build main infrastructure for the whole area and design the master plan, then allow private developers to build buildings along with internal infrastructure. Different policies could be applied. In one option, all developers are required to follow the master plan strictly. In another option, developers are required to buy development rights to build buildings in the case land is already residential or commercial land, and developers have to buy both development and land conversion (from agriculture land to other purposes) rights. Prices of these rights would depend on the purpose of buildings; public-oriented uses could receive a lower fee and more commercial-oriented uses, higher fees, for example. The fees will be based on the cost for building basic infrastructure including the land compensation.

A variation of this could apply a general assessment fee where holders of undeveloped land also are required to pay a fee for infrastructure upgrades (this fee could be lower than other developed areas). The city could also combine this with its land-use policies and charge a tax for land that is not put into operation after a certain period (e.g. 2 years). The result from the collection of these policies would be a source of revenue for infrastructure investments and required land acquisition for only main infrastructures that would be much less than the 690 hectares in the current plan. One may conjecture that the process would be faster and less costly than the current route.

Other Issues

This paper supposes that investment decisions have already made, so that economic value of projects was not mentioned or estimated. The bottom line is that which financing mode is appropriate. The main focus of our paper is to find appropriate solutions to finance infrastructure planned to be build.

We did not answer the question whether an infrastructure is economically good decision or not. To do this, the net present value of a project needs to be estimated. In this case the most challenge is to estimate opportunities cost of alternatives. As Altshuler and Gomez-Ibanez have shown "to estimate the effect of a new development on local services and revenues, the baseline must be established what the alternative might be. What might happen to the patterns of local land uses and public service demand in the absence of some contemplated or proposed new development?"[79] Studying the economic results of a project to learn whether it is a good decision is an option for further study.

University of Malaya

The knowledge of equity style of PRS funds has benefited investors by mitigating the issue of asymmetric information between fund managers and investors. Using a return-based style analysis with PRS fund data from April 2013 to February 2015, our study found that: First, moderate funds have the highest degree of style of 61.31, followed by growth funds (52.37) and conservative funds (51.75). In other words, the fund managers of moderate funds practise more passive than active styles. Second, on average, conservative funds have the highest degree of selection (48.25) and lower degree of style. One would expect the opposite as conservative funds should act more like passive rather than active fund. Third, growth funds have higher degree of section (47.63) as compared to moderate funds. Fourth, conservative funds, as the name implies, have strong focus on the fixed income products rather than equity. Lastly, in terms of asset allocation to equity, on average, growth funds have higher allocation to foreign equity of 16.28, followed by moderate funds (9.18). In addition, growth funds focus on large growth stocks, while moderate funds focus on large value stocks. To the best of the authors' knowledge, this study is the first academic research done on PRS funds after the scheme was launched in July 2012. It is hope this study can be the catalyst for more academic work on this subject.

Keywords: style analysis, equity style management, asset allocation, performance, retirement fund

1. Introduction

A new private pension fund scheme known as Private Retirement Scheme (PRS) was launched by the Prime Minister of Malaysia Datuk Seri Mohd Najib on 12 July 2012 as part of the Capital Market Master Plan 2 (CMP2). The PRS scheme is a voluntary retirement savings scheme structured by private sector fund providers which are licensed by the Securities Commission. In order to facilitate the management of PRS, a new body known as Private Pension Administrator (PPA) is established to oversee the operation of PRS. First group of funds were made available to the public in September 2012 by eight asset management companies.

This new scheme aims to supplement the existing stated sponsored retirement scheme known as Employees Provident Fund (EPF). Studies by Asian Development Bank (ADB) and EPF have shown that there is a need to have more retirement scheme for Malaysian. An economist from ADB, Park (2012) reported that in Malaysia, only 48 per cent of the labour force and 32 per cent of the working age population 15 – 64 were covered by pension system in 2007.

In addition, as per the report by EPF (2015), it is reported that in 2014, 68 per cent of the EPF members at the age group of 54 has savings equal to RM50,000 or less in their retirement account. It is also found that 50 per cent of the retirees will spend their EPF retirement monies in 5 years or less. From the perspective of demographics, these findings are alarming in view that the average life expectancy for Malaysians is 75 years old, and given the retirement age at 60, there is 15-year gap. Hence, it is hoped that the Private Retirement Scheme (PRS) industry is able to complement and supplement the existing mandatory Employees Provident Fund (EPF). The schemes will be able to provide employees and self-employed people with an additional avenue to save for their retirement.

As a national project to uplift the country to a higher-income level society, the Private Retirement Scheme (PRS) is one of the entry point projects for the Financial Services National Key Economic Area (NKEA) under the Malaysia's Economic Transformation Programme (ETP). It is hoped the PRS will further enhance the growth of fund management industry and other ancillary business services which will create new values and income to the society. As stated by The Prime Minister, Najib Mohd during the launch of PRS on 12 July 2012:

> "*...A high income nation must have a sound and sustainable social framework to ensure adequate retirement savings. Private retirement schemes form an integral feature of the private pension industry with the objective of improving living standards for Malaysians at retirement through additional savings of funds….*"

The newly PRS has shown some outstanding result, as per the statistics as at 31 December 2013, there are 72,990 accounts registered with a total net asset value (NAV) of RM299.2 millions.[2]

1.1 The Benefits and Fund Type of PRS

The contribution can be made by the employees and employers without any fixed amount or interval. Employees and the self-employed have the option of specifying the type of fund they want to contribute to. To encourage savings, individuals are granted tax relief of up to RM3,000 and employees are provided tax deduction on contributions above the statutory rate of 19 per cent.

As shown in Figure 1, the PRS funds are divided into three types, namely the growth fund, moderate fund and conservative fund. The asset allocation are matched with age group and risk tolerance level, in line with the concept of life cycle of investing.

As accessed on 08 January 2015

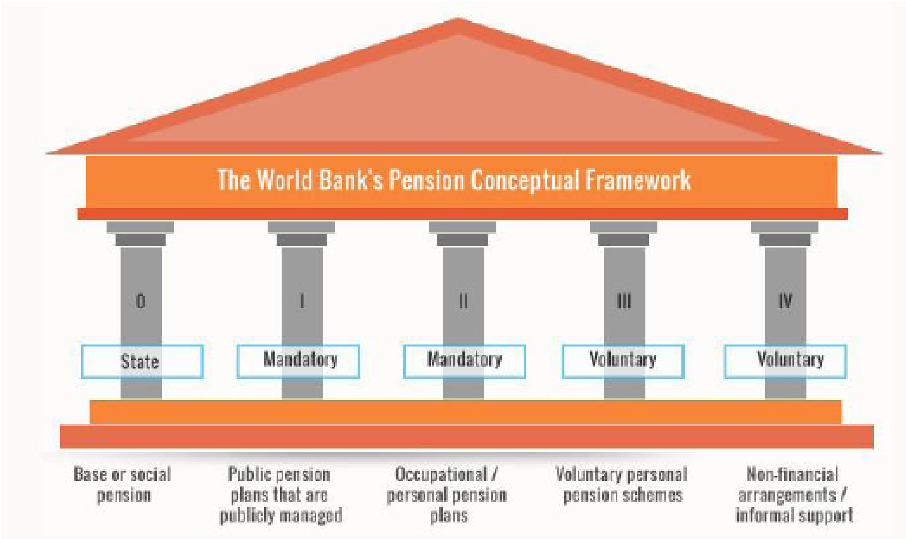
Conservative fund, as the name implies, is more suitable to the risk profile of older age group from 50 and above. They are not encouraged to hold risky asset as their time horizon for investment is shorter as compared to younger age group. Hence, no foreign asset class is allowed in their portfolio. In contrast, investment outside is permitted for both growth and moderate funds.

1.2 Conceptual Framework of Pension System

As fertility rate drops and aging society develops over the years, under the auspices of the World Bank, Holzmann and Hinz (2005) has developed the World Bank's Pension Conceptual Framework or which is also known as the World Bank's Five Pillar System. In an effort to reform the global pension system, they has provided a scheme of five-pillar model to classify the various ways to fund for the retirement system.

Everybody needs to have an adequate retirement provision when one reaches old age. Pension provisions or retirement benefits consist of various building blocks. The PRS is expected to contribute towards the Third Pillar to supplement the mandatory Employment Provident Fund (EPF) which is under the First Pillar, in order to have a robust pension system for Malaysia.

Figure 2: The World Bank's Five-Pillar System

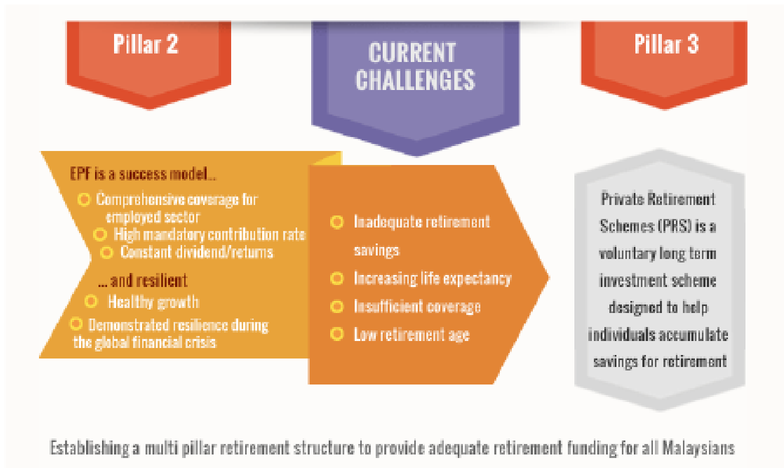


Source: www.ppa.my
As accessed on 08 January 2015

Under the Zero Pillar, there is no contributory social assistance from the State. Under Pillar One, there exists mandatory contribution which is linked to earnings. Under Second Pillar, there is mandatory defined contribution plan with independent management. There is voluntary savings under Third Pillar. Finally, retirees whom have no formal pension scheme will have to rely on informal support or their assets for post-retirement lives.

In this respect, Malaysia's PRS aims to promote the welfare of the population at retirement through a robust multi-pillar pension framework. The Securities Commission is reviewing the existing retirement landscape to make recommendations within the context of developing the private pension industry, which will complement the mandatory contribution to our existing Employees Provident Fund.

Figure 3: Current challenges in Malaysian Pension System



Source: www.ppa.my
As accessed on 08 January 2015

As identified by the Securities Commission and Private Pension Administrator (PPA), there exists four key challenges to retirement planning in Malaysia. They are inadequate retirement savings, low retirement age, insufficient coverage and increasing life expectancy.

1.3 Motivation

Like other funds managed by asset management companies or plan sponsors, *there is always asymmetric information between the fund managers and investors*. In our context, individuals or households who place their monies would like to know the asset allocation of their funds and the accompanying risk. As shown in the past studies using the US pension fund data, Brinson *et al.*(1986, 1991) show that asset allocation is the key determinant of portfolio performance in the long run.

Secondly, there exists the issue of over-rewarding the fund managers. Investors often could not tell whether the excess return to the fund (alpha) is contributed by the fund manager's selection or timing skills or simply the random occurrence of luck. As shown by past studies, using the US data, the Nobel Laureate, William Sharpe (1988, 1992) shows that the decomposition of returns to underlying asset allocation is possible through the return-based style analysis (RBSA). In addition, this technique enables one to examine the degree of styles and selection of a fund.

1.4 Research Objectives

There are two research objectives for this study:

Firstly, this study intends to attribute the performance of PRS funds to their respective underlying asset allocation; and

Secondly, this study intends decompose the returns to their respective of style and selection, how much the fund managers are able to add value or excess return per unit risk to the fund.

1.5 Organization of this study

The paper is organized as follows. The second section briefly reviews the literature on equity style classification and Malaysian mutual funds. The third, four and fifth sections are on data, methodology and results respectively. In final section, with respect to findings obtained from this study, this paper concludes on the application of return-based style analysis on decomposing asset allocation of PRS funds and its contribution to add to the extant literature in portfolio management in Malaysia.

2. Literature Review

2.1 Pension System and Social Security System

As discussed in section 1, numerous studies have touched on the need to reform the pension system in the world. Lee (1997) discussed the concern of sustainability of Government pension scheme in Malaysia in view increasing number of size of civil servants, and hence increasing cost of pension which will certainly add to the financial burden of the government.

There are also numerous studies on pension reform from Austria, Finland, Latin America and Japan (Brunner, 1994; Barrientos, 1996; Horiba and Yoshida, 2001; Hakola and Uusitalo, 2005). It shows the awareness is high as there are worries as to the sustainability of pension system in the respective countries. Interestingly, there is no study which focuses solely on private retirement scheme.

2.2 Investment Policy, asset allocation and fund performance

A fiduciary relationship exists between investors and their fund managers has underscored the importance of *investment policy*. In this respect, Gibson (1996) has enlisted a four-step approach in designing an investment portfolio for investing clients.[i] Of which, the first step being deciding which asset classes to be represented in the portfolio, and second, determining the long-term 'target' percentage of the portfolio to allocate to each of these asset classes. The third step being specifying the range within the allocation can be altered, and the fourth step being selection of securities within each of these asset classes. Therefore, it is pertinent for fund manager to follow his investment policy over a predetermined time horizon or until such time when the policy is altered.

Why investment policy is being emphasized in mutual fund investment? How does investment policy dictate asset allocation strategy and fund performance? In recent times, studies conducted in advanced financial markets notably the United States, have linked the performance of mutual funds to their respective asset allocation strategies [Brinson, Hood and Beebower (1986], Brinson, Singer and Beebower (1991), Ibbotson and Kaplan (2000)]. In addition, the emergence of style analysis research on mutual funds has also answered some of the questions on the relationship between asset allocation and the styles as well as performance of mutual funds [Sharpe (1992), Fama and French (1992 & 1993), Carhart (1997)].

2.3 Equity Style Classification

It is inevitable for the problem of asymmetric information between fund manager and investors to exist as timely mutual fund holdings are not readily updated even in the developed market as discussed by Lucas and Reipe (1996). Furthermore, they identified style analysis to be a useful tool for investors to comprehend a trust fund's investment policy and objective.

In a number of subsequent studies, in the course of identifying a system of classification for equity trust funds, the researchers have also presented the evidence of mis-classifications if self-reported investment objectives were to be compared to the estimated styles (diBartolomeo and Witkowski, 1997; Brown and Goetzmann, 1997; Kim, Shukla and Tomas, 2000).

In one of the recent studies, Amenc Sfeir and Martellini (2002) have proposed an integrated framework for assessing the risk-adjusted performance of mutual fund managers. This methodology is designed to be consistent with modern portfolio theory and constraints imposed by practical implementation of investment management where a variety of styles have to be accounted for. In another study, TerHorst, Nijman and DeRoon (2004) states that while the estimated portfolio may indeed differs from actual portfolio holdings, but "…if the aim is to predict future fund returns, factors exposures seem to be more relevant than actual portfolio holdings, and return-style based style analysis performs better than holding-based style-analysis"[5].

Recent studies have focused on the concept of equity style management in mutual funds. Using return based style analysis, Lau (2002) states that in addition to market benchmark comparison, the performance of funds can also be compared against their respective peer groups. In subsequent study, Lau (2005) finds that the risk-adjusted performance of growth style fund managers is more persistent than value style funds. The same effect was not found under mutual fund objective classification. In addition, Lau (2006) finds that under style classification based on MSCI style indices, investment style is found to communicate economic trends to investors. It is found that during the period of economic recovery, value style funds recover faster from distressed economic environment than growth style funds. On the other hand, during economic recovery, growth style funds exhibit recovery momentum better than value style funds.

In another study using an integrated framework of style analysis, Lau (2007) states that the inclusion of asset classes with negative correlation coefficient enhances the performance of funds and funds with relatively high degree of style (above 70 percent) that hold large-cap stocks together with high portion of liquid asset class (6 to 35 percent) tend to have higher alpha, translating into higher information ratio.

3. Data and Methodology

The sample of PRS fund data from 30 April 2013 to 27 February 2015 is obtained from Thomson Reuters Datastream. The Net Asset Value (NAV) for the last trading of the month is used in the analysis.

As discussed in section 1, there are three types of fund under the PRS definition. The study only focuses on core categories, namely Conservative, Growth and Moderate. Islamic funds are excluded as they are invested in asset classes different from conventional funds. In addition, REITS and feeder funds are also excluded as they constitute less than 1 per cent of available funds.

Table 1: Sample of PRS funds

No.	Fund name	Morningstar Category	Malaysia PRS Category
1	Affin Hwang PRS Conservative Fund	Cautious Allocation	Core (Conservative)
2	Affin Hwang PRS Growth Fund	Aggressive Allocation	Core (Growth)

Source: www.ppa.my
As accessed on 08 January 2015

Referring to table 1, a total of 30 funds from growth, moderate and conservative categories are chosen for this study.

The continuous compounding return for the fund is used as the dependent variable. It is calculated as

$$R_{j,t} = \ln(P_{j,t} / P_{j,t-1})$$

$$R_{m,t} = \ln(I_{m,t} / I_{m,t-1})$$

$$R_{f,t} = \ln(1 + r_{f,t})$$

Where:

$R_{j,t}$	=	the continuous compounded return for j unit trust fund at time t
$R_{m,t}$	=	the continuous compounded return for m benchmark portfolio for the month t
$R_{f,t}$	=	the continuous compounding risk free rate of interest for month t
$P_{j,t}$	=	the net asset value for j unit trust fund at time t
$I_{m,t}$	=	the asset class index at the end of month t
$r_{f,t}$	=	the discount rate of the 90-day T-Bill for month t as the proxy for the risk free rate of interest

Independent variables are returns series of asset classes invested by fund managers. The asset classes that represent the investment universe are shown in table 2. The continuous compounding return of independent variables are also calculate as per the formula in above. However, the KLIBOR rate is transformed in logarithmic form to avoid the problem heteroscedasticity. There is an effect of variance reduction for the overnight inter-bank rate, and this will assist in obtaining a more accurate and unbiased estimation.

Table 2. Asset class indices

Asset Class	Description
Growth Stocks	Represented by MSCI Malaysian Growth Index* quoted in local currency.
Value Stocks	Represented by MSCI Malaysian Value Index* quoted in local currency.
Cash	A proxy for short-term Ringgit money market instruments. Represented by Kuala Lumpur Inter-bank Offer Rate (KLIBOR). KLIBOR 1-month deposit rate is used.
Government Bonds	Represented by MGS-bond all tenure Index#, which account for MGS with value above RM100 million on issues for maturity greater than one year.
Corporate Bonds	Represented by Corporate Bond Index#, which account for all bonds and loan stocks listed on KLSE a term to maturity of more than one year. A proxy for listed private debt securities.
International Stocks	Represented by MSCI World Index*. A proxy for all international stocks index.

* Available from http://www.msci.com

Style analysis in equation (2) attempts to capture the investment universe in the model, careful consideration has been taken to ensure that asset classes chosen are not correlated to one another. As stated by Sharpe (1992) "…while not strictly necessary, it is desirable that such asset classes should be 1) mutually exclusive, 2) exhaustive and 3) have returns that 'differ', and the asset classes returns should either have low correlations with one another or, in cases in which correlations are high, different level of standard deviations".

As shown in table 4, there is no close correlation between the indices on the right hand side.

4. Methodology

Style Analysis

As in Sharpe (1992), this study initially introduces the generic factor model in equation (1) before adapting it into style analysis in equation (2).

$$\tilde{R}_i = \left[b_{i1}\tilde{F}_1 + b_{i2}\tilde{F}_2 + b_{ik}\tilde{F}_k + \ldots\ldots + b_{in}\tilde{F}_n \right] + \tilde{e}_i \qquad (1)$$

Where

$\tilde{R}_i$ = return of fund i

$\tilde{F}_k$ = return of factor k for fund i

b_{ik} = sensitivity of fund i to factor k

$\tilde{e}_i$ = non-factor return of asset i of mean zero with the assumption that the non-factor returns are uncorrelated $\sigma_{eiej} = 0$

Style Analysis is the use of constrained quadratic programming for solving the asset allocation problem. This approach incorporates two specific constraints: first, the coefficients must sum to 100 percent and second, coefficients must be positive. Negative coefficients can be interpreted as short positions in asset classes. This type of strategy is rarely used by the funds examined, and prohibiting these coefficients provides better, more usable results.[8]

The factor is rewritten as

$$\tilde{e}_i = \tilde{R}_i - [b_{i1}\tilde{F}_1 + b_{i2}\tilde{F}_2 + b_{ik}\tilde{F}_k + \ldots + b_{in}\tilde{F}_n] \qquad (2)$$

Where

$\tilde{e}_i$ = selection

$\tilde{R}_i$ = return of fund i

$\tilde{F}_k$ = return of factor k for fund i

b_{ik} = sensitivity of fund i to factor k

To obtain the style, minimize variance of residual return $\tilde{e}_i$
Subject to Constraints

$$\sum_{j=1}^{n} b_{ik} = 1 \text{ for any fund } i \text{ and asset class k}$$

$$\text{and } 0 < b_{ik} < 1$$

With the two specific constraints, the coefficients tabulated in equation (2) will resemble the weights within a portfolio and conveniently displayed as part of the portfolio. The asset class indices in table 2 which represent the factors in equation (1) and the sensitivity of each of the fund's return series to each of the asset class index factors is used to construct a passive benchmark portfolio return series for performance measurement. In other words, the return of funds will be measured against the style-based, passive benchmark contained as second, bracketed terms in the right hand side of equation (2).

Upon obtaining results from the quadratic programming in equation (2), the proportion of variance 'explained' by the selected asset classes, for fund i can be obtained as below:

$$R^2 = 1 - \frac{Var(\tilde{e})}{Var(\tilde{R})} \qquad (3)$$

The second term of the right-hand side of the above equation represents the proportion of variance 'unexplained" or due to active management (selection). In other words, the return of unit trust fund is decomposed into return on a set of asset classes and residual return. The former is attributed to *style* and represented by the R-square while the latter is attributed to *selection*.

In order to take into account the added (or subtracted) value provided by a fund i.e. its benchmark and the added risk, the monthly mean selection returns is divided by the standard deviation of monthly selection returns. This calculation gives an information ratio as stated in equation (4).

$$\text{Information Ratio} = \frac{E(\tilde{e}_i)}{\sigma_{\tilde{e}_i}} \qquad \textbf{(4)}$$

The monthly mean selection returns can be measured for its statistical significance using a t-statistic. The null hypothesis is stated as selection return equals to zero.

$$t = \frac{(r_s - \mu)}{s/\sqrt{n}} \qquad \textbf{(5)}$$

Where

r_s = the monthly mean selection returns

μ = zero, the null hypothesis

s = the standard deviation of monthly selection return

n = the number of observations

4. Result and Discussion

As per the discussion in section 3, the result of estimation is listed as below:

Table 5 Degree of Styles, Selection and Asset Allocation of Different Fund Types

No	Fund	Style	Selection	Large Growth	Large Value	MGS	Corporate Bonds	Money Market	MSCI World	Total
1	Affin Hwang PRS Conservative Fund	37.61	62.39	20.03	0.00	41.66	38.31	0.00		100

7	CIMB-Principal PRS Plus Moderate - Class X	58.80	41.20	28.32	36.64	22.40	0.00	1.76	10.88	100
8	Manulife PRS-Moderate Fund Class A	36.49	63.51	10.09	28.35	61.55	0.00	0.00	0.00	100
9	Public Mutual PRS Moderate Fund	77.62	22.38	30.42	14.69	0.00	0.00	0.00	54.89	100
10	RHB Retirement Series - Moderate Fund	51.51	48.49	17.52	36.24	38.97	0.00	7.27	0.00	100
	Moderate Fund	**61.31**	**38.69**	**13.41**	**27.39**	**37.95**	**1.79**	**1.52**	**9.18**	**100**

Overall, Moderate funds have the highest degree of style of 61.31, followed by growth funds (52.37) and conservative funds (5175). In other words, the fund managers of moderate funds practise more passive style than active styles.

On the contrary, on average, conservative funds have the highest degree of selection (48.25) and lower degree of style. One would expect the opposite as conservative funds should act more like passive fund rather than active fund. Growth funds have higher degree of section (47.63) as compared to Moderate funds.

Looking at each category, it is interesting to note that for conservative funds, on average, they have allocated 59.47 per cent in corporate bonds, followed by 23.35 per cent in MGS, with a total of 82 per cent in debt instruments. In other words, conservative funds, as the name implies, have strong focus on the fixed income products rather than equity.

In terms of asset allocation to equity, on average, Growth funds have higher allocation to foreign equity of 16.28, followed by moderate funds (9.18). In terms of asset allocation between growth and value stocks, Growth funds, as name implies focus on large growth stocks, while moderate funds focus on large value.

However, within each respective category, it can be observed that the asset allocation does not follow a clear pattern and at times, the disparity can be wide between one another. For example, for conservative funds, Affin Hwang PRS has large growth of 20 percent of which around 4 times above the average. For growth funds, it is observed that AmPRS Growth Fund Class D has near to 50 per cent of asset allocation in MGS, while Affin Hwang PRS Growth Fund has 62.43 per cent in MGS. This brings to the issue of misclassification of fund objective in PRS fund. Hence, the comparison among the funds are not accurate.

Table 6 Cumulative Return Difference (Fund versus Style) and Selection Sharpe Ratio

***, ** and * denote level of significance at 1, 5 and 10 percent level respectively.

Table 6 highlights the results of the cumulative return difference (fund versus style) and selection sharpe ratio which are useful as performance measurements. As both measurements are originally obtained from the *cumulative selection return*[ii] from the style analysis, they report the same results with respect to performance of funds intuitively.

Across the fund styles, from the point of view of cumulative return difference, it could be observed that conservative funds are the best performers, followed by moderate funds and growth funds. From selection sharpe ratio point of view, it is observed that conservative funds are the best performer as compared to moderate and growth funds.

Individual funds that perform well in each category is CIMB-Principal PRS Conservative – Class C with selection sharpe ratio of 0.56, Public Mutual PRS Growth Fund of 0.65 and RHB Retirement series – moderate fund of -0.41 respectively

5. Conclusion

5.1 Findings and Original contribution

Through return-based style analysis, the study has managed to decompose the return to its asset allocation. This study contributes in a few aspects:

First, using the return-based style analysis (RBSA), the returns of various PRF can be decomposed into asset allocation. Second, the PRF holders would be able to mitigate the asymmetric information between the fund sponsor and PRF holders. Third, there is clear sign of misclassification of fund type as shown by the analytical result. To the best knowledge of the author, this study is first of its kind using PRS fund data in Malaysia.

5.2 Limitation of the study

Despite much effort has been put into data cleaning and analysis to ensure the accuracy of the output, the study is not without limitation. As PRF is relatively new, the fund data has not been sufficient long enough like other study which uses 3 years of data.

Much efforts have been put into cleaning the fund data as described:

(i) different starting period for the funds; and

(ii) relatively short period of data starting from 2012.

This study examines the effect of a unique institutional setting on the relation between the quality of corporate governance practices and firm valuation in Vietnam, where there are two major stock exchanges, one located in Ho Chi Minh City, the country's business center but far away from the regulators whereas the other one located in Hanoi, the capital city close to government offices and regulatory agencies. This setting allows a test of the impact of listing location on corporate governance while controlling for the effect of legal jurisdiction. Although firms in the two exchanges exhibit the same levels of the quality of corporate governance practices, the market valuation of firms listed in Ho Chi Minh City appear to be more responsive to the quality of corporate governance practices than that of firms listed in Hanoi. The findings suggest that corporate governance related to market valuation as a result of product market competition rather than regulation.

Keywords: Corporate governance, Firm value, Vietnam

JEL Classification: G32, G34

The authors are indebted to the Ho Chi Minh Stock Exchange and Hanoi Stock Exchange for providing technical support and to the International Finance Corporation (IFC) for the financial support in the data collection process. We also thank Bui Hoang Hai from the State Securities Commission of Vietnam, Juan Carlos Fernandez Zara from the IFC and Anne Molyneux for their counsel and guidance in developing the scorecard. All remaining errors are our own.

1. Introduction

Finance literature suggests that the legal and institutional settings play critical roles in facilitating financial development. La Porta, Lopez-de-Silanes, Shleifer and Vishny (1997, 1998, 1999, 2000) posit that enforcement of private property rights, support of contractual arrangements and protection of legal rights of investors are pillars of financial market developments. Although there are disagreements on the impact of legal origins on investor protection and financial development (Rajan and Zingales, 2003; Roe, 1994), the consensus is that law and finance are interrelated. In addition, economists have noted that legal institutions, such as courts and regulatory agencies, influence corporate finance and financial development (Beck and Levine, 2008; Coffee, 2002). The main reason is that, under these conditions, corporate governance systems can effectively mitigate agency problems and other governance conflicts specific to the particular economy (Shleifer and Vishny, 1997; John and Senbet, 1998; Gompers, Ishii and Metrick, 2003).

This study contributes to the literature by examining the marginal effect of unique financial and institutional settings on the quality of corporate governance practices and firm valuation while controlling for the effect of legal jurisdiction. The main research question is whether economic forces or regulation has dominant impact on corporate governance within the same legal setting. Vietnam provides an ideal setting for this investigation because it has a unique institutional structure. Specifically, a Vietnamese firm can choose from two major stock exchanges for its listing. One stock exchange is located in Ho Chi Minh City (formerly Saigon), the largest city in Vietnam, thriving with economic activities but far away from the government and regulators. The second exchange is located in Hanoi, the capital city and a home to all government offices and regulatory agencies. In addition to geographic separation, the two cities also differ in other significant ways, including various distinct demographic and economic characteristics. Although these unique differences should not play a major role in developed economies, they may have significant impact on financial market development in emerging economies. Examining the two exchanges in Vietnam should provide additional insights on the issue.

Furthermore, political forces can affect the desired outcomes of the legal and regulatory frameworks (Rajan and Zingales, 2003). Previous research shows that political forces can distort the role that the legal setting and the financial institution setting play in corporate governance. Empirical evidence shows that firms benefit from political connections (Claessen, Feijen, and Laeven, 2008; Faccio, 2006; Fisman, 2001). In Asia, it is common to find many state-owned enterprises listed on the stock exchange. In theory, this structure can be more efficient than the normal widely-held corporate structure. The main reason is that state-owned enterprises can make better decisions and better serve the public without the agency conflicts observed between managers and shareholders. As a result, various forms of state-owned enterprises are observed in many countries. However, state-owned enterprises can also be detrimental to the public especially when under control by self-serving bureaucrats (Shleifer and Vishny, 1997). In Vietnam, state-owned enterprises are prevalent and politically connected. This provides a unique opportunity to examine the quality of corporate governance practices of state-owned enterprises in Vietnam and whether corporate governance affects market valuation of state-owned enterprises in Vietnam.

The remainder of this paper is organized as follows. Section 2 discusses the institutional background and corporate governance developments in Vietnam. Hypotheses are proposed at the end of this section. The data and empirical methods are presented in Section 3. Section 4 presents the empirical results and Section 5 concludes the paper.

2. Hypothesis Development

2.1 Regulatory structure in Vietnam

The Vietnam legal system is a civil law system, with some common law influences, especially the corporate governance framework (Robinett, Benedetta and Anh, 2013). There are three main laws underpinning the corporate governance framework in Vietnam, and the laws are quite recent. The three laws are: the Law on Enterprises and the Law on Investment, both of which were enacted in 2005, and the Law on Securities, which took effect in 2007. The Model Charter, introduced in 2002, is also an important document. In addition to the enactment of new laws, there have been rapid changes in the legal and regulatory frameworks which support corporate governance practices. For example, the Law on Enterprises mandates each shareholding company have an inspection committee. The inspection committee is charged with supervising the board of directors and the top executive at the firm. Another example of a recent change in the law concerns the 2007 Corporate Governance Regulations. The Regulations are mandatory for all public companies, as was the adoption of the Model Charter from its introduction in 2007. In 2012, the SSC revised the 2007 version of its Corporate Governance Regulations. After 2012, companies can create their own charters. The SSC issued a revised Model Charter for companies to use as a template. The Law on Enterprises was revised in 2009, while the Law on Securities was revised in 2010. New laws have been introduced since. The Law on Credit Institutions came into effect in 2010, replacing a 1997 law. The Law on Independent Audit took effect in 2011. The new laws have encouraged shareholder participation, protected shareholders' rights, and boosted disclosure (Robinett, Benedatta and Anh, 2013).

Regulations covering securities market disclosure were issued and revised in 2012. The Ministry of Finance, the State Securities Commission, and the State Bank of Vietnam have been especially active. These organizations have issued many decrees, decisions, and circulars. The overall legal framework has been strengthened by the new laws and regulations (Robinett, Benedatta and Anh, 2013). However, the laws, rules, and regulations have changed frequently, and the number of decrees issued by the three top regulatory agencies has increased markedly as well. The increase in the numbers of regulations, plus the frequent changes, has led to overlaps in the rules. Most importantly, there are some notable gaps and inconsistencies in the rules. The plethora of rules, along with frequent changes, has brought not a small amount of confusion by companies and investors (Robinett, Benedatte and Anh, 2013).

In general, the three key regulators, the Ministry of Finance, the State Securities Commission, and the State Bank of Vietnam, have clear areas of authority. The Ministry of Finance oversees insurance companies and the practices of auditing and accounting. The State Securities Commission (SSC), under the jurisdiction of the Ministry of Finance, regulates the securities market. The State Bank of Vietnam supervises bank and non-bank financial institutions. There are some areas of overlap, but cooperation between the three agencies is not common (Robinett, Benedatta and Anh, 2013). The SSC is charged with supervising the securities market. However, in the early part of its life, the SSC was not an independent securities regulator (World Bank, 2006). The actions of the SSC, as a regulator, were initially limited to the issuance of notices, rather than the invoking of stiffer penalties. The SSC received new powers after the enactment of the Law on Enterprises (2005) and the Law on Securities (2007). With its new-found powers, the SSC became much more active in its enforcement role. From 2008-2013, the SSC issued 150 fines on average each year. Most of the fines were assessed to public companies. Other enforcement actions, such as warnings, civil or criminal charges, or other administrative penalties, are quite rare however (Robinett, Benedetta and Anh, 2013).

2.2 Corporate governance reform in Vietnam

Corporate governance in Vietnam is in the early stages of development. The impetus for reform of corporate governance practices began in earnest in 2004. The International Finance Corporation (IFC), a branch of the World Bank, completed a baseline study of corporate governance practices in 2006. The purpose of the baseline study was to profile the current corporate governance practices of Vietnamese, identify ways to improve governance practices, and offer recommendations that regulators and legislators could use to overhaul and strengthen the existing legal and regulatory framework pertaining to corporate governance (World Bank, 2006). One of the main conclusions of the baseline study was Vietnamese firms did indeed comply with the existing laws and regulations. Though firms appeared to comply with the laws and regulations, the observed practices were often a significant departure from the spirit or intent of the laws and regulations. The study concluded that the current laws, rules, and regulations in effect in 2006 were not drafted clearly enough to provide guidance and direction for the firms. In addition, the enforcement or implementation of the regulations was not deemed effective. The report concludes with several clear recommendations to improve disclosure, strengthen the role of the board of directors and inspection committee, plus measures to strengthen and protect shareholder rights. Moreover, the institutions tasked to enforce, regulate, and develop the capital market were often constrained by insufficient resources. The World Bank Report highlights the many obstacles which needed to be overcome in order for corporate governance practices in Vietnam to reach levels equal to the practices of observed in its regional peer nations. Three major challenges: (i) implementing new laws, (ii) granting enhanced powers to the regulatory agencies, and (iii) strengthening enforcement, remain for the Vietnam capital market.

The baseline study predated the passage of the Enterprise Law and other regulatory and legal changes. The draft of the Enterprise Law included many of the recommendations included in the baseline report. As noted earlier, the passage of the Enterprise Law was followed by a flurry of other legal and regulatory changes from the Ministry of Finance, the State Securities Commission, and other regulatory bodies. Both the 2006 and the 2013 reports (World Bank, 2006; Robinett, Benedetta and Anh, 2013) summarize the observance of OECD Corporate Governance in Vietnam. The results in the table show corporate governance practices have improved at listed companies in Vietnam. However, recent surveys by the IFC paint a somewhat different picture.

In 2010, the IFC sponsored a series of studies designed to evaluate the corporate governance practices of the 100 largest public companies listed on the Hanoi and Ho Chi Minh City stock exchanges (Corporate Governance Scorecard Report, 2010, 2011, and Vietnam Corporate Governance Scorecard, 2012). The yearly studies, completed in 2010 through 2012, consistently found corporate governance practices at Vietnamese public companies lagging behind their peers in neighboring Asian countries. The surveys show firms included in the surveys struggling to make meaningful changes in their governance practices. The Vietnam Corporate Governance Scorecard 2012 report notes that the difficulty in improving practices was not for lack of a legal and regulatory framework. The report spotlights "[Corporate governance] practices in Vietnam remain more evident in rules than in application and implementation (p. 14)". The report also notes "[Corporate governance] developments in Vietnam have been 'top down' and led by the legal framework and regulatory action… (p. 23)". The report states that listed companies have not responded to the enhanced and clarified rules and regulations with substantive changes in their governance practices. Investors continue to wait for companies to take on their responsibilities and make meaningful changes.

In the end, it is concluded that the development of corporate governance in Vietnam has been advancing gradually. Most of the reform measures and activities occurred during the past decade. Question remains on the impact of the improvement in the quality of corporate governance practices on firm valuation.

2.3 The two cities

There are two major cities in Vietnam. Hanoi is the capital and the second largest city in Vietnam. It is the political center of the country with all the government offices located in the city. The agriculture sector plays a major role in Hanoi's economic development. Ho Chi Minh City (formerly known as Saigon) is the largest and most populous city in Vietnam. More importantly, Ho Chi Minh City is the economic center of the country. The city is home to many export processing zones and industrial parks. It is also the leading receiver of foreign direct investment (FDI) in Vietnam. The economy of Ho Chi Minh City consists of industries ranging from mining, seafood processing, agriculture, and construction, to tourism, finance, industry and trade. The service sector accounts for half of the economic activities while the manufacturing and construction sectors account for the other half. Agriculture sector only accounts for a small portion of economic activities in Ho Chi Minh City.

Table 1 presents demographic and economic data of the two cities. It is apparent that Hanoi has a larger area but less populous than Ho Chi Minh City. However, the contribution to the economic output of Ho Chi Minh City to Vietnam is much larger than Hanoi. For example, total value of export for Ho Chi Minh City is more than twice the amount for Hanoi. The real estate sector is booming because of many large multinational corporations established their headquarters in Ho Chi Minh City. In contrast, the agricultural sector is much more important to Hanoi than Ho Chi Minh City. The growth rate of Ho Chi Minh City is also slightly higher than that of Hanoi. In summary, the market development and competition are much stronger in Ho Chi Minh City than in Hanoi. Nevertheless, Hanoi remains the focal point when it comes to government affairs and regulatory activities.

2.4 The two exchanges

The capital markets in Vietnam are still in infancy stage. The country's first stock exchange, the Ho Chi Minh City Stock Exchange (HOSE), was established only in 2000. By 2006, there were 47 companies listed on HOSE and HNX (World Bank, 2006). In 2012, there were more than 700 public companies listed on HNX and HOSE. A larger number of firms are listed on HNX than

HOSE, but the total market capitalization for HOSE is greater than that of HNX. Figure 1 shows the index values and trading volume of HOSE and HNX since inception.

Both HNX and HOSE come under the purview of the State Securities Commission (SSC). Historically, listed companies in Vietnam must comply with the relevant regulations established by the State Securities Commission (SSC) and other regulatory bodies. In 2007, a newly-drafted Securities Law enhances the powers and responsibilities of the two stock exchanges. Additional amendment of the Securities Law in 2010 left the exchanges under the oversight of the SSC, but the exchanges were transformed into self-regulating organizations. As self-regulating organizations, each exchange was given more power over the regulations covering the rules for listings, trading, and information disclosure. Both HNX and HOSE independently have the responsibility to monitor the firms listed on their exchange and are expected to discipline (usually with fines) wayward companies. In addition, HNX and HOSE have separate listing rules that companies must meet in order to be listed in respective exchange. In practice, both exchanges are also free to alter their listing rules. Though the general regulatory framework is common to both exchanges, the listing requirements differ is several respects, as shown in the Table 2.

From Table 2, it is apparent that the listing requirements for HNX are not as strict as those for HOSE. Not apparent from public and official information is the disclosure and transparency requirements. Although firms listed in either HNX or HSX must follow the same regulation (Circular 52/2013/TT-BTC or disclosure rule issued by the Ministry of Finance), the actual enforcements of the two exchanges are different. Firms on both exchanges must follow the disclosure rule issued by the Ministry of Finance. However, the Ho Chi Minh City Stock Exchange has a reputation of being stricter and more willing to impose sanctions or fines against violators. A a result, the general perception is that HOSE is stricter and has more leverage over listed companies than HNX does. Anecdotal evidence gleaned from company executives suggests that listing on HOSE is more desirable. Firms listed on the HOSE are perceived to have a higher reputation and image by virtue of their choice of listing venue. From Figure 1, it is also apparent that HOSE-listed firms enjoy better liquidity compared to firms listed in HNX. In the end, a listing in HNX may be a more desirable choice for firms that cannot meet the stricter listing requirements of HOSE, or for firms whose managers have with good relations with the Hanoi. Overall, there appears to be a spillover effect from the product market competition in Ho Chi Minh City on to the stock exchange.

2.5 Hypotheses

There are two main hypotheses to be tested in this study.

H_{01}: There is no difference in the quality of corporate governance practices between firms listed in HNX and firms listed in HOSE.

The first hypothesis implies that the proximity to the regulators does not improve corporate governance. At the same time, it also implies that the market development or economic force do not have an impact on corporate governance.

H_{02}: There is no difference in the relation between the quality of corporate governance practices and firm valuation between firms listed in HNX and firms listed in HOSE.

The second hypothesis implies that neither the proximity to the regulator nor the market development and competition affects the relation between corporate governance and firm valuation.

3. Data and Methodology

3.1 Sample

The data are obtained from three major studies sponsored by the IFC during 2010-2012. Each year, 100 companies are chosen from the listed firm on the Hanoi Stock Exchange (HNX) and the Ho Chi Minh City Stock Exchange (HOSE). Selected firms selected were typically the largest firms, in terms of market capitalization, at the time. Most firms are included in the survey for at least two years.

3.2 The Corporate Governance Index (CGI)

The proxy for the quality of corporate governance practices used in this study is the Corporate Governance Index (*CGI*). In each survey year, the research team collected financial and company data that are available to the general public, from the prior fiscal year. The types of source documents used were annual reports, published financial statements, plus meeting announcements and other documents pertaining to the general meetings of shareholders (GMS) or annual general meeting (AGM). The research team also searched publicly available filings made with the stock exchanges in Hanoi and Ho Chi Minh City, the State Securities Commission or SSC, plus information from company websites and other information firms made available to media outlets.

The survey instrument used to assess firms' corporate governance practices each year contained 110 questions (see Appendix). The survey is designed based on the OECD's Principles of Corporate Governance (1999), an internationally accepted set of corporate governance standards. Consequently, the survey instrument consists of five parts: (A) the rights of shareholders (21 questions on the survey and 15 percent a firm's total score), (B) equitable treatment of shareholders (18 questions and 20 percent), (C) role of stakeholders in corporate governance (8 questions and 5 percent), (D) disclosure and transparency (32 questions and 30 percent), and € the responsibilities of the board of directors (31 questions and 30 percent). The survey instrument is similar to other corporate governance surveys used in corporate governance studies in other emerging market nations in Asia such as Thailand, Hong Kong, the Philippines, China, and Indonesia.[1] Questions in each area also considered the local Vietnam regulations and requirements with regard to corporate governance. In the final survey questionnaire the number of questions on each individual area and the relative weight given to each area in the CG score, as determined by the project committee consisting of officers from the IFC and the regulators. The final composite score (*CGI*) is used as a proxy for the firm's quality of corporate governance practices.

---

[1] See for example Cheung, Jiang, Limpaphayom and Lu (2010) for China, Cheung, Connelly, Limpaphayom and Zhou (2007), Cheung, Connelly, Jiang and Limpaphayom (2011) for Hong Kong, Connelly, Limpaphayom and Nagarajan (2013) for Thailand and Cheung, Connelly, Estanislao, Limpaphayom, Lu and Utama (2014) for selected Southeast Asian economies including Indonesia and the Philippines.

Table 4 present the summary statistics for the Corporate Governance Index (*CGI*) during the study period. Panel A shows the descriptive statistics for the *CGI* for the full sample plus the statistics for the sample in each of the three survey years (2010-2012). Panel A also presents the statistics with the sample divided according to the stock exchange where each survey firm is listed, the Hanoi Stock Exchange (HNX) or the Ho Chi Minh City Stock Exchange (HOSE). The survey includes more firms listed in Ho Chi Minh City than firms from Hanoi. This is simply an artifact of the sample, as firms on HOSE tend to be larger than firms listed on HNX.

The average *CGI* score for the full sample, across three years, is 43.7 percent with a maximum of 60.1 percent and a minimum of 17.4 percent. This average corporate governance score is quite low, when compared to CGI scores from other nations.[2] The yearly averages show the mean and median CGI scores are relatively stable through time. The survey results show *CGI* scores actually slipping in 2012, as the mean, median, and maximum scores in 2012 all declined from their 2011 levels. These figures are consistent with the notion that the quality of corporate governance practices in Vietnam is progressing at a slow pace. Panel B shows the corporate governance index score divided by exchange, and divided by industry group. The sample of firms listed in Ho Chi Minh City includes firms from a wider range of industries than the firms listed in Hanoi.

3.3 Empirical approach

In the initial analyses, the relation between the quality of corporate governance practices and firm valuation is examined using OLS regression analyses. Tobin's *q*, a measure of firm market valuation, is the dependent variable. The quality of corporate governance practices is measure by the composite scores from the *CGI*. Variables for family ownership and various board characteristics are included in the regressions, as are other firm characteristics serving as control variables. The first model, shown below as Equation 1, is evaluated using the whole sample.

$$
\begin{aligned}
q_i = {} & \beta_0 + \beta_1 \mathrm{CGI}_i + \beta_2 \mathrm{ROA}_i + \beta_3 \mathrm{SIZE}_i + \beta_4 \mathrm{LEV}_i + \beta_5 \mathrm{SGR}_i + \beta_6 \mathrm{LIQ}_i + \beta_7 \mathrm{IND}_i \\
& + \beta_8 \mathrm{BSIZE}_i + \beta_9 \mathrm{SOWN}_i + \varepsilon_{1i}
\end{aligned} \tag{1}
$$

Control variables used in the study are defined as follows. ROA is a proxy of profitability calculated as the ratio of net income after taxes divided by total assets. Firm size (SIZE) is the natural log of total assets. LEV is the ratio of long-term debt divided by total assets. Sales growth (SGR) is the year-on-year change in total revenue. LIQ is a measure of liquidity calculated as cash and cash equivalents divided by total assets. SOWN indicates the proportion of outstanding shares held by the State. A number of board-related measures have been used in other studies as control variables. These elements (i.e., board size and board composition) and their relation to firm performance have been investigated in the literature but show mixed results. In this study, board size (BSIZE) is the number of directors on a firm's board while board independence (BIND) is the proportion of directors who are independent/outside directors. To ensure robustness of the results,

[2] For example, the Vietnam Corporate Governance Scorecard 2012 report, prepared by the International Finance Corporation (IFC, 2012; p. 13), specifically notes corporate governance practices at Vietnamese firms, on average, lag firms in other Asian nations. The report states "[T]here were much higher average scores in similar, but not identical, CG Scorecards across Asia. For example, Thailand in 2011 scored 77%, Hong Kong in 2009 scored 73% and the Philippines in 2008 totaled 72%."

both Random and Fixed Effect specifications are employed. In the Random Effect specification, a series of dummy variables indicating industry affiliations are included in the model (Equation 1).

To test the effect of listing location on the relation between the quality of corporate governance practices and firm valuation, regression analyses (Equation 1) are performed separately on firms listed in each exchange. In the random effect specification with the whole sample, further, a dummy variable indicating listing location and the interaction term are included as shown in the following model.

$$q_i = \beta_0 + \beta_1 CGI_i + \beta_2 \mathrm{ROA}_i + \beta_3 \mathrm{SIZE}_i + \beta_4 \mathrm{LEV}_i + \beta_5 \mathrm{SGR}_i + \beta_6 \mathrm{LIQ}_i + \beta_7 \mathrm{BOD}_i + \beta_8 \mathrm{BSIZE}_i + \beta_9 \mathrm{SOWN}_i + \beta_{10} \mathrm{HNX}_i + \beta_{11} \mathrm{HNX}\times CGI_i + \varepsilon_{1i} \quad (2)$$

To control for the effect of endogeneity, the following model (Equation 3) with the *CGI* as the dependent variable is included in the next analysis. The simultaneous regression analysis using the Two-Stage Least Squares (2SLS) Regression is performed on both (2) and (3).

$$CGI_i = \beta_0 + \beta_1 q_i + \beta_2 \mathrm{ROA}_i + \beta_3 \mathrm{SIZE}_i + \beta_4 \mathrm{LEV}_i + \beta_5 \mathrm{SGR}_i + \beta_6 \mathrm{LIQ}_i + \beta_7 \mathrm{BOD}_i + \beta_8 \mathrm{BSIZE}_i + \beta_9 \mathrm{SOWN}_i + \beta_{10} \mathrm{HNX}_i + \beta_{11} \mathrm{HNX}\times CGI_i + \varepsilon_{1i} \quad (3)$$

Subsequent analyses focus on the choice of listing location by Vietnamese firms. A Logistic Regression Analysis is performed on the following model (Equation 4). The dependent variable is a dummy variable indicating firms listed on Hanoi Stock Exchange (DHNX). The dummy variable HQHNX indicates whether firm's headquarters is located in Hanoi. This variable is included to test whether the proximity to the exchange has any impact on the choice of listing location. The Logistic regression model is show below.

$$HNX_i = \beta_0 + \beta_1 q_i + \beta_2 CGI_i + \beta_3 \mathrm{ROA}_i + \beta_4 \mathrm{SIZE}_i + \beta_5 \mathrm{LEV}_i + \beta_6 \mathrm{SGR}_i + \beta_7 \mathrm{LIQ}_i + \beta_8 \mathrm{BOD}_i + \beta_9 \mathrm{BSIZE}_i + \beta_{10} \mathrm{SOWN}_i + \beta_{11} \mathrm{HQHNX}_i + \varepsilon_{1i} \quad (3)$$

The last series of regression analyses add a few key variables to the first model (Equation 1) to test the interaction between state ownership, proximity to Hanoi and *CGI*.

4. Empirical Results

Descriptive statistics for all variables used in the regression analyses are presented in Table 5. All variables used in the study have been Winsorized to eliminate extreme values. Panel B also shows the results for testing of differences in means and median values between the firms listed on the HNX and HOSE. The results indicate that firms in HNX and HOSE are quite different in many aspects. Specifically, firms listed on the HNX tend to have low market valuation, as measured by Tobin's q, low profitability, and located close to HNX compared to firms listed on HOSE. However, firms listed on HNX, on average, have high liquidity, a high percentage of independent directors on the board, and high state ownership compared with firms listed on HOSE. The tests for differences in median values are mostly consistent with the mean tests. Table 6 contains a correlation matrix. Overall, the correlation coefficients do not indicate any serious issue with multicollinearity.

Table 7 contains the regression results, using the full sample, for two types of regressions. Models 1 and 2 employ the Random Effect specification (OLS) while Model 3 uses the Fixed Effect specification. The main dependent variable is Tobin's *q*. IN the univariate test (Model 1), the regression coefficient for the Corporate Governance Index (*CGI*) is positive and statistically significant. This finding suggests that there is a positive relation between the quality of corporate governance practices and firm valuation, as measured by Tobin's *q*. This result is also consistent with those documented by other emerging market studies in Asia. To control for effects of other factors, Model 2, a random effects model, includes control variables for profitability, size, leverage, growth, liquidity, board characteristics, and state ownership along with industry fixed effects and time fixed effects. Dummy variables for the industries and for each survey year are included in the regression. The results from Model 2 also confirm a positive and statistically significant relation between the *CGI* and firm valuation even when the control variables are included. The results from Model 2 also show positive and significant relations between Tobin's *q* and profitability, leverage, and liquidity. The results also show negative relations between Tobin's *q* and the size of the board of directors. The results from the Fixed Effect specification confirm the positive relation between *CGI* and Tobin's *q*.

In Table 8, the sample is split by listing exchanges (HNX or HOSE). Models 1 and 3 are random effects models while Models 2 and 4 are fixed effects models. The results for Model 1 through Model 4 show a consistent pattern for the relation between *CGI* and Tobin's *q*. The *CGI* consistently shows a positive and statistically significant relation for firms listed on HOSE in both the random effects (Model 3) and fixed effects (Model 4) models. The positive and significant relation holds even when the full spectrum of control variables, and industry, time, and firm fixed effects. In contrast, there is no observed relation between *CGI* and firm valuation for firms listed on HNX. Model 5 is a random effects model utilizing the full sample. Model 5 contains two additional terms: a dummy variable that equals one if a firm is listed on HNX, and an interaction term, multiplying the HNX dummy variable with *CGI*. The results for Model 5 clearly show a positive relation between *CGI* and Tobin's *q*. The coefficient for the Hanoi dummy is positive and statistically significant, whereas the coefficient for the interaction term is negative and statistically significant. Netting the coefficients of the HNX dummy and the interaction term, the results show a negative relation between *CGI* and firm value for firms listed on the HNX. It appears that the positive relation between *CGI* and Tobin's *q* in earlier models for the full sample were driven mostly by firms listed on HOSE. Finally, there is also a positive relation between firm value and profitability, leverage, and liquidity, but a negative relation between state ownership and the *CGI*.

There is a possibility that the results are driven by endogeneity. As a robustness check, a Two-Stage Least Squares Regression analyses are performed with both *CGI* and Tobin's *q* as dependent variables. Table 9 shows the results from a two-stage least squares (2SLS) regression. The dependent variable in the first equation is Tobin's *q*, while the dependent variable in the second equation is the CGI. The first equation shows a positive relation between *CGI* and contemporaneous value of Tobin's *q*. The coefficient for the HNX dummy is positive and statistically significant, while the coefficient for the *CGI* and HNX interaction term is negative and statistically significant. This result is the same as in previous analyses. The net effect, just as before, shows that HNX-listed firms have lower firm valuation than HOSE-listed firms. In the second equation with *CGI* as the dependent variable, the coefficient for the lag of Tobin's *q* is positive and statistically significant, implying a positive relation between prior market valuation and the quality of corporate governance practices in current year. This is consistent with the notion that good companies try to improve their quality of corporate governance practices. Most importantly, the coefficient for HNX is not statistically significant indicating that there is no difference in terms of the levels of quality of corporate governance between the two exchanges.

Table 10 contains two Logistic regression models. The models are structured such that the probability of listing in Hanoi is the dependent variable. A range of explanatory variables, including the *CGI*, Tobin's *q*, and the same control variables as in the previous models, are also included in the regressions. Two other noteworthy explanatory variables are included in the logistic regressions: the percentage of state ownership (the percentage of a firm's outstanding shares owned by the government or government agency), and a measure of proximity. The proximity or location measure is the distance, in kilometers, from a company's headquarters office to the HNX. To control for the industry, Model 2 includes industry fixed effects.

The results for Model 1 show no relation between *CGI* or Tobin's *q* and the probability of listing on the HNX. Interestingly, the coefficients for sales growth and liquidity both show a positive and statistically significant relation with the probability of listing on the HNX. In contrast, profitability shows a negative and statistically significant relation, implying less profitable firms are more likely to list on HNX. Interestingly, nearness to Hanoi exhibits a positive and statistically significant relation with the probability of listing on HNX. This implies that firms tend to list in the markets close to their headquarters. The results for Model 2 largely confirm the results in Model 1, except the coefficient for liquidity is no longer statistically significant. In addition, the results for Model 2 show that firm size has a negative and statistically significant relation with the probability of listing on HNX. This finding confirms that, consistent with the implications from the listing requirements, firms listed on HNX tend to be smaller than those listed on HOSE.

Table 11 divides the sample data into different categories in an effort to more clearly discern the relations between firm value, *CGI*, state ownership, and location (proximity to HNX). Panel A splits the sample first by the percentage of state ownership and next by the exchange on which a sample firm is listed, yielding four subgroups. There is no significant difference in *CGI* across the four sample subgroups, whether the sample is divided by exchange or level of state ownership. However, there is a statistically significant difference between the Tobin's *q* for HNX-listed firms versus HOSE-listed firms. The average Tobin's *q* value for HNX-listed firms is 0.657 compared with 0.798 for HOSE-listed firms. The difference is statistically significant indicating that companies in HOSE tend to have higher market valuation than firms in HNX.

For the whole sample, the average state ownership percentage, for firms with the government as a shareholder, is 44.89 percent. About 70 percent (184 out of 270 firm-year observations) of the sample have some level of state ownership. The results show that there is a statistically significant difference in the level of state ownership for HNX-listed firms versus HOSE-listed firms. The average state ownership percentage for HNX-listed firms is 39.4 percent compared to 28.1 percent for HOSE-listed firms. The difference is also statistically significant indicating that the state has more control over firms listed on HNX than those listed on HOSE.

Panel B divides the sample according to the location a firm's headquarters office, and by exchange. As in Panel A, there are no significant differences in *CGI* across the four sample subgroups. The sample is split by exchange in both Panels A and B. As a result, the differences in the average Tobin's *q* value and the percentage of state ownership for Hanoi-listed firms versus Ho Chi Minh City-listed firms are significant, as in Panel A. There is a statistically significant difference between the levels of state ownership at firms with headquarters closer to Hanoi versus Ho Chi

Minh City. The average state ownership percentage for firms with a corporate headquarters closer to Hanoi is 38.1 percent, versus 25.7 percent for firms with their corporate office closer to Ho Chi Minh City. The difference is significant at the 5 percent level or better.

Table 12 presents ordinary least squares random effects models to tease out the effects of state ownership and headquarters location on firm value. Two additional explanatory variables are added to the regressions in Table 12: the percentage of state ownership, and a measure of proximity or location. These two explanatory variables were used in the logistic regressions in Table 10. Two interaction terms are also included: *CGI* multiplied by the percentage of state ownership, and *CGI* multiplied by the distance from a firm's headquarters to the Hanoi stock exchange. The effect of state ownership is evaluated separately in Model 1, while the effect of proximity is examined in Model 2. The combined effect of state ownership and proximity is evaluated in Model 3. Model 4 is a full model, including a dummy variable and an interaction term for Hanoi-listed firms.

The results for control variables in Table 12 confirm the earlier findings. The coefficient of *CGI* is not statistically significant in Models 1 and 3, but positive and statistically significant in Models 2 and 4. The coefficients for profitability and liquidity are positive and statistically significant. The results provide robust evidence of a positive relation between profitability and firm value, and a positive relation between liquidity and firm value. The coefficient for board size is negative and statistically significant only in Models 1 and 3. This is weak evidence of a negative relation between board size and firm value. The coefficients for state ownership and proximity, and the related interaction terms, are not statistically significant in any regression. Model 4 is the full model, including variables for state ownership, distance from Hanoi, a dummy variable for HNX-listed firms, plus interaction terms with *CGI*, ownership, proximity, and HNX-listed firms. The results confirm a positive relation between corporate governance index and firm value, but not for HNX-listed firms. The variables for state ownership and proximity, together with the interaction terms, are not statistically significant.

5. Conclusion

Finally, previous research also shows that institutions may not only shape the nature of the dominant governance problems in different countries, but also influence the efficacy of firm-level governance solutions. This study examines the effect of the financial and institutional settings on the relation between the quality of corporate governance practices and firm valuation in Vietnam. The objective is to under the factors that influence corporate governance development. Vietnam provides an ideal setting because it has a unique institutional structure. Specifically, a Vietnamese firm can choose from two major stock exchanges for its listing. In the case of Vietnam, the development of the financial and regulatory structures varies significantly between the two stock exchanges. The Ho Chi Minh Stock Exchange (HOSE) is located in the center of the country's economic activities and is known for its business-friendly environment. In contrast, the Hanoi Stock Exchange (HNX) is located in the country's political center where all securities market regulators are situated. In addition, firms listed on HNX tend to be state-owned enterprises governed closely by the central government. In contrast, firms listed on HOSE tend to be more heterogeneous.

Moreover, the two cities also differ in other significant ways, including geographical separation, along with distinct demographic and economic characteristics. This provides a unique setting to test the impacts of listing location on various aspects of corporate governance while controlling for the effect of legal jurisdiction. The competing hypotheses focus on comparing the impact of market competition and proximity to regulators on corporate governance in Vietnam. The purpose of this study is to investigate the ways in which institutional structure, specifically the listing locations, can shape the dynamics of corporate governance structure and practices in an emerging market.

This study employs the data on the quality of corporate governance practices obtained from the three yearly corporate governance scorecard projects funded by the IFC. The sample consists of the 100 largest companies listed in HOSE and HNX during 2010-2012. The empirical results show that companies in both markets are quite similar with respect to size and financial leverage. However, companies listed on the HOSE are, on average, more profitable and have higher market valuation than companies in HNX. In contrast, companies listed on the HNX tend to be more liquid and have higher proportions of independent directors on their boards than those listed on HOSE. Interestingly, there is no discernible difference in terms of the quality of corporate governance practices among firms listed on the two exchanges. The descriptive results suggest that the listing location or proximity to the regulators does not affect the quality of corporate governance practices.

The most striking finding is a difference between the relation between the quality of corporate governance practices and firm valuation in the two markets. For companies listed on the HOSE, the relation is positive and statistically significant indicating that the quality of corporate governance relates to market valuation. In contrast, the relation is not statistically significant among companies listed on the HNX. Although firms in the two exchanges exhibit the same levels of the quality of corporate governance practices, the market valuation of firms in HOSE appear to be more responsive to the quality of corporate governance practices than firms in HNX. Robustness tests show that the results are not driven by endogeneity.

In order to find possible explanations of the previous findings, the final part of the study focuses on examining the differences in the listing rules of the two exchanges and potential causes for self-selection biases. Relevant factors such as state ownership, the location of companies' headquarters, and the choice of listing location are examined and eliminated as potential explanations. In the end, the findings reveal that the differences are attributable to the dissimilarities between the two cities and the two exchanges.

Table 1
Characteristics of Hanoi and Ho Chi Minh City

Table 1 presents demographic and economic data for the entire kingdom of Vietnam and its two major cities, Hanoi and Ho Chi Minh City.

	Unit	Ho Chi Minh City	Hanoi	Entire Country
Total land	KM^2	2,095.6	3,324.3	330,972.4
Population	Thousands	7,818.2	6,936.9	89,708.9
Population Density	people/KM^2	3,731.0	2,087.0	271.0
# of hospitals		50	41	963
Primary schools		523,403	520,355	7,202,767
High school		329,415	322,676	4,869,839
Secondary schools		193,954	206,472	2,674,472
Gross domestic product (in current price)	*Billion dong*	764,562	451,213	3,584,300
Gross domestic product (at 2010 price)	*Billion dong*	609,350	321,691	2,543,600
Growth rate	*%*	9.3	8.5	5.4
Total revenue of state budget	*Billion dong*	229,514	163,043	790,800
Gross output of industry (2010 prices)	*Billion dong*	775,267	423,542	3,841,000
Investment outlay (in current price)	*Billion dong*	227,033	279,201	1,091,000
Retail sale of general trade (in current price)	*Billion dong*	582,635	193,960	2,669,000
Total value of export	*Million USD*	26,575	9,913	132,135
Gross output of agriculture (at 2010 prices)	*Billion dong*	10,840	30,594	798,909
Output of food crops	*1000 tons*	94	1,257	49,250

Table 2
Listing Requirements in Vietnam

Table 2 compares listing requirements for the Hanoi Stock Exchange (HNX) and the Ho Chi Minh City Stock Exchange (HOSE).

	Ho Chi Minh City Stock Exchange (HOSE)	**Hanoi Stock Exchange (HNX)**
Equity	• Minimum 120 billion dong (VND)	• Minimum 30 billion dong (VND)
	• Operating as a joint stock company for at least 2 years	• Operating as a joint stock company for at least 1 year
Profitability	• Profitable for two consecutive years prior to listing date	• Profitable for two consecutive years prior to listing date
	• No cumulative loss on date of listing	• No requirement
Financial Performance	• No bad debts more than 1 year overdue	• No bad debts more than 1 year overdue
	• ROE > 5 percent for the most recent fiscal year	• ROE > 5 percent for the most recent fiscal year
Shareholding structure	• At least 20 percent of the outstanding shares owned by at least 300 shareholders (not including the major shareholders)	• At least 15 percent of the outstanding shares owned by at least 100 shareholders (not including the major shareholders)

Table 3
Comparisons of Stock Exchanges in Vietnam

Table 3 presents the characteristics of the Hanoi Stock Exchange (HNX) and the Ho Chi Minh City Stock Exchange (HOSE) and the summary statistics for stocks listed in respective exchange.

	Hanoi Stock Exchange (HNX)	Ho Chi Minh City Stock Exchange (HOSE)
Trade Volume/Day (million shares)	48.2	56.1
Trading Value/day (billion dong)	438.4	877.9
Index Value	55.0	399.7
Number of listed companies	398.0	314.0
Market capitalization (trillion dong)	85.9	655.8
EPS	2,063.2	3,478.6
P/E	12.6	11.3
P/B	0.7	1.5
ROA (%)	4.4	9.0
ROE (%)	10.9	18.9
D/E	1.9	1.4
Dividend yield (%)	9.7	3.7

Table 4
Descriptive Statistics of Corporate Governance Index by Survey Year

Table 4 presents the average of the corporate governance index (*CGI*) based on the OECD Corporate Governance Principles (1999) for three *CGI* surveys. The surveys were completed in three consecutive years from 2010 – 2012. The sample is drawn from publicly-traded firms in Vietnam which are listed on the Hanoi Stock Exchange (HNX) and the Ho Chi Minh City Stock Exchange (HOSE). The *CGI* is expressed as a percentage and ranges from 0 to 100. The survey questions are shown in the Appendix.

Panel A: Full Sample, Divided by Exchange and by Year

Survey Year	Mean	STD	Median	Max	Min	Number of Firms
Full Sample, All Years	43.7%	6.9%	44.1%	60.9%	17.4%	147
Full Sample, 2010	44.1%	8.1%	45.1%	60.9%	20.5%	86
Full Sample, 2011	44.6%	5.7%	44.4%	57.8%	28.8%	90
Full Sample, 2012	42.5%	6.5%	43.0%	57.5%	17.4%	94
Hanoi Stock Exchange (HNX) Firms						
2010	41.7%	9.8%	43.3%	54.7%	20.5%	21
2011	43.9%	5.9%	44.4%	52.5%	28.8%	20
2012	42.7%	6.8%	44.2%	50.3%	23.1%	18
Ho Chi Minh City Stock Exchange (HOSE) Firms						
2010	44.8%	7.4%	45.4%	60.9%	21.9%	65
2011	44.8%	5.7%	44.4%	57.8%	31.7%	70
2012	42.5%	6.5%	42.1%	57.5%	17.4%	76

Panel B: Full Sample, Divided by Exchange and by Industry

Survey Year	Mean	STD	Median	Max	Min	Number of Firms
Hanoi Stock Exchange (HNX) Firms						
Basic Materials	30.3%	7.9%	29.1%	38.7%	23.1%	3
Consumer Goods	43.8%	- -	43.8%	43.8%	43.8%	1
Financials	44.6%	3.9%	44.3%	51.3%	36.8%	13
Industrials	42.6%	9.4%	44.5%	54.7%	20.5%	12
Oil & Gas	41.9%	8.2%	45.4%	50.1%	25.0%	3
Ho Chi Minh City Stock Exchange (HOSE) Firms						
Basic Materials	46.3%	5.4%	46.1%	58.2%	36.0%	13
Consumer Goods	43.7%	6.7%	43.6%	57.8%	21.9%	21
Consumer Services	44.4%	6.0%	43.3%	54.8%	39.0%	4
Financials	44.2%	6.6%	44.0%	55.3%	24.0%	33
Healthcare	51.8%	5.3%	51.6%	60.9%	42.9%	4
Industrials	41.7%	6.8%	43.7%	50.5%	17.4%	26
Oil & Gas	45.1%	5.4%	45.3%	52.1%	37.3%	2
Technology	43.2%	8.2%	43.7%	54.8%	26.9%	5
Utilities	42.1%	4.9%	42.2%	50.6%	35.0%	7

Table 5
Descriptive Statistics

Table 5 presents summary statistics of variables used in the study. The sample is drawn from publicly-traded firms listed on the Hanoi Stock Exchange (HNX) and the Ho Chi Minh City Stock Exchange (HOSE) during 2010-2012. Corporate governance index (*CGI*) is the percentage score from the Corporate Governance Index Survey based on the OECD Corporate Governance Principles (1999). Tobin's *q* is the book value of long-term debt plus the market value of equity divided by the book value of total assets. Corporate governance index (*CGI*) is the percentage score from the Corporate Governance Index Survey based on the OECD Corporate Governance Principles (1999). Profitability (ROA) is the ratio of net income after taxes divided by total assets. Firm size (SIZE) is the natural log of total assets. Financial leverage (LEV) is the ratio of long-term debt divided by total assets. Sales growth (SGR) is the year-on-year change in total revenue, expressed as a decimal. Liquidity (LIQ) is cash and cash equivalents divided by total assets. Board composition (BIND) is the number of directors on the executive board who are independent or outside directors divided by board size. Board size (BSIZE) indicates the number of directors on the executive board. State ownership (SOWN) is the percentage of shares owned by the government or a government agency. Distance from HNX is the distance in kilometers between a firm's headquarters and the Hanoi Stock Exchange (HNX). Standard deviations are shown in parentheses. t-statistics are calculated for the differences in the averages between HNX-listed firms and HOSE-listed firms. Z-statistics are calculated for the Wilcoxon's Rank Sum Test for median difference. *, **, and *** denote statistical significant differences at the 10, 5, and 1 percent level (two-tailed) respectively. The sample comprises 270 firm-year observations.

	All Firms (1)	Hanoi Stock Exchange (HNX) (2)	Ho Chi Minh City Stock Exchange (HOSE) (3)	Difference (2) – (3) and t-statistics	Z-statistics (Wilcoxon's Median Test)
CGI	43.7 (6.90)	42.8 (7.66)	44.0 (6.64)	-1.20 (-1.19)	-0.40
Tobin's *q*	0.767 (0.37)	0.657 (0.33)	0.798 (0.37)	-0.140*** (-2.62)	-2.81***

Table 6
Correlation Matrix

Table 6 presents correlation coefficients among variables used in the study. The sample is drawn from publicly-traded firms in Vietnam which are listed on the Hanoi Stock Exchange (HNX) and the Ho Chi Minh City Stock Exchange (HOSE). Panel A contains the descriptive statistics for the full sample. Panel B contains a comparison of the mean and median values for each variable, with the sample split according to the exchange: the Hanoi Stock Exchange (HNX) or the Ho Chi Minh City Stock Exchange (HOSE). Corporate governance index (*CGI*) is the percentage score from the Corporate Governance Index Survey based on the OECD Corporate Governance Principles (1999). Tobin's *q* is the book value of long-term debt plus the market value of equity divided by the book value of total assets. Corporate governance index (*CGI*) is the percentage score from the Corporate Governance Index Survey based on the OECD Corporate Governance Principles (1999). Profitability (ROA) is the ratio of net income after taxes divided by total assets. Firm size (SIZE) is the natural log of total assets. Financial leverage (LEV) is the ratio of long-term debt divided by total assets. Sales growth (SGR) is the year-on-year change in total revenue, expressed as a decimal. Liquidity (LIQ) is cash and cash equivalents divided by total assets. Board composition (BIND) is the number of directors on the executive board who are independent or outside directors divided by board size. Board size (BSIZE) indicates the number of directors on the executive board. State ownership (SOWN) is the percentage of shares owned by the government or a government agency. Distance from HNX is the distance in kilometers between a firm's headquarters and the Hanoi Stock Exchange (DHNX). Standard deviations are shown in parentheses. t-statistics are calculated for the differences in the averages between HNX-listed firms and HOSE-listed firms. Statistically significanCE at the 10 percent level are shown in bold.

Table 7
Regression Results for Tobin's *q*

Table 7 presents ordinary least squares (OLS) and fixed effects regression results with Tobin's *q* as the dependent variable. The sample is drawn from publicly-traded firms listed on the Hanoi Stock Exchange (HNX) and the Ho Chi Minh City Stock Exchange (HOSE) during 2010-1012. Tobin's *q* is the book value of long-term debt plus the market value of equity divided by the book value of total assets. Corporate governance index (*CGI*) is the percentage score from the Corporate Governance Index Survey based on the OECD Corporate Governance Principles (1999). Profitability (ROA) is the ratio of net income after taxes divided by total assets. Firm size (SIZE) is the natural log of total assets. Financial leverage (LEV) is the ratio of long-term debt divided by total assets. Sales growth (SGR) is the year-on-year change in total revenue, expressed as a decimal. Liquidity (LIQ) is cash and cash equivalents divided by total assets. Board composition (BIND) is the number of directors on the executive board who are independent or outside directors divided by board size. Board size (BSIZE) indicates the number of directors on the executive board. State ownership (SOWN) is the percentage of shares owned by the government or a government agency. Reported standard errors are adjusted for heteroskedasticity. t-statistics are shown in parentheses. *, **, and *** denote statistical significant differences at the 10, 5, and 1 percent level (two-tailed) respectively.

Table 8
Regression Results for Tobin's *q* by Exchange

Table 8 presents ordinary least squares (OLS) and fixed effects regression results with Tobin's *q* as the dependent variable. The sample is drawn from publicly-traded firms listed on the Hanoi Stock Exchange (HNX) and the Ho Chi Minh City Stock Exchange (HOSE) during 2010-2012. Tobin's *q* is the book value of long-term debt plus the market value of equity divided by the book value of total assets. Tobin's *q* is the book value of long-term debt plus the market value of equity divided by the book value of total assets. Corporate governance index (*CGI*) is the percentage score from the Corporate Governance Index Survey based on the OECD Corporate Governance Principles (1999). HNX is a dummy variable with a value of one if a firm is listed on HNX and zero otherwise. Profitability (ROA) is the ratio of net income after taxes divided by total assets. Firm size (SIZE) is the natural log of total assets. Financial leverage (LEV) is the ratio of long-term debt divided by total assets. Sales growth (SGR) is the year-on-year change in total revenue, expressed as a decimal. Liquidity (LIQ) is cash and cash equivalents divided by total assets. Board composition (BIND) is the number of directors on the executive board who are independent or outside directors divided by board size. Board size (BSIZE) indicates the number of directors on the executive board. State ownership (SOWN) is the percentage of shares owned by the government or a government agency. Reported standard errors are adjusted for heteroskedasticity. t-statistics are shown in parentheses. *, **, and *** denote statistical significant differences at the 10, 5, and 1 percent level (two-tailed) respectively.

Table 9
Two-Stage Least Squares Regression Results

Table 9 presents two-stage least squares (2SLS) regression results with Tobin's *q* and *CGI* score as the dependent variables. The sample is drawn from publicly-traded firms listed on the Hanoi Stock Exchange (HNX) and the Ho Chi Minh City Stock Exchange (HOSE). Tobin's *q* is the book value of long-term debt plus the market value of equity divided by the book value of total assets. Corporate governance index (*CGI*) is the percentage score from the Corporate Governance Index Survey based on the OECD Corporate Governance Principles (1999). HNX is a dummy variable with a value of one if a firm is listed on HNX and zero otherwise. Profitability (ROA) is the ratio of net income after taxes divided by total assets. Firm size (SIZE) is the natural log of total assets. Financial leverage (LEV) is the ratio of long-term debt divided by total assets. Sales growth (SGR) is the year-on-year change in total revenue, expressed as a decimal. Liquidity (LIQ) is cash and cash equivalents divided by total assets. Board composition (BIND) is the number of directors on the executive board who are independent or outside directors divided by board size. Board size (BSIZE) indicates the number of directors on the executive board. State ownership (SOWN) is the percentage of shares owned by the government or a government agency. t-statistics are shown in parentheses. *, **, and *** denote statistical significant differences at the 10, 5, and 1 percent level (two-tailed) respectively.

Table 10
Logistics Regression Results

Table 10 presents logistics regression results. The dependent variable is the probability of listing on the Hanoi Stock Exchange (HNX). The sample is drawn from publicly-traded firms listed on the Hanoi Stock Exchange (HNX) and the Ho Chi Minh City Stock Exchange (HOSE). Tobin's *q* is the book value of long-term debt plus the market value of equity divided by the book value of total assets. Corporate governance index (*CGI*) is the percentage score from the Corporate Governance Index Survey based on the OECD Corporate Governance Principles (1999). HNX is a dummy variable with a value of one if a firm is listed on HNX and zero otherwise. Profitability (ROA) is the ratio of net income after taxes divided by total assets. Firm size (SIZE) is the natural log of total assets. Financial leverage (LEV) is the ratio of long-term debt divided by total assets. Sales growth (SGR) is the year-on-year change in total revenue, expressed as a decimal. Liquidity (LIQ) is cash and cash equivalents divided by total assets. Board composition (BIND) is the number of directors on the executive board who are independent or outside directors divided by board size. Board size (BSIZE) indicates the number of directors on the executive board. State ownership (SOWN) is the percentage of shares owned by the government or a government agency. HQHNX is a dummy variable with a value of one if a firm's headquarters is located nearer to the Hanoi Stock Exchange (HNX) than the Ho Chi Minh City Stock Exchange (HOSE), and zero otherwise. Wald Chi-square statistics are shown in parentheses. *, **, and *** denote statistical significant differences at the 10, 5, and 1 percent level (two-tailed) respectively.

Table 11
Summary Statistics by Exchange Characteristics

Table 11 presents the averages of *CGI*, Tobin's *q* and state ownership (SOWN) categorized by exchange and headquarters location. The sample consists of publicly-traded firms listed on the Hanoi Stock Exchange (HNX) and the Ho Chi Minh City Stock Exchange (HOSE). Panel A splits the sample by percentage of state ownership while Panel B divides the sample according to the location a firm's headquarters office. Tobin's *q* is the book value of long-term debt plus the market value of equity divided by the book value of total assets. *CGI* is the percentage score from the Corporate Governance Index Survey based on the OECD Corporate Governance Principles (1999). State ownership (SOWN) is the percentage of shares owned by the government or a government agency.

Panel A: CGI and Tobin's q Categorized by Exchange and Percentage of State Ownership

	HNX	HOSE	Total
State Ownership > 0			
CGI	43.2	43.8	43.7
Tobin's *q*	0.654	0.784	0.751
State Ownership Percentage	50.6	43.0	44.89[a]
	n = 46	n = 138	n = 184
State Ownership = 0			
CGI	41.2	44.3	43.8
Tobin's *q*	0.667	0.824	0.800
State Ownership Percentage	0.0	0.0	0.0[a]
	n = 13	n = 73	n = 86
TOTAL			
CGI	42.8	44.0	43.7
Tobin's *q*	0.657[b]	0.798[b]	0.767
State Ownership Percentage	39.4[c]	28.1[c]	30.6
	n = 59	n = 211	n = 270

[a, b, c] Difference between group means is statistically significant at the five percent level.

Panel B: CGI and Tobin's q Categorized by Exchange and Location of Company Headquarters (HQ)

	HNX	HOSE	Total
HQ Closer to HNX			
CGI	43.2	42.6	42.9
Tobin's *q*	0.665	0.758	0.715
State Ownership Percentage	42.1	34.6	38.1[a]
	n = 49	n = 57	n = 106
HQ Closer to HOSE			
CGI	40.5	44.5	44.3
Tobin's *q*	0.616	0.812	0.800
State Ownership Percentage	26.2	25.7	25.7[a]
	n = 10	n = 154	n = 164
TOTAL			
CGI	42.8	44.0	43.7
Tobin's *q*	0.657[b]	0.798[b]	0.767
State Ownership Percentage	39.4[c]	28.1[c]	30.6
	n = 59	n = 211	n = 270

[a, b, c] Difference between group means is statistically significant at the five percent level.

Table 12
Regression Results for Tobin's *q* with Exchange Characteristics

Table 12 presents ordinary least squares (OLS) regression results with Tobin's *q* as the dependent variable. The sample is drawn from publicly-traded firms listed on the Hanoi Stock Exchange (HNX) and the Ho Chi Minh City Stock Exchange (HOSE) during 2010-2012. Tobin's *q* is the book value of long-term debt plus the market value of equity divided by the book value of total assets. Corporate governance index (*CGI*) is the percentage score from the Corporate Governance Index Survey based on the OECD Corporate Governance Principles (1999). HNX is a dummy variable with a value of one if a firm is listed on HNX and zero otherwise. Profitability (ROA) is the ratio of net income after taxes divided by total assets. Firm size (SIZE) is the natural log of total assets. Financial leverage (LEV) is the ratio of long-term debt divided by total assets. Sales growth (SGR) is the year-on-year change in total revenue, expressed as a decimal. Liquidity (LIQ) is cash and cash equivalents divided by total assets. Board composition (BIND) is the number of directors on the executive board who are independent or outside directors divided by board size. Board size (BSIZE) indicates the number of directors on the executive board. State ownership (SOWN) is the percentage of shares owned by the government or a government agency. CGI×SOWN is the product of the Corporate Governance Index (*CGI*) multiplied by state ownership. Distance from HNX is the distance in kilometers between a firm's headquarters and the Hanoi Stock Exchange (HNX). *CGI*×Distance is the product of the Corporate Governance Index (*CGI*) multiplied by Distance from HNX. The standard errors of the coefficients are adjusted for heteroskedasticity. t-statistics are shown in parentheses. *, **, and *** denote statistical significant differences at the 10, 5, and 1 percent level (two-tailed) respectively.

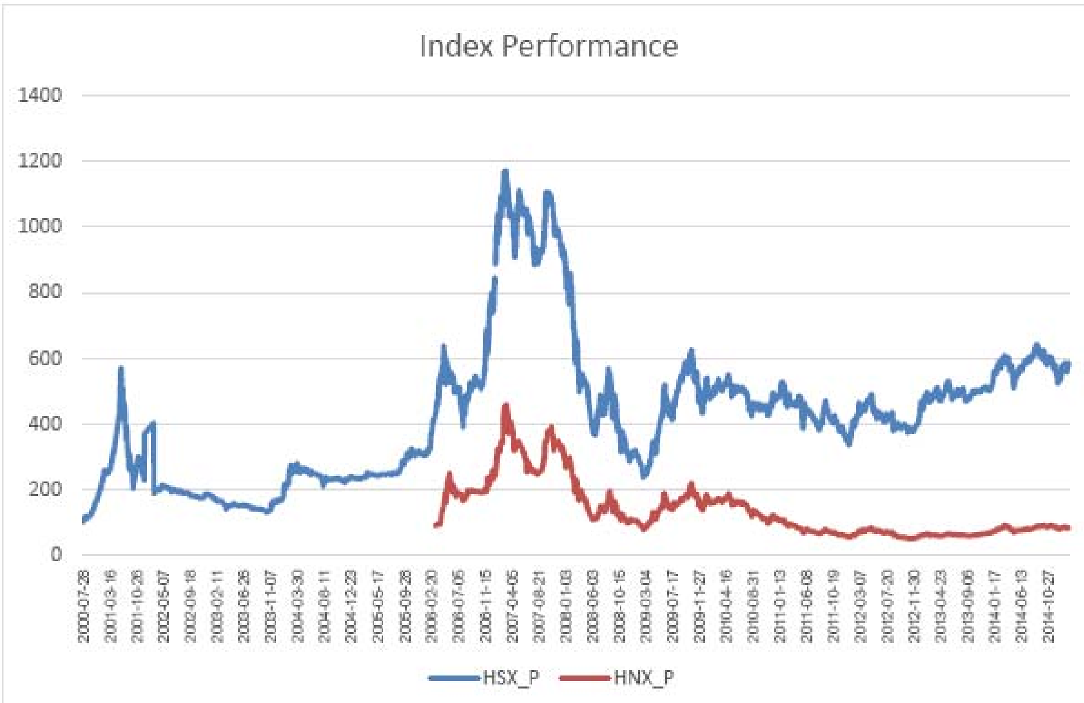
Figure 1
Stock Market Performance in Vietnam

Figure 1 presents the index values and trading volume since inception for both the Hanoi Stock Exchange (HNX) and the Ho Chi Minh City Stock Exchange (HOSE). HNX_P indicates the index values for HNX (in red) while HSX_P indicates the index values for HOSE (in blue).



Appendix

The scorecard employed in this study is constructed based on the OECD's Principles of Corporate Governance (1999). Following the principles delineated by the OECD, the survey consists of five parts. Part A contains 21 questions. Part B contains 18 questions. Part C has 8 questions. Part D has 32 questions. Part E has 31 questions. For each question, there are three levels of responses: 0 point for non-compliance, in which an expected practice is not observed, deficient, missing or non-compliant information; 1 point for fair compliance, in which an expected practice is partially observed; and 2 points for good compliance, in which an expected practice is observed or exceeded.

PART	
A	**Rights of shareholders (Scorecard weight – 15 percent)**
	Shareholder rights defined and disclosed
A.1	Are the voting rights of shareholders clear and unequivocal?
A.2	Does the company offer ownership rights, more than basic rights (voting rights, right to freely transfer shares and right to timely information)?
A.3	Do shareholders have the right to nominate and remove members of the BOD and the SB?
A.4	Are the dividend and dividend payment policies transparent?
A.5	Do shareholders have the right to approve major corporate transactions (mergers, acquisitions, divestments and / or takeovers)?
A.6	Was the AGM held within four months of end of fiscal year?
A.7	Are there adequate company systems for shareholder attendance at AGMs?
A.8	Are the AGM shareholder meeting notices effective?
A.9	Are the policies and processes for shareholders to ask questions at the AGM clear and time is allowed on the agenda?
A.10	Does AGM information record opportunities for shareholders to ask questions?
A.11	Is the attendance at the last AGM of Chairman / Head of Supervisory Board / other board members / CEO / evident?
A.12	Are AGM policies and processes in the last year (if no nomination in the last year, go to check the two years back, or even three years back) two years (notices and information) sufficient for shareholders to evaluate individual board nominations?
A.13	Do shareholders effectively vote (receive information on, make their views known and vote) on board and key executive remuneration annually?
A.14	Did the external auditor attend the AGM and the express his views on audit/financial statements issues?
A.15	Did the shareholders effectively approve the appointment of the external auditor?
A.16	Did information provided to shareholders for the appointment of the external auditor include information on independence?
A.17	Is a full report provided to AGM on BOD performance?
A.18	Is a full report provided to AGM on the performance of the Supervisory Board?

PART	
A.19	Did the AGM notice include explicit information on accessible systems for proxy voting and voting in absentia?
A.20	Do AGM meeting minutes and the company website disclose individual resolutions, with voting results for each agenda item?
A.21	Are there no additional items included in the AGM minutes not included on the original meeting notice?

PART	
B	**Equitable treatment of shareholders (Scorecard weight – 20 percent)**
B.1	Does each share in the same class of shares have the same rights?
B.2	Does the company have a 'one share, one vote' policy?
B.3	Can minority shareholders impact the composition of the board?
B.4	Are directors' required to be re-nominated and re-elected at regular intervals?
B.5	Is cross border voting facilitated by the company?
B.6	Is a description of the company group structure available and clear and transparent?
B.7	Is there evidence of structures / mechanisms that have the potential to violate minority shareholder rights?
B.8	Are there mechanisms that provide effective redress for complaints of shareholders?
B.9	Do shareholders have the right to approve fundamental company changes?
B.10	How many days before the AGM were the meeting notices sent out?
B.11	Can a small shareholder place an item on the AGM agenda?
B.12	Are there company policies in place that effectively prohibit the misuse of information by directors, management and staff?
B.13	Are there any known cases of insider trading involving the company directors, management or staff in the past year?
B.14	Are there effective company policies for the company to approve relevant related-party transactions?
B.15	For large company transactions, does company policy require the provision of information to explain RPTs and require shareholder approval of RPTs above a certain threshold?
B.16	Have there been cases of non-compliance with requirements relating to related party transactions in the past year?
B.17	How does the board deal with declarations of conflict of interest?
B.18	Does the company have an effective investor relations / information policy and program?

PART	
C	**Role of stakeholders (Scorecard weight – 5 percent)**
C.1	Does the company recognize company obligations (in law and agreements) to key stakeholders and engage them?
C.2	Does the company provide a range of performance enhancing employee benefits to align company and employee interests?
C.3	Have mechanisms been introduced that facilitate communication to board members of illegal and unethical company practices?
C.4	Does company policies / information recognize the safety and welfare of employees?
C.5	Does company policies/information mention the environment?
C.6	Are stakeholders able to directly communicate on company performance with the BOD, BOM and Supervisory Board?
C.7	Is there some company recognition of its obligations to the broader community?
C.8	Is there a clear framework for the enforcement of creditors' rights?

PART	
D	**Disclosure and transparency – (Scorecard weight – 30 percent)**
D.1	Is there evidence that the concept of 'material information' is well understood by the company?
D.2	Does the Annual Report give a full and clear picture of the financial performance of the company?
D.3	Are the financial reports disclosed in a timely manner?
D.4	Did the company provide quarterly and semi-annual reports in the past year?
D.5	Do the CEO and Chief Accountant certify the annual financial statements, audited and unaudited?
D.6	Does the company use internationally accepted accounting standards?
D.7	Does the Annual Report include a full and clear picture of company operations, its competitive position and other non-financial matters?
D.8	Are details of current largest shareholdings provided?
D.9	Are directors' (BOD and SB) shareholdings disclosed?
D.10	Are senior management's shareholdings disclosed?
D.11	Are the company shares broadly held?
D.12	In the Annual Report is board member experience disclosed?
D.13	In the Annual Report, are non-executive directors specifically identified?
D.14	Does the Annual Report specifically identify 'independent' directors?
D.15	Does the Annual Report disclose BOD / SB meeting attendance of individual directors?
D.16	Is the basis (level and mix) of board remuneration disclosed in the Annual Report?
D.17	Does the latest Annual Report identify the company's main executives and their responsibilities?
D.18	Does the latest Annual Report disclose the remuneration of key executives?
D.19	Does the company have evidence for a disclosure policy requiring disclosure of related-party transactions?
D.20	Are statements requesting directors to report their transactions in company shares evident?
D.21	Does the Annual Report explain foreseeable business risks?
D.22	Does the Annual Report include a separate, quality corporate governance report?
D.23	Does the company have an annual external audit undertaken by an authorised auditor?
D.24	Do AGM and/or company documents refer to the 'independence' of the external auditor?
D.25	If a change of auditor is noted in the past two years, were the reasons for the change disclosed?

PART	
D.26	Is there a policy that reviews the external auditor when undertaking non-audit services?
D.27	Is the external auditor's opinion publicly disclosed?
D.28	Has there been any accounting / audit changes, qualifications or queries related to the financial statements in the past two years?
D.29	Does the company provide a variety of communication methods?
D.30	Is the information on the company website comprehensive and accessible?
D.31	Does the company have a policy and process to ensure continuous ad hoc disclosure of important matters?
D.32	Does the company provide easy public access to and contact details for the Investor Relations person or unit?

PART	
E	**Responsibilities of the board (Scorecard weight – 30 percent)**
E.1	Has the company promulgated good CG guidelines?
E.2	Does the company have clear company values and direction led by the BOD?
E.3	Does company CG guidance disclose the material transactions that must be approved by the board?
E.4	Is the Chairman's role at board meetings clearly described in the company CG guidance?
E.5	Is the Chairman a non-executive director?
E.6	Is the Chairman 'independent' of the company?
E.7	How many BOD members are non-executive?
E.8	What percentage of the BOD is 'independent'?
E.9	Is there evidence of the BOD being a 'balanced board'?
E.10	Does company information and director information clearly state/disclose the number of board seats each director holds?
E.11	Does the company have a board induction policy and program for new appointments to the BOD and SB?
E.12	Do the BOD and SB undertake an annual self assessment / evaluation?
E.13	Did BOD and SB members and CEO participate in CG training and report this?
E.14	How often did the BOD meet in the past year?
E.15	How often did the SB meet in the past year?
E.16	Are there mechanisms in place to ensure board members receive adequate notification of the board meeting for all BOD / SB meetings?
E.17	Do the BOD and SB keep meeting minutes and resolution records of each meeting?
E.18	Has the BOD established BOD committees (Audit Committee, Remuneration Committee and Human Resource Committee) or designated a BOD person?
E.19	Is there evidence the BOD receives regular management reports on the company activities and its financial position?
E.20	Is there evidence the BOD is responsible for the strategy and business plans of the company?
E.21	Is the BOD and SB is responsible for and oversees the risk management system of the company?
E.22	Do the BOD / SB assess the CEO and key executives annually?
E.23	Is there any evidence of non-compliance of the company over the last year?
E.24	Do company documents cover/explain internal control structures, policies and practices?
E.25	Does the internal audit function provide an independent evaluation of the internal control process and risk management of the company annually?

PART	
E.26	Does the company report on the activities of internal audit in its Annual Report and / or SB Report?
E.27	Is there evidence of the practical SB oversight of the external auditor?
E.28	Is there evidence of the SB review and approve the Annual Report and financial statements?
E.29	Does the SB report include discussion of the SB supervision of operational and financial condition of the company; and of the performance of BOD, BOM and executive officers?
E.30	Does the SB Report include reference to the SB's performance, issues discussed and decisions taken?
E.31	Does the SB report on its evaluation of the coordination between the SB, BOD, BOM and shareholders?

Firm’s operant resources and service value – a customer perspective

Departing from the commonly understanding that a firm’s operant resources are used by firm to create service value, the purpose of this study is to examine how a customer’s perception of a firm’s operant resources (representational, cultural and social resources) affects the service value in a highly interaction service context. An empirical analysis was conducted on 263 patients in health care service in Vietnam. The results show that firm’s operant resources as viewed by customers have significant impact on service value. Of which, cultural resource has strongest weight on customer perceived value. Discussions and managerial implications have been presented accordingly.

Keywords: firm operant resources, service value, word-of-mouth, healthcare services, Vietnam..

1. Introduction

The term of value is essential for any firms (Woodruff, 1997) but it is not consistently understood by researchers because of its overuse in variety of fields such as finance, economics, management, information systems, ethics, marketing… (Khalifa, 2004). However, most of scholars agree that service value is formed by the perception of customers (Khalifa, 2004) when experiencing of any kinds of services (Heinonen, Strandvik and Voima, 2013). The customers' service experience may associate with both benefits that they enjoy after using a service, and what that they have during the service process (Heinonen, Strandvik and Voima, 2013).

In service dominant logic (SDL), firms and customers are considered as value co-creators, and both have to integrate their resources including operand and operant ones, in order to create value for customers. Firm's operant resources which refer reputation, employees' skills/knowledge, relationship value… (Baron and Warnaby, 2011) play an important role in the value creating process (Vargo and Lusch, 2004; 2008). Moreover, operant resources with their characteristics of dynamic and infinite can create additional values for themselves and additional operant resources (Vargo and Lusch, 2004). Therefore, it is necessary for service firms to understand the way their operant resources create value for customers will help them improving their performance to satisfy their customer. However, to the service where the quality of outcomes heavily depends on the service encounter credence, and requires intensity interaction of customers at each encounters in the service process, there are two questions should be concerned: How customers evaluate operant resources of a service firm during an intensity interaction process? And what kind of firm's operant resources has strongest effect on customer's service value which leads to positive word-of-mouth?

Based on previous argument, this study developed a model to test the different impacts of firm's operant resources including representational, cultural and social relational resources on service value co-created by both parties, and to validate the relationship of perceived value and positive word-of-mouth effect. The health care service was chosen because this service requires intensity interaction of patients and physicians during service process. The study was conducted in HoChiMinh city where this service occupies the biggest market share in Vietnam, which served 31 million cases in 2013 (according HCMC General Statistics Office).

Following this introduction, the literature review and hypothesis development, method, result, discussion and conclusion are presented.

2. 2. Literature review and hypothesis development

2.1. *Firm's operant resources*

In general, a firm's resources can be categorized as operand resources and operant resources. Operand resources are the typical material properties such as financial resources, infrastructure, and legal ownership while operant resources are the typical factors related to human, organization, communication and relationships (Constantin & Lusch (1994). They have different features in terms of value and the ability to copy (Clulow, Barry & Gerstman, 2007). Operant resources of a firm represent its capacity and capabilities that fluctuate when firms adapt to the surroundings to maintain operations and create value (Baron & Warnaby, 2011).

Although operant resources are properties of a firm, they can be observed and evaluated by customers (Clulow et al., 2007). On this view, Baron and Warnaby (2011) describe operant resources of a firm under the clients' perspective through three elements: representational resources: reputation, credibility and comfort; cultural resources: knowledge, management skills, capacity, quality of service and technical expertise; and social resources: the friendliness of staff, relations, C2C networking.

Cultural Resources are resources related to the mission of the organization, customs, skills and staff expertise, ability of organizing service, etc. They are divided into small groups: (1) the secret, capacity, staff expertise, (2) ability of organizing service, and (3) technical skills, technology, materials, etc. (Baron & Warnaby, 2011). This research borrows Dagger, Sweeney and Johnson (2007) who specify the components of cultural resources and suggest measurement scales for them including staff expertise, service process, and staff interaction. Staff expertise describes what the customer receives as a result of the interactions with the staff of a service company (Brady & Cronin, 2001; Donabedian, 1992; Grönroos, 1984; Rust & Oliver 1994). Staff expertise reflects the ability of a service provider adhering to high standards of service delivery (Zifko-Baliga & Krampf 1997). Adapting this notion to this specific research setting, staff expertise is manifested by the capacity and knowledge of physicians. Service process does not only facilitate the production of the core values of a service, but also increases the value in use for customers (Grönroos 1990, Lovelock, Patterson & Walker, 2001). This service process is reflected by timeliness, organizational management (i.e., the collaboration between the departments, the ability to organize and manage services, and support (i.e., convenience and ease in the administrative procedures for customers) (Dagger et al., 2007; Wensing, Grol & Smits, 1994). Staff interaction refers the communication between service provider and customer (Brady & Cronin, 2001; Grönroos 1984). It covers three core themes: manner, communication and relationship. Manner relates to the customer's perception on the attitude of service provider or service provider's employees in common discussion. Communication refers to the interaction between service provider and customer which bears a nature of interpersonal process and information transfer between both parties. Relationship refers to the close and strong relationship with provider and customer (Dagger et al., 2007).

Representational resources are things related to firm image, reputation that customers feel about a service provider when making decision to choose its service. Representational resources mostly imply a customer's positive mood, reflecting hospitality and reasonable comfort that he or she feels about the firm (Baron & Warnaby, 2011).

Social resources are resources relating to the relationships between a firm and its customers; between a firm and its employees, and between a firm and its partners and community (Baron & Warnaby, 2011). Madhavaram and Granot (2014) propose that network competences should also be seen as a firm's social resources which help to establish and use relationships with other firms.

2.2. *Service value*

Service value is defined as a consumer's overall assessment of the utility of a service based on perceptions of what is received and what is given (Zeithaml, 1988). There have been several approaches to the dimensionality of this highly abstract construct (Babin & James, 2010). For parsimonious reason, the current study adopts service value as consisting of two interrelated components, namely process value (or functional value) and outcome value (or technical value) (Hau and Thuy, 2012). Process value is the value which customers experience during the service process, while outcome value refers to customer's perception of its outcome benefits after using the service (Hau and Thuy, 2012).

The service-dominant logic (S-D logic) (Vargo and Lusch, 2004, 2008) emphasizes the role of customers as value co-creators. In the service process, value for customers is created and varied across different customers who possess different skills and knowledge (Vargo and Lusch, 2004; Grönroos, 2008). In contrast, providers play the role of value facilitators who provide foundation to facilitate customer's value creation (Grönroos, 2008). If service firms want to actively join in the process, they have to understand their customers. To do that, firms need to interact with their customers through which their operant resources can be deployed and integrated into the customer's value creation process (Grönroos, 2008).

2.3. *Firm's operant resources and customer perceived value*

According Vargo and Lusch (2004), during the service interaction process, customers may assess the firm operant resources which are manifested via frontline staff's capability and skills (i.e., cultural resources). Moreover, when customers take part in the service process, they experience service scripts at each of service encounters. Service value at that time will be formed via their behavioral procedures. The form of "activity-based experience" or "mental experience" provides customers with chances to see how good the firm provides operant resources to assist them having better service value (Heinonen et al., 2013).

When experiencing a healthcare service, customers embed their bodies and mental during the process. Consequently they are aware that the provider has reputation (1) and its employees show comfort and goodwill; realizes that physicians are skillful, and have good interaction with them. Additionally, the service process is reasonable and effective (2) and recognize that this healthcare service center has good connection with others. These positive assessments would lead to positive perception of the service value. Therefore, hypotheses are presented as follows:

H1: Firm's representational resource has positive impact on perceived service value.

H2: Firm's cultural resource has positive impact on perceived service value.

H3: Firm's social resource has positive impact on perceived service value.

2.4. *Service value and positive word-of-mouth effect*

Word-of-mouth effect refers to a process of personal influence, in which interpersonal communications between customers can change the customer's behavior or attitudes (Sweeney, Soutar & Mazzarol, 2008, Harrison-Walker, 2001). This effect is believed to result from a positive evaluation of an acquired service (Abdolvand et al., 2012). Hartline and Jones (1996) find a significant influence of perceived value on word-of-mouth, especially in the service context. In the context of health care service, patients are unwilling to use the service again. Therefore, loyalty through repeat patronization is not appropriate, whereas loyalty through positive word-of-mouth can be a powerful marketing tool. Ferguson et al. (2007) find that perceived value significantly affect word-of- mouth related to recommending the hospital to potential patients. Therefore, it is hypothesized that:

H4. There is a positive impact of perceived service value on word-of-mouth effect.

3. Method

The target respondents of this empirical research were the patients in HoChiMinh city. Data were collected by face-to-face interview and online survey using structured questionnaire which was administered at several hospitals and clinics. Convenient sampling was used in this study.

The measurement scales for firm's operant resources were adopted from Dagger et al. (2007) which included representational resources (3 items), cultural resources including service process (4 items), expertise (4 items) and staff interaction (7 items); and social resources (3 items). The scale measuring word-of-mouth was derived from Chaudhuri (2002) and Jurisic and Azevedo (2011) which includes 4 items. The scale measuring service value was adopted from Hau and Thuy (2012) which process value (2 items) and outcome value (4 items). All the scales were adjusted to the health care service context.

4. Results

In total, there were 263 patients responding the survey. Table 1 shows key characteristics of the sample.

Exploratory factor analysis was first employed to preliminary check construct validity and 14 variables was eliminated, then confirmatory factor analysis (CFA) was conducted in AMOS (Arbuckle & Wothke, 1999). The distributions of variables showed kurtosis values within -0.473 to +0.882 and skewness values range from -0.790 to +0.175 which proved that it is appropriate for maximum likelihood (ML) estimation to be applied (Kline, 1998). The CFA of the full measurement model with the remaining 17 items yielded the following measures: $\chi 2$ = 173.058; df = 91; p = 0.000; $\chi 2$/df = 1.902; GFI = 0.925; TLI = 0.956; CFI = 0.970; RMSEA = 0.059. It is also noted there is no requirement being violated (Hair et al., 2006).

	Frequency	%		Frequency	%
Gender			**Marital status**		
Male	111	42.2	Single	112	42.6

Female	152	57.8	Married, no child	25	9.5
Age			Married with child	126	47.9
< 25	32	12.2			
25-34	118	44.9	**Frequency in using service/year**		
35-44	61	23.2	1 time	63	23.95
≥ 55	52	19.7	2 – 3 times	134	50.95
Income			4 – 6 times	48	18.25
< 5 millions	97	36.9	> 6 times	18	6.85
5 – 10 millions	88	33.5			
10 –< 15 millions	51	19.4			
≥ 15 millions	27	10.3			

Besides, results showed that all item loadings on operant firm resources, perceive value and customer word-of-mouth constructs range from 0.668 to 0.928 indicating satisfactory convergent validity. Discriminant validity was also satisfactory as the correlations between 28 pairs of constructs resulted in the range from 0.304 to 0.831 which are well below 1. The composite reliability of the constructs range from 0.75 and 0.89 and the extracted variances ranged from 0.53 to 0.81, all exceed acceptable standards for exploratory research (Kline, 1998).

Next, the structural equation model was estimated using ML method. The result showed the research model fit the data satisfactorily: $\chi^2 = 227.293$; df = 107; p = 0.000; χ^2/df = 2.124; GFI = 0.899; TLI = 0.945; CFI = 0.957; RMSEA = 0.06. The results (Figure 1) indicated that Cultural Resource has a strongest significant standardized effect ($\beta = 0.733$; p = 0.036), the next one is Representational Resources ($\beta = 0.239$; p = 0.023) and the weakest significant standardized effect is Social Relation ($\beta = 0.126$; p = 0.039) on Service Value. Service Value in turn has a strongly significant standardized effect on word-of-mouth ($\beta = 0.718$; p = 0.025).

The results also show that three standardized coefficients representing the reflective paths from cultural resource (second-order construct) to its three dimensions (first-order construct) were Service process ($\beta = 0.703$; Expertise ($\beta = 0.728$; Staff Interaction ($\beta = 0.948$). Another second-order construct Service Value has been reflected by Outcome Value ($\beta = 0.927$) and then Process Value ($\beta = 0.894$).

5. Discussions

This research focuses on how customer's perception on a firm's operant resources affects his or her perceived value by conducting the empirical test in the health care service. The results show that all three constructs of firms' operant resources (i.e., representational resources, cultural resources and social resources) positively affect the service value. In other words, a positive assessment of customers on firms' operant resources enhances their perception of service value, leading to customers' positive word-of- mouth.

Particularly, there reveal different impacts of three forms of operant resources. Culture resource has strongest influence on customer perceived value of service ($\beta = 0.733$). In health care context, the physician's expertise, enthusiastic interaction and efficient service process (fast and accurate administrative procedures) are the required and requisite conditions. Moreover, patients come to see the physician with the primary need to diagnose, cure and receiving advice related to their health problems. Therefore, they would care less about the trade-off between hospital reputation (Representational Resource) and the relationship of this hospital and other health service centers/other hospitals as well as its relationship with community (Social Resources)

The interaction between suppliers and customers increases the chance they influence each other in a process (service process and the service used) (Grönroos, 2011). In the health care industry, the interaction between physician and patient is the nature of service providing process. This dialogue would be information collection for further procure process and methods.

Consultation requires time, patience, active thinking and behavior of the doctor which might effect to recognizing the health problem and solution making. A good interaction requires qualities, skills and the willingness from the doctor. The interaction between doctor and patient (communication through the information exchange) has impacted significantly on the results of examination and treatment. And the results are directly affected to the service value of the patients when they use medical services.

This result is also in line with the research of McColl-Kennedy, Vargo, Dagger, Sweeney & van Kasteren (2012) which showed that the value evaluation of treatment process in health care service related to the interactions between individuals and their doctors (Michie, et al., 2003, McColl-Kennedy et al., 2012).

For physician expertise**,** following S-D logic mindset, expertise factor is considered as a non-physical important resource (Hunt, 2007; Baron, 2009) including doctor's specialized skills, know-how and knowledge and experience. Patients could easily observe and assess those resources during their medical examinations (Clulow et al., 2011; Baron & Warnaby, 2011). Moreover, health services are directly impacts on people health and lives. The accurate service is paramount requirement which need to be controlled via doctor's skills. Therefore, seeing well trained skill doctor, the patient will perceived the higher value compared to their time and efforts spending for the service.

Service process in healthcare service included the registration procedure, payment procedures, time on process. In the customer point of view the simpler administration procedure the less time and effort customer need to spend. Besides, patients using health services often worried about their health situation therefore they do not want to psychologically wait during the medical examination.

The relationship of the other two remain constructs of operant firm resources (Social Resource and Representational resources) and service value and customer word of mouth provide some implication on the operationalization in healthcare service but weaker impact on service value (β = 0.239 for Representational Resources and β = 0.126 for Social Relation). Since Representational Resources and Social relation did not directly affect to patient body and procure healthcare examination (related to hospital reputation and its relationship to other healthcare center/community or exchanging professional experience with other hospitals), their role in deriving value to customer is small consequently. So this can explain their low impacts on service value.

The significance of this paper is to explore whether customers' view on firms' operant resources affects their perception of value co-created. The result proved that customers perceive not only how strong process and how good usage operant resources of a firm to be in creating/offering the service outcomes/profits, but how strong and how favorite customers' view on operant resources would make customers perceive more value.

6. Conclusion

In an attempt to examine how a customer's view on firm's operant resources affect his or her perception of value co-created by both parties, this research conducted an empirical test in healthcare service in Ho Chi Minh city. This research enriches our understanding of firm's operant resources being viewed from customer side, which have received relatively little attention from service marketing literature. As being commonly understood, firm operant resources create service value by better exploiting operand resource and other operant resources (Vargo and Lusch, 2004, 2008). This study shows that positive views of customers on firm operant resources also lead to their better value perception.

The results of this study provide a base for drawing managerial implications. Accordingly, service providers should invest in training professional skills for service encounters to enhance quality of interaction, to encourage staff to show professional service procedure during service process. Besides, service providers could increase their service competitive advantages by reducing complicated administrative procedure in service process (e.g., well-setup system with clear and well-conducted service process) to create a fast and convenient service access for the customer with his/her minimal effort participation.

Numerous studies have examined the effects of country of origin (COO). However, previous studies mainly focus on consumers' quality evaluations and intentions to purchase a product. Only a very limited number of research address strategic issues for those unfortunate firms suffering from negative COO stereotype.

Price is quite often used as a product quality cue – high price implies high quality. However, previous studies showed that charging high prices for products with weak COO did not work. The purpose of this research is to examine the effectiveness of adding a high-priced item in the product line in enhancing the quality perception and choice for products from emerging markets.

To achieve the above purpose, an experiment was conducted. The experiment tested the hypotheses that for a brand with a weak COO, adding a higher-priced item will enhance the quality perception, preference, purchase intention toward the products, and increase the choice share of the brand. The results supported the hypotheses.

This work showed that a negative COO cue can be overcome by putting forth multiply positive cues item. The contributions add to our knowledge related to COO and offer strategies for firms to overcome negative COO stereotyping.

Keywords: country of origin, extension upward.

1. Introduction

Since Dichter (1962) indicated that a product's country of origin influence the acceptance of a product and Schooler (1965) empirically tested it, numerous studies have examined the effects of country of origin (COO). COO, serving as an extrinsic information cue, influences consumer's product evaluations. Products from developed countries in general are perceived to have high quality, while products from emerging countries are perceived to have lower quality (Bartlett and Ghoshal, 2000; Verlegh and Steenkamp, 1999). Although COO research has been extensive, previous studies mainly focus on consumers' quality evaluations and intentions to purchase a product (Koschate-Fischer, Diamantopoulos and Oldenkotte, 2012). Only a very limited number of research address strategic issues for those unfortunate firms suffering from negative COO stereotype (Chao, 1989a).

Deshpandé (2010) offered several strategies to improve the quality perception of products from emerging markets, such as building a brand for the long haul, as Toyota and Honda did, flaunting country of origin, as Colombian coffee did, and downplaying your country of origin, as Corona beer, a Mexico product, focused on lifestyle. Kumar and Steenkamp (2013) proposed diaspora marketing, i.e., targeting emigrants abroad, for emerging market companies to build international brands. However, these strategies take decades to succeed and may require collaboration from channel members. For instance, research shows a product selling through a high-end channel would be perceived as having higher quality, as compared with selling through other channels (Dodds, Monroe and Grewal, 1991). However, high-end channels are unlikely to accept the products unless quality perception is already superior. Since COO is an extrinsic cue, i.e., a cue not related to the objective quality of the product, this research seeks to employ extrinsic cues to overcome the effects of COO stereotyping. Using extrinsic cues have the advantages of easy implementation, low costs, instant effects and no need to rely on other firms such as high-end retailers. Furthermore, extrinsic cues can be more effective than intrinsic cues in improving quality perception as Richardson, Dick and Jain (1994) demonstrated for store brand grocery items.

Price is quite often used as a product quality cue – high price implies high quality. However, setting price for products from emerging markets presents a dilemma for firms. Charging a price comparable to those from developed countries would not attract enough customers (Deshpandé, 2010) and cannot improve the quality perception of the product (Chao, 1993; Miyazaki, Grewal and Goodstein, 2005). On the other hand, setting a low price for the product would exacerbate further unfavorable quality perception. In this research, We suggest adding a high-price item in the product line. A high-price item had the potential of enhancing the quality perception of the products. In addition, upward extension may also incur context effects so as to enhance choice behavior. Consumer behaviors in general and choice behavior in particular, are rarely touched by the stream of COO research.

2. Literature Review

Numerous studies have examined the relationship between price and perceived quality in the marketing literature. Rao and Monroe (1989), in a meta-analysis of 36 studies that collectively report 85 effects of price, brand name or store name on perceived quality, found that, for consumer products, the price-perceived quality relationship was positive and statistically significant. In other words, consumers rely on price cue to make product quality judgment. One explanation for this phenomenon is that using price-perceived quality heuristic was cognitively much more efficient than evaluating product quality carefully. Although not statistically significant, their study also supported the notion that price-perceived quality effects actually increased slightly in the presence of brand information (Monroe and Krishnan, 1985). In other words, strong brands enhance the price-perceived quality relationship somewhat. Thus, consistent cues, meaning two or more positive cues, may reinforce price-perceived quality relationship, rather than suppressing it.

Recently, Völckner and Hofmann (2007) conducted a meta-analysis of study results published from 1989 to 2006 and include 71 effects of price on perceived product quality. The mean effect size r is 0.273, which is moderately strong, although it is lower than the mean effect size (r = 0.341) of Rao and Monroe (1989). They also found that the number of cues does not affect the price-perceived quality relationship significantly.

Although both meta-analysis studies show that high price enhances quality perception, setting a high price for a product from emerging country without any other considerations is not going to work. Miyazaki, Grewal and Goodstein (2005) indicated that price-perceived quality relationship is more pronounced when two cues are consistent. When two cues are inconsistent, the negative cue became more salient, resulting in ineffectiveness of the positive cue. In an experiment, they found that high price cue results in a significantly higher quality rating of tires from Germany, a strong COO, but not tires from Mexico, a weak COO. That is, when high price paired with a strong COO, a situation of cue consistency, resulting in positive price-perceived quality relationship. However, when high price paired with a weak COO, i.e., cue inconsistency, the price manipulation had no significant effect on quality perception. Since cue consistency is important in consumers' quality evaluation, two or more positive cues may be able to overcome the ineffectiveness of using only high price as a cue for weak COO. To overcome the cue inconsistency for products with weak COO, We will test two positive cues: adding a high-priced product, i.e., upward product line extension, and third-party approval.

Only a few studies examined the effects of product line extension in the same product category. Randall, Ulrich, and Reibstein (1998) show that for low-end products, brand equity is positively correlated with the quality level of the highest-quality model. Lei, De Ruyter, and Wetzels (2008) showed that a parent brand receives more positive evaluations after the introduction of an upward extension than that of a downward extension for a hotel chain. Kirmani, Sood, and Bridges (1999) examined owners versus non-owners in evaluating upward extension and downward extension. Their data for non-prestige products showed that upward extension enhances parent brand prestige for both owners and non-owners, although other attitude measures showed mixed results. Heath, DelVecchio, and McCarthy (2011) found that extending brands to higher quality improve brand evaluation, including attitude toward the overall brand, perceived brand expertise, brand prestige, and brand innovativeness. They indicated that higher-quality extensions are associated with overall brand evaluation, adds variety to the product line, and signals brand expertise.

Hamilton and Chernev (2010) demonstrated that the impact of product line extensions on price image is influenced by consumer goals: browsing or buying. Browsing tend to have broad focus, form impressions by integrating each piece of information. Thus, an upward extension would increase the overall price impression of the product. On the other hand, buying goals have relative narrow focus, causing consumers to pay their attention to a single alternative. Consumers would compare the focal option with other alternatives. Because of contrast effect, an upscale extension would make the focal option to be perceived as lower price. This viewpoint would make the upward extension by a product from an emerging country ever more appealing. An upward extension has the potential of enhancing overall price image of the brand, while at the same time, lower the perceived price of the focal option, resulting in increased purchase intention of the focal option.

Although Miyazaki, Grewal and Goodstein (2005) showed that cues consistency affect consumer perceptions, other characteristics, such as credibility, certainty, importance and the degree of inconsistency of the cues, may also play important roles. Adding a higher-price option is likely to be more consist with COO stereotyping and more credible than just setting a higher price for the product.

H1: For a brand with a weak COO, adding a higher-priced alternative will enhance the quality perception, preference and purchase intention toward the product

2.1. *Context Effects*

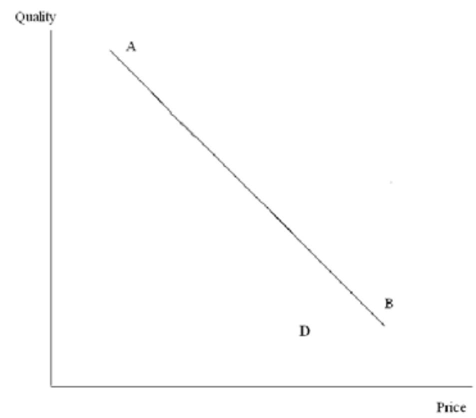
The rational choice theory assumes that consumers choose between two alternatives based on the subjective utility of each alternative, which is independent of the presence of the third alternative. However, consumer preference is often influenced by the set of options under consideration. This phenomenon is referred to as context effect, of which most notable are similarity, attraction, and compromise effects (Rooderkerk, Heerde and Bijmolt, 2011; Usher and McClelland, 2004).

Attraction effect means that adding a similar, but inferior, item raise the favorable perceptions of the original similar item in the choice set. In Figure 1(a), suppose there are only two options A and B in a choice set, the probability of a consumer choose A is P(A; [A, B]) and the probability of choosing B is P(B; [A, B]). Adding a third option D would change the relative probability of choosing A versus B. Because D is worse than B in both attributes, i.e., D is dominated by B, adding D would make B more attractive. The probability of choosing B relative to A when D present would be higher than when D does not present. That is, P(B, [A, B, D])/{P(A, [A, B, D])+ P(B, [A, B, D])} > P(B, [A, B]). For example, when only A and B present, the probability of choosing A is 0.7 and the probability of choosing B is 0.3. Adding option D may change the probability of choosing A, B and D to, say, 0.5, 0.4 and 0.1 respectively. The relative probability of choosing B out of A and B would increase from 0.3 to 0.4/(0.5+0.4) = .44.

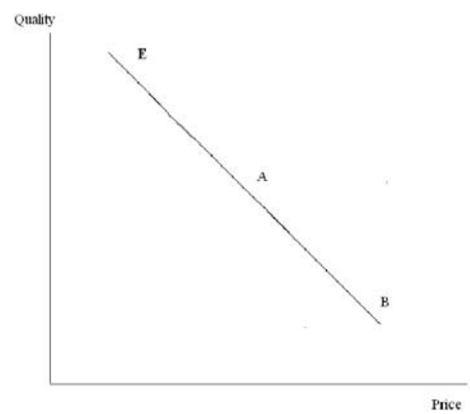
Compromise effect refers to the phenomenon that a middle option obtains a relatively large choice share than the extreme options. In Figure 1(b), suppose there are only two options A and B in a choice set, the probability of a consumer choose A is P(A; [A, B]) and the probability of choosing B is P(B; [A, B]). Adding a third option E would change the relative probability of A versus B. After adding E, E is the extreme option and A is in the middle, resulting in relative large share of A. Therefore, the probability of choosing A relative to B when E present would be higher than when E does not present. That is, P(A, [A, B, D])/{P(A, [A, B, D])+ P(B, [A, B, D])} > P(A, [A, B]). For example, when only A and B present, the probability of choosing A is 0.5 and the probability of choosing B is 0.5. Adding option E may change the probability of choosing A, B and E to 0.6, 0.3 and 0.1 respectively because of the compromise effect. The relative probability of choosing A would increase from 0.5 to 0.6/(0.6+0.3) = .67 Similarity effect stands for the phenomenon that adding an item decreases the choice share of a similar item more than a dissimilar item in the choice set. In Figure 1(c), suppose there are only two options A and B in a choice set, the probability of a consumer choose A is P(A; [A, B]) and the probability of choosing B is P(B; [A, B]). After adding F, which is similar to A, but not dominated by A, resulting in relative large decrease of A share. Therefore, the probability of choosing B relative to A when F present would be higher than when F does not present. That is, P(B, [A, B, F])/{P(A, [A, B, F])+ P(B, [A, B, F])} > P(B, [A, B]). For example, when only A and B present, the probability of choosing A is 0.7 and the probability of choosing B is 0.3. Adding option F may change the probability of choosing A, B and E to, say, 0.4, 0.3 and 0.3 respectively. That is, option F grab share from A. The relative probability of choosing B would increase from 0.3 to 0.3/(0.4+0.3) = .43.

Based on the context effects, upward extension can improve the choice of the brand. In the literature, the context effects are usually demonstrated with experiments in which the quality of products in the experiments was very clear cut. For example, a computer with 1000K memory as opposed to a computer with 640K memory, or a price discount of 35% vs. a discount of 10% (Simonson and Tversky, 1992). In real world, the quality perception may not be that apparent. For example, carbonated water may be considered as having higher quality than pure water. But, how much higher may vary among consumers. Hence, if a bottled-water company introduces carbonated water with a higher price, as compared with regular water, some customers may consider the carbonated water as having not much higher quality, but with much higher price, so that the carbonated water occupies the C1 position, as shown in Figure 1(d). This results in attracting effect, i.e., making B more attractive, which will increase the share of product B relative to product A, as compared with the situation with no C. If some consumers perceive the carbonated water as having somewhat higher quality, the product would occupy the C2 position, resulting in compromise effect, at least partially, since C2 is not exactly on the line connecting A and B. C2 would attract relatively large share of customers. Although the trade off line in the context effects literature is usually assumed to be a straight line, in microeconomics textbook the indifference curve is assumed to be convex. Thus, some consumers may switch to C, increasing the share of the brand as compared with the situation with no C introduced. If some consumers perceive the carbonated water as having much higher quality than the pure water, product C will occupies the C3 position, resulting in similarity effects. Again, this effect will increase the overall share of the brand (product B + product C). So by introducing a higher-priced alternative, brand B will enhance its image and increase its share relative to A.

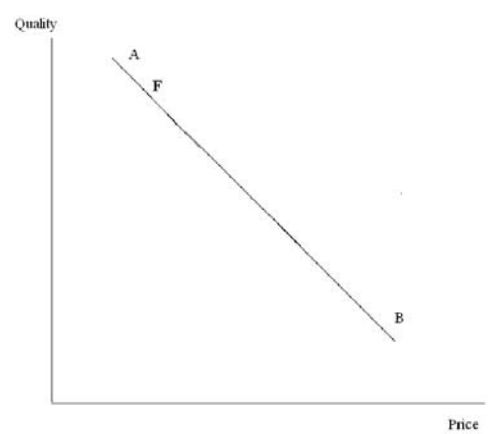
Figure 1 Context Effects



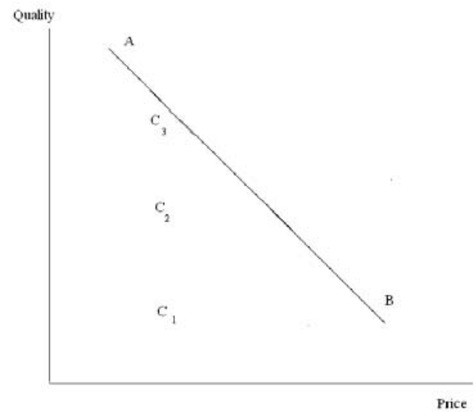
(a)



(b)



(c)



(d)

H2: For a brand with a weak COO, adding a higher-priced alternative will increase its choice share.

2.2. *Third Party Organization Endorsement*

Third-party organization (TPO) endorsement has been used quite frequently for enhance quality perception. For example, PC advertisements show PC Magazine rating, automobile ads utilize J.D. Power satisfaction rating, mutual funds employ Morningstar ranking, companies tout their ISO certifications and business schools promulgate their AACSB accreditation. TPO may come from a variety of sources, including but not limited to magazines (e.g., PC Magazine), for-profit companies (Morningstar), independent organizations (e.g., ISO), and government agency (e.g., FDA – U.S. Food and Drug Administration). TPO endorsement enhances message believability because consumers believed the information is unbiased (Wang and Muchling, 2012).

Working as a cue for product quality, TPO endorsements thus may reduce consumer uncertainty and risk perception of purchasing the product. Dean and Biswas (2001) found that, for a desktop computer or auto insurance, subjects exposed to an ad containing a TPO endorsement showed higher perceived quality, better attitude toward the manufacturer, and lower purchase risk than subjects exposed to either a celebrity endorsement or a no-endorsement ad for the same brand.

Among limited research into the effect of TPO endorsement, most show that TPO endorsement is effective in enhancing perceived product quality and improved purchase intention. However, not all studies come to similar conclusions. Peterson, Wilson and Brown (1992) found that claims of customer satisfaction contained in print advertisements were not more effective in improving attitude and purchase intention than comparable ads that did not contain such claims. The sources of the claims, including typical individual consumer, scientific survey from an independent marketing research firm, company survey, scientific survey plus personal endorsement, and company survey plus personal endorsement, did not produce any significant differences in attitude and purchase intention.

TPO endorsement may work better for less well-known brands than for well-known brands. Wu and Shaffer (1987) showed that indirect experience attitude were more susceptible to a counter-attitudinal message than were direct experience attitudes. Indirect experience attitude is believed to be less certain and less clear, hence is less confidently held. The indirect experience attitudes tend to be affected by communicator characteristic, i.e., going through the peripheral route to persuasion. On the other hand, the direct experience attitude tends to be affected by cognitive elaborations of the message arguments, i.e., the central route to persuasion. Dean and Biswas (2001) showed that well-known brands, which consumers are likely to have direct experience, may be less susceptible to attitude change. On the other hand, less well-known brands, which consumers are more likely to have no direct experience, are more susceptible to the persuasive influence of positive endorsements by TPOs. Hence, TPO endorsements are more effective for less well-known brand than for well-known brands. Similarly, Wang and Muchling (2012) found that TPO endorsement enhances advertising message believability and producing more favorable brand attitudes for underdog brands more than for topdog brands.

H3: For a brand with a low COO, TPO will enhance quality perception, affection and purchase intention of the brand

3. Research Methods

3.1. *Pretest*

We use four items, involving innovativeness, design attractiveness, prestige, and workmanship, from Roth and Romeo (1992) to measure the country image of France, Italy, Thailand and China. These four countries were used in the following experiments. Fifty respondents, 62% students and 38% young office workers, answered the four items on the web. The four items measure respondents' perception of a country on innovativeness, design attractiveness, prestige, and workmanship on a 7-point scale. The Cronbach alpha value is 0.837. The means and standard deviation of average scores for the four countries are as follows: France 5.75 (.691), Italy 5.48 (.709), Thailand 3.83 (.907), China 2.90 (.970). One-way ANOVA show that the means are significantly different ($F(3, 196) = 134.62$, p-value $< .001$). Scheffe's multiple comparison shows that respondents' perception of France and Italy are not significantly different, while perception of France and Italy are significantly better than that of Thailand, and finally perception of Thailand is significantly better than that of China. Thus the pretest shows that respondents perceive France and Italy much better than Thailand and China in terms of innovativeness, design attractiveness, prestige, and workmanship.

3.2. *Measurement items*

We measure brand image (8 items), from Park, Joworski and MachInnis (1986) and Porter and Claycomb (1997), perceived quality (6 items) from Dodds, Monroe and Grewal (1991), brand affect (6 items) from Voss, Spangenberg and Grohmann (2003), and Batra, and Ahtola (1991), and purchase intention (5 items) from Swinyard (1993) and Dodds, Monroe and Grewal (1991). All items are measured on a five point Likert-type scale with 1 indicating strongly agree and 5 indicating strongly disagree.

3.3. *Experiment*

An experiment was conducted to examine whether stretching up product line, i.e., adding a high-priced item and adding a TPO endorsement will enhance the product image, purchase intention and choice of a product from a less favorable COO. We use bottled water as the tested product since bottled water has been used in many previous studies. A 2 (without a high-priced item, with a high-priced item) x 2 (no seal of approval, with seal of approval) experiment was conducted. One of the bottled water is Evian from France and the other is Crystal from Thailand. Evian is marketed in Taiwan, while Crystal is not. Many people are familiar with Evian, but few know the Crystal brand. Three ads were created for three bottled water. One is for Evian, another one is for Crystal bottled water. The third one is for Crystal bubble water which is used as the stretch-up item.

In the questionnaire, respondents saw the ads of the two or three products first, depending on the cells they were in. In the ad, the origins of the products are clear indicated. The price of a bottle of Evian was NT$60 (around 2 U.S. dollars), while Crystal water is also NT$60, but given a discount of 30% off. The stretch up product is Crystal bubble water, selling for NT$80 per bottle, but given a discount of 10%. After seeing the ads, respondents were requested to answer questions about the Crystal bottled water, the focal brand. The measurement items also include respondent’s knowledge about water, price sensitivity and their traveling experience to Thailand. Those items were used as covariates in MANOVA analysis. The respondents were also asked to make a choice between the two items (without stretch-up product line extension) or among the three items (with stretch-up product line extension).

A total of 176 respondents answer the questionnaire.

4. Results

The results show that adding a high-priced item greatly enhance the effectiveness of brand image ($p = .041$), value ($p = .005$), and preference ($p = .037$), but not quality perception ($p = .121$). Thus, H1 was mostly supported. The results show that TPA enhances quality perception greatly ($p = .004$), but not brand image ($p = .135$), value ($p = .778$), and preference ($p = .290$). Thus, H3 was mostly not supported. The interaction between TPA and adding a high-priced item are not significant, meaning that TPA does not enhance the effectiveness of adding a high-priced item. An ANOVA analysis shows that adding a high-priced item greatly enhance the purchase intention of the original brand ($p = 072$).

Choice

We also asked respondent to make a choice of either Evian water or Crystal water for cells without the stretch-up products, and make a choice of either Evian water, Crystal water or Crystal bubble water for cells with the stretch-up products. We expect that the proportion of respondents who choose Crystal water would increase significantly for those cells with the stretch-up product. The results are shown on Table 1. In the cell with stretch-up product but no seal of approval, the proportion of respondents choosing Crystal water is not different from that in the no stretch-up product cells. However, in the cell with stretch-up product and seal of approval, the proportion of respondents who chose Crystal water is much higher than those in other cells. Adding the number of respondents who choose Crystal bubble water would make the choice share of Crystal brand higher than the choice share of Evian water (24/40 vs. 16/40), compared with other cells with choice share are 1/3 vs. 2/3. A logistic regression analysis shows that the odd of choosing Crystal brand is significantly higher for the cell with stretch-up product and seal of approval, as compared with other cells. This results support H2.

		Cell				
		No high-Priced Product No Approval	No high-Priced Product Approval	High-Priced Product No Approval	High-Priced Product Approval	Total
Choice	1.00	33	30	31	16	110
	2.00	15	15	10	15	55
	3.00	0	0	2	9	11
Total		48	45	43	40	176

Table 1 Cross Tabulation of Choice and Cell

5. Conclusions

An experiment was conducted to test three hypotheses. The results supported two hypotheses. This research contributed to the literature in several ways. First, this research showed that adding a high-priced product extension can enhance the quality perception, preference, and purchase intention of products for product from emerging markets. Second, this study revealed the effects of adding a high-priced item on brand choice.

The effect of upward extension and TPA on attitude (i.e., quality perception, preference, and purchase intention) and the effect of upward extension and TPA on choice differ in one important aspect. TPA does not enhance quality perception, preference, and purchase intention of product from an emerging market. However, TPA greatly increase the choice share of the product from an emerging market. The underlying reasons deserve further investigation.

This work showed that a negative COO cue can be overcome by putting forth positive cues, especially for improving choice. The contributions add to our knowledge related to COO and offer strategies for firms to overcome negative COO stereotyping.

Marginal Conditional Stochastic Dominance (MCSD) states the probabilistic conditions under which, given a specific portfolio, one risky asset is marginally preferred to another by all risk-averse investors. Further- more, by increasing the share of dominating assets and reducing the share of dominated assets one can improve the portfolio performance for all these investors. We use this standard MCSD model sequentially to build optimal portfolios that are then compared to the optimal portfolios obtained from Chow's MCSD statistical test model. These portfolios are furthermore compared to the portfolios obtained from the recently developed Almost Marginal Conditional Stochastic Dominance (AMCSD) model. The AMCSD model restricts the class of risk-averse investors by not including extreme case utility functions and reducing the incidence of unrealistic behavior under uncertainty. For each model, an algorithm is developed to manage the various dynamic portfolios traded on the New York, Frankfurt, London, and Tel Aviv stock exchanges during the years 2000-2012. The results show how the various MCSD optimal portfolios provide valid investment alternatives to stochastic dominance optimization. MCSD and AMCSD investment models dramatically improve the initial portfolios and accumulate higher returns while the strategy derived from Chow's statistical test performed poorly and did not yield any positive return.

1 Introduction

The essence of portfolio theory is to design rules that will satisfy the choices of investors to increase wealth in an environment of risk and uncertainty. In a static world the simplest model amounts to choosing a portfolio of assets that maximizes the total expected return while keeping risk at a satisfactory level. This basic model has suffered major setbacks when the variance was used to estimate portfolio risk because in order to be compatible with investors preferences, it requires that assets be normally distributed. The failure of the mean-variance paradigm became evident when it appeared that, empirically, financial assets were not normally distributed and higher moments such as skewness and kurtosis could not be easily dismissed.[1] Afterwards, the mean-variance model was theoretically remedied with the use of expected utility maximization.

In practice, the solution of using expected utility empirically came with the advent of Second Degree Stochastic Dominance (SSD) by Hanoch and Levy (1969), Hadar and Russell (1969), and Rothschild and Stiglitz (1970) all of whom devise rules based on the entire statistical distribution of risky assets instead of a finite number of moments. Because of this, less restrictive assumptions regarding investor's behavior were needed, with the only requirement being that the utility functions describing a rational risk-averse investor be monotonically increasing and concave. SSD compares cumulative probability distributions of

[1] Furthermore, as shown by Lambert and Yitzhaki (2014), higher variance would not be so bad for low risk-averse investors.

risky assets to determinate their dominance. The main advantage of SSD lies in its ability to discriminate among existing assets. However, it lacks the power to reach portfolio optimality.

To overcome this last obstacle Shalit and Yitzhaki (1994) developed the concept of Marginal Conditional Stochastic Dominance (MCSD) in finance. Under the SSD assumptions, MCSD allows an investor holding a given portfolio to derive dominance relations between two assets. Then, a marginal increase in the share of the dominating asset at the expense of the dominated one will improve the portfolio for all risk-averse investors. A series of marginal improvements will lead to a SSD efficient portfolio regardless of whether a change in portfolio structure or a new investment opportunity is being considered. MCSD has enjoyed some success owing to the papers of Chow, Huang, and Hu (2007), Clark and Kassimatis (2012), Clark and Kassimatis (2013), Shalit and Yitzhaki (2003) and Shalit (2010) to cite a few. Most notably is that for portfolio management, Clark, Jokung, and Kassimatis (2011) used MCSD to develop a new methodology aimed at constructing SSD efficient portfolios.

Chow (2001) improved upon MCSD by introducing a statistical test to confine the number of assets to those with significant dominance relations. He basically reformulated the model to make it more suitable for statistical computation and testing. An additional issue regarding SSD and MCSD is that some extreme utility functions that satisfy the mathematical definition of risk aversion are hardly present in the real world. [2] To tackle this issue Denuit, Huang,Tzeng, and Wang (2014) recently developed the concept of Almost Marginal Conditional Stochastic Dominance (AMCSD). The basic idea of AMCSD is that the set of relevant utility functions is reduced by putting restrictions on the second derivative. Accordingly, Denuit et al (2014) obtained new MCSD conditions

[2]For instance, a lottery with equal probabilities prizes of 999$ or 100,000$ does not dominate a certain prize of 1,000$, although any rational agent will choose the lottery.

whose purpose was to increase the number of dominance relations.

In this paper, we apply the three different MCSD approaches to test active portfolio management. Our purpose is to show in practice how a series of small portfolio improvements leads to portfolio optimization for all risk-averse investors. Although MCSD was applied successfully to active portfolio management we are providing here a new comparison of three approaches related to MCSD. Our data consists of historical returns for the 2000-2012 period from four financial markets to test our optimization algorithms written in MATLAB.

In the next section we provide the theoretical framework of the three MCSD models. In section 3, we outline the optimization methodology . In section 4, we present the data and in Section 5 we show the main results. Section 6 concludes the paper as well as the implications of our findings.

2 MCSD Theory

We begin by providing the theoretical background for the three models we use to construct optimal portfolios, namely the original Shalit and Yitzhaki (1994) MCSD, the model derived from Chow's (2001) statistical test for MCSD, and Denuit et. al.'s (2014) recent model of AMCSD . The three models are rooted in the concept of SSD that expresses the probabilistic conditions under which all risk-averse investors prefer one risky asset to another. SSD was developed independently by Hadar and Russell (1969), Hanoch and Levy (1969) and, Rothschild and Stiglitz (1970) who derived the necessary and sufficient conditions by using the asset's cumulative probability distributions functions (CDF) as we now present. Let us consider a risk-averse investor who maximizes the expected utility of asset returns $EU(r)$ where U is non-decreasing and concave. Given two risky assets with random returns r_k and r_j and CDF $F_k$andG_j the SSD necessary and sufficient conditions are stated as follows:

Theorem 1. : $E_F[U(r_k)] \geq E_G[U(r_j)]$ *if and only if* $\int_{-\infty}^{x}[G_j(r_j) - F_k(r_k)] \geq 0$ *for all* x *and all concave* U.

It should be noted that these conditions are not so practical when applied to optimizing portfolios as they require infinite comparisons of CDFs, their intersections, and their areas under these CDFs. A more accessible and intuitive alternative for using CDFs was provided by Shorrocks (1983) who developed the absolute (generalized) Lorenz curves to rank distributions and derive appropriate necessary and sufficient conditions for SSD.[3] To see this equivalence, let us define the absolute Lorenz curve as the function relating conditional mean return to the cumulative probability of getting that return, namely:

$$L(\xi) = \int_{-\infty}^{x} r dF(r) \text{ } for \text{ } all \text{ } x, \tag{1}$$

where ξ is the cumulative probability $\xi = \int_{-\infty}^{x} dF(r)$. Gartswith (1977) has simplified the notation of the Lorenz curve as $L(\xi) = \int_{0}^{\xi} F^{-1}(\omega)d\omega$ and thus only one equation is needed to formulate the Lorenz curve. As shown by Thistle (1989), the SSD conditions using the Lorenz become:

Theorem 2. : $E_F[U(r_k)] \geq E_G[U(r_j)]$*if and only if* $L_k(\xi) - L_j(\xi) \geq 0$ *for all* $\xi \in (0, 1]$,

where $L_k(\xi)$ and $L_j(\xi)$ are the absolute Lorenz curves of asset k and asset j, respectively. In other words, the absolute Lorenz of the dominating asset must not lie below the absolute Lorenz curve of the dominated one. The main reason to prefer the SSD concept over some other alternatives is that there is no need for restrictive assumptions regarding the utility function and the distribution of the risky assets. Nonetheless, there are major shortcomings, the

[3]In welfare economics, relative Lorenz curves are used to measure income inequality and wealth distribution. In financial economics, absolute Lorenz curves are used to rank distributions and measure the risk and return of assets and portfolios. See Shalit (2014).

main one being SSD's ineptitude to obtain optimal portfolios. Indeed, once an optimum portfolio is attained it can always be improved by altering the allocation increasing the dominating asset and shortening the dominated asset and raising the portfolio expected return.

To correct upon SSD lacunae, Shalit and Yitzhaki (1994) developed the concept of MCSD, which as mentioned previously, provides dominating and dominated assets conditional upon holding a portfolio. For all risk-averse expected utility maximizers, MCSD provides the probabilistic rules for one asset to marginally dominate another one and improve upon the initial portfolio. Consider a risk-averse investor holding a portfolio p of n risky assets defined by the shares $\alpha \equiv \{\alpha_i\}$ such that $\sum_{i=1}^{n} \alpha_i = 1$. The assets yield risky returns $r \equiv \{r_i\}$and the portfolio return is obtained by $p = \sum_{i=1}^{n} \alpha_i r_i$. Expected utility maximizers who want to improve their current positions, but without the trouble of reorganizing their entire portfolios, can marginally alter some of their holdings. Usually MCSD provides the conditions for dominance in the case of two assets. To marginally increase the share of dominating asset j, one can marginally decrease the share of dominated asset k, such as: $d\alpha_k = -d\alpha_j$. Accordingly, portfolio return changes as $dp = d\alpha_k (r_k - r_j)$and the change in expected utility becomes: $dE[U(p)] = E[U'(p)\, d\alpha_k (r_k - r_j)]$, leading to:

$$\frac{dE[U(p)]}{d\alpha_k} = \int_{-\infty}^{\infty} U'(t)\,[\mu_k(t) - \mu_j(t)]\, f_\alpha(t)\, dt \qquad (2)$$

where $\mu_i(t)$ is the conditional expected return on asset i given the portfolio return t, i.e., $\mu_i(t) = E(r_i | p = t)$ and $f_\alpha(t)$ is the *pdf* of portfolio returns t. (See Shalit and Yitzhaki (1994)). Asset k dominates asset j if, and only if Equation (2) is non-negative and is increasing the share of asset k on account of asset j increasing expected utility. Since $U'(t)$is positive for all returns Equation (2) can be expressed in terms of Absolute Concentration Curves (ACCs) which are defined as the cumulative expected returns on an asset conditional on the return on the portfolio α. Namely,

$$ACC_i^{\alpha}(\xi) = \int_{-\infty}^{p} \mu_i(t)\, f_\alpha(t)\, dt \tag{3}$$

where p is the return implicitly defined by the CDF of the portfolio and ξ the cumulative probability:

$$\xi = \int_{-\infty}^{p} f_\alpha(t)\, dt\ . \tag{4}$$

Theorem 3. ($MCSD$) *Given portfolio α asset* k *dominates marginally asset* j *for all risk-averse investors if and only if*

$$ACC_k^{\alpha}(\xi) \geqq ACC_j^{\alpha}(\xi) \tag{5}$$

Proof: (See Shalit and Yitzhaki (1994))

MSCD conditions are provided for two assets given a portfolio. As shown by Shalit and Yitzhaki (2003) in the case of m assets, the conditions are derived by trying to maximize the Lorenz of Equation (1) which is written as:

$$L(\xi) = \int_{-\infty}^{p} t f_\alpha(t) dt = \sum_i^n \alpha_i \int_{-\infty}^{p} r_i f_\alpha(t) dt = \sum_i^n \alpha_i ACC_i^{\alpha}(\xi) \tag{6}$$

For a given portfolio $\{\alpha_0\}$, an alternative portfolio$\{\alpha_1\} = \{\alpha_0 + d\alpha\}$ is preferred by all risk-averse investors if portfolio $\{\alpha_1\}$ leads to a higher Lorenz i.e.,:

$$\textstyle\sum_i^n \frac{\partial L(\xi)}{\partial \alpha_i} d\alpha_i = \sum_i^n ACC_i^{\alpha}(\xi) d\alpha_i \geqq 0 \quad for\ all\, \xi \tag{7}$$

subject to $\sum_i^n d\alpha_i = 0$. One of the advantages of MCSD is that a series of marginal improvements will eventually lead to an optimal SSD portfolio. The main shortcomings of the method is that the inclusion of abnormal concave utility functions are compulsory. Another less important one is the lack of a statistical test, which, however was later devised by Chow and which is described as follows.

2.1 Chow's Statistical Test

The main issue not addressed by standard MCSD is whether dominance relations can be established from a sample of asset returns. Chow (2001) answered this question by developing a procedure that tests whether ACCs intersect statistically. The test is described as follows: Define anew the ACCs and the Lorenz to be more suitable for statistical computations. From Equation (4) the inverse $p = F_{\alpha}^{-1}(\xi)$ defines portfolio return p for the probabilityξ. Furthermore let $I(t)$ be an index function mapping 1 for $t \leq p$ and 0 otherwise. Hence, the ACC for asset i can be written:

$$ACC_i^{\alpha}\left(r_i | t \leq F^{-1}(\xi)\right) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} r_i I(t) f_{\alpha}(t, r_i)\, dr_i dt\,. \tag{8}$$

Equation (8) allows us to construct a test that checks whether two unique ACCs intersect. Consider a sample of n assets and T time periods. We choose a set of S target returns from the portfolio distribution as indicated by $\{p_s | s \in [1, 2, ..., S]\}$. Every target return is a test point that checks the intersection of ACCs. From Equation (8) we can compute the ACC of asset i, at a target point $p_s$by averaging all the observations of vector $r_i I(p_s)$ which is calculated as:

$$\widehat{ACC}_i(r_i | t \leq p_s) = \frac{1}{T}\sum_{j=1}^{T} r_{i,j} I_j(p_s) = \overline{r_i I(p_s)}. \tag{9}$$

Using Equation (9) we then estimate the difference between two ACCs at the target return p_s as:

$$\widehat{\Phi}^{k-j}(p_s) = \widehat{ACC_k}(r_k|t \leq p_s) - \widehat{ACC_j}(r_j|t \leq p_s) \tag{10}$$

This allows us to obtain a vector of length S for all the target returns. The next step is to estimate the standard deviations using Rao's theorem and computing:

$$\widehat{\sigma}\left[\widehat{\Phi}^{k-j}(p_s)\right] = \frac{1}{T}\sqrt{\widehat{var}\left[r_k I(p_s)\right] + \widehat{var}\left[r_j I(p_s)\right] - 2\widehat{cov}\left[r_k I(p_s), r_j I(p_s)\right]} \tag{11}$$

Finally, we obtain the Z statistic of the estimator of (10) by dividing with the standard deviation in Equation (11) :

$$Z^{k-j}(\tau_t) = \frac{\widehat{\Phi}^{k-j}(p_s)}{\widehat{\sigma}\left[\widehat{\Phi}^{k-j}(p_s)\right]} \tag{12}$$

When parts of ACCs lie close to each other, conventional statistical inference methods cannot distinguish weak dominance relations from intersections. In this case, Chow suggests to obtain the critical values for every test point by using the Studentized Maximum Modulus distribution, with the normal approximation for large samples. The critical value given S test points and significance level α can be computed by the following approximation:

$$SMM(\alpha, S, \nu \to \infty) \to Z\left(0.5\left(1 - (1-\alpha)^{\frac{1}{S}}\right)\right) \tag{13}$$

Using the values obtained by (12) and (13) it is possible to test the dominance relations for the desired significance level using the following rule: Asset k dominates asset j if $Z^{k-j}(\tau_t) \geq SMM(\alpha, S, \nu \to \infty)$for all t and asset j dominates asset k if$Z^{k-j}(\tau_t) \leq -SMM(\alpha, S, \nu \to \infty)$ for all t . For other cases there are no significant dominance relations either because ACCs intersect or lie close to each other.

This statistical test can help us make real-life decisions when investment portfolios need to be revised. Though, generally, such a test can limit the number of pairs of assets with dominance relations only to those with strong and significant dominance and thus be very helpful for portfolio management. In practice, however, some questions remain unanswered regarding the desired significance of the test and its power. Indeed, one doesn't know what significance levels will produce the best operative results, as lower significance levels will be less discriminative and higher levels will show poor dominance relations to choose from.

2.2 Almost Marginal Conditional Stochastic Dominance

Some of the issues incurred with MCSD deal the inclusion of extreme utility functions in the set of risk-averse investors. Most of these extreme functions do not appear in the real world and hence should not be considered when optimizing portfolios of risky assets. Denuit, Huang, Tzeng, and Wang, (2014) developed "Almost Marginal Conditional Stochastic Dominance" (AMCSD) that applies the dominance relations to a smaller set of risk-averse investors by excluding those extreme utility functions. Thus, AMCSD reduces the set of risk-averse agents by restricting the second derivative of the utility function. This can be seen as follows: Let U^1 be the entire set of increasing and concave utility functions that are defined on portfolio return p. A new set, U^2 is defined using a single parameter $\epsilon \in (0, 0.5)$ that limits set of utility functions:

$$U^2(\epsilon) \equiv \left\{U(p) \in U^1 \middle| \forall p : -U''(p) \leq inf\left(-U''(p)\right)\left(\epsilon^{-1} - 1\right)\right\} \qquad (14)$$

Where $inf(\centerdot)$ is the infimum function. It can be easily shown that $U^2(0) = U^1$ and $U^2(0.5) = \emptyset$. In that case, U^2 can be considered as a set without extreme behavior functions,with the critical limit being set by a sole parameter ϵ.

By using Equation (4) and taking into consideration the fact that portfolio return p can be obtained for the probability ξ by applying $p = F_{\alpha}^{-1}(\xi)$ we can redefine the ACCs to be a function of p instead of ξ, and can define the set of portfolio returns in which there is a "transgression" of the standard MCSD criteria as : $\Omega \equiv \left\{p|ACC_k^{\alpha}(p) - ACC_j^{\alpha}(p) < 0\right\}$

Theorem 4. : (AMCSD) *For any utility function in* U^2*, the expression in (2) is non-negative if, and only if:*

$$\begin{cases} \int_{-\infty}^{\infty} -\left[ACC_k^{\alpha}(p) - ACC_j^{\alpha}(p)\right] | p \in \Omega \leq \varepsilon \int_{-\infty}^{\infty} \left|ACC_k^{\alpha}(p) - ACC_j^{\alpha}(p)\right| dp \\ \mu_k \geq \mu_j \end{cases} \tag{15}$$

Proof: See Denuit et al (2014)

We have shown that it is possible to derive dominance relations on a confined set of risk-averse utility functions. It is likely that by using the criteria described in (15) we can better model the behavior of real-world investors, and thus produce better performance. Still a valid question remains regarding what the proper value for ϵ is in limiting the extreme behavior utility functions. Levy, Leshno, and Leibovitch (2010) used a series of laboratory experiments to derive the value of 0.3. In the following we will try to shed some light on this issue.

3 Managing the MCSD Portfolios

We now present the rules directing the investment algorithm for the three portfolios. It is assumed that market participants behave rationally in the sense that, learning from historic returns, investors derive the dominance relations and then, buy the dominating stocks and sell the dominated ones. For each MCSD approach we start with two portfolios, one where the assets are weighted according to the market index of that specific stock exchange and the other where all assets are weighted equally, i.e., the so called 1/N portfolio.

3.1 Moving Window, Sample Size, and Computation Procedure

Following Chow's suggestion that a sample of 600 is the minimal size needed to achieve satisfying test power, the sample size upon which the dominance relations are established is set to 600 observations,. Going beyond 600 observations would probably introduce irrelevant and noisier data into the analysis. To be more consistent with the activity of a real-life portfolio manager, we assume that the portfolio changes every 30 observations, which accounts for approximately a month and a half of daily trades. For every data set, the first day a portfolio changes is with the 601-th observation, since dominance relations are established with the 1- 600 observations. The second trading day is with the 631-th observation since the sample used to compute dominance includes the 31-630 observations, and so on. After composing the new portfolio, it is used for the next 30 days until a new portfolio is formed, and the process is renewed all over again.

For every update point, i.e., observations 601,631, etc., a sample of 600 previous daily returns of K stocks and the initial portfolio consisting either in the market index, either the 1/N portfolio is used. With this data we construct the marginal change of $\alpha^{\Delta}$of K elements and compute the new portfolio returns for the next 30 days as follows: If R_p are the returns on the initial portfolio, then the returns on the new portfolio are $R_p^* = R_p + \sum_{i=1}^{K} \alpha_i^{\Delta} r_i$. This method was chosen because we ignore the exact weights of stocks in the initial market index portfolio and know only their returns. We restrict the marginal change to be in the±100% interval in order to avoid infinite loops and stay close to real life portfolios. We now explain how the α^{Δ} vector is constructed.

3.2 Pairing the Stocks

We choose a pair of stocks whose dominance relation is defined according to the model at hand. Using the sample data, two matrices are constructed: a Boolean dominance matrix and a dominance strength matrix. The Boolean dominance matrix indicates whether the i-th stock dominates the j-th stock with "1" in the i-th column and j-th row and "0" elsewhere. The dominance strength matrix quantifies the strength of the dominance relations. For example, in MCSD and AMCSD this value is the maximum difference between the ACCs of the two stocks. In the Chow test this value is the maximum of the Z-statistic for the two stocks. Once the matrices are computed, all pairs are sorted with respect to their dominance strength index. A pair is chosen that has the largest strength index value under two conditions: the pair was not used in the previous 10 iterations in order to avoid internal loops, and none of the stocks in the pair reached the ±100% limit. After a pair is chosen, the marginal change is obtained when the share of dominating stock is increased at the expense of the dominated stock. Thereafter, the Boolean dominance relation matrix and dominance strength matrix is computed again and the whole process is reiterated. Unless it is terminated due to lack of pairs with definite dominance relations, the process is restricted to a maximum of 1000 iterations.

3.3 Marginal Change

After a pair with a defined dominance is selected, a subroutine is conducted to compute the best marginal change of the weight of the dominating stock on account of the weight of the dominated stock. First, the weight of the dominating stock is increased by 50% and the weight of the dominated stock is subsequently decreased by 50%. Then, the dominance relations are computed for those two stocks again. If the dominance relation persists, then the change is preserved; otherwise it is discarded. Next, the whole process is reiterated with a change of 25%. At every step n, the change is $1/2^n$. This method allows us to get close enough to the point where dominance relations disappear within 20 fixed steps. For every step the $\pm 100\%$ limit is checked and the process stops if this weight exceeds this interval.

4 The Data

The research was performed in four different stock exchanges: For the Tel-Aviv stock exchange, we use daily prices for the period 03.01.2000 - 28.06.2012. The stocks were chosen from the constituents of the Tel-Aviv-100 index, and the index itself was taken as one of the initial portfolios. The constituents weights were computed by the market shares in the index. The New York stock exchange was represented with the S&P-500 index, and its constituents were the subsequent stocks listed for the period 03.01.2000 - 31.12.2011. The London stock exchange had a smaller sample for the period 03.03.2003 - 30.12.2011 and included the FTSE-100 index, and its constituents. The Frankfurt stock exchange had a similar sample for the period 02.01.2003 - 30.12.2011. The difference between the Frankfurt exchange and the other exchanges is the incongruence of the initial portfolio index DAX-30 and the list of the assets based on the DAX-100. The reason for this disparity is the lack of accessible data regarding the DAX-100 returns.[4] All the returns were corrected for dividends and splits. Assets with more than half of the data missing were eliminated and therefore in some mar-

[4]The data for the Tel-Aviv Stock Exchange data were obtained from its website and for the other three datasets were obtained from Yahoo! finance.

kets the final number of assets was less than 100. For the missing data, a linear interpolation was made using the prices before and after the gap. After these corrections, the daily return for day t was computed as $r_t = {}^{P_t}/_{P_{t-1}} - 1$.

5 Optimization Results

To check which MCSD managed portfolio approach produces statistically significant excessive returns, we used two tests: the simple mean difference test and the sign test. We begin to show the first test. Let $r_p^M$and r_p^I be the returns of the actively managed and initial portfolio, respectively. We set the null hypothesis as $H_0 : E\left(r_p^M - r_p^I\right) \leq 0$ and use the statistic $\bar{r}_p^M - \bar{r}_p^I$ where $\bar{r}_p^M$and $\bar{r}_p^I$ are the sample means. Hence, we use the standard Z-test with standard deviation $\hat{\sigma}\left(r_p^M - r_p^I\right)/\sqrt{N}$ as follows:

$$Z_{st} = \frac{\bar{r}_p^M - \bar{r}_p^I}{\hat{\sigma}\left(r_p^M - r_p^I\right)/\sqrt{N}} \ . \tag{16}$$

The sign test counts the instances that returns of the managed portfolio exceed those of the initial portfolio. When there is no significant increase in returns, the probability of sampling an occurrence with greater returns must be not different from 0.5. Thus, under the null $H_0 : Prob\left(r_p^M - r_p^I > 0\right) \leq 0.5$ we compute the subsequent Z-statistic as follows:

$$Z_{st} = \frac{N^+ - 0.5N}{0.5\sqrt{N}} \tag{17}$$

where $N^+$is the number of instances that the managed portfolio has outperformed the initial one. Since the procedures use the first 600 observations to establish dominance, MCSD-managed portfolios started from the 601st observation.

5.1 MCSD

At first, in every stock exchange, we use the market index as the initial portfolio and apply the standard MCSD portfolio management to check whether the method can improve portfolio performance. In financial theory the market index is often considered an efficient portfolio, hence, this test amounts to checking market efficiency. The results for the two tests are given in Table 1:

Table 1: Excess Returns of MCSD Managed Portfolios

	Tel-Aviv	New York	London	Frankfurt
$\bar{r}_p^{MCSD} - \bar{r}_p^I$	0.000367	-0.000037	0.000081	0.000417
p-value of the mean diff. test	0.076045	0.552780	0.402263	0.125767
p-value of the sign test	0.079495	0.508111	0.167100	0.042489
Observations	2470	2419	1631	1699

The results show that in three out of the four stock markets the portfolio management algorithm using the MCSD criterion produced greater average daily returns than the initial portfolio. In two of the markets the improvement was statistically significant. In the Tel-Aviv and the Frankfurt exchanges the algorithm produced an additional 0.0367% and 0.0417% to the average daily return, which amounts to approximately to 9.175% and 10.425% in annual returns. In the US market, the managed portfolio produced poorer results than the initial one, although those results were not statistically significant. We have established that the management algorithm efficiency depends upon which market it is applied and it generally improved the initial portfolio.

5.2 MCSD with the Integrated Chow Test

Although the purpose of the Chow test is to improve the performance of the standard MCSD, questions remain as to the validity of the parameters used. For one thing, what is the optimal value of the significance level α? As we would like to find only viable dominance relations, a small α should be chosen. However, a small α would lead to poor test power and viable dominance relations could be ignored due to statistical "noise". Another question regards the number of points that should be used in the simultaneous test. In his original work, Chow used simulated data and came to the conclusion that 10 points received higher power than 20 points. Finally, the location of these points seems completely arbitrary. To tackle these issues we used values of α of 0.05, 0.1, 0.2 and 0.3 and checked anew the notion that 10 points were better than 20 points. Finally, two approaches were used to locate the test points: either to place them equally on the return distribution or else to place them on the equal quantiles.

The combinations of these parameters produced different results and we reached the conclusion that using 10 test points instead of 20 yields better test power. Furthermore, placing the test points at equally spaced quantiles results in a better test power. Finally, for the significance level the best results were obtained using the greater values of α. In Table 2, we show the results using 10 test points placed at equally spaced quantiles, and setting $\alpha = 0.3$.

Table 2: Chow Test-Managed Portfolios

	Tel-Aviv	New York	London	Frankfurt
$\bar{r}_p^{Chow} - \bar{r}_p^{I}$	0.000267	-0.000082	0.000105	0.000195
p-value of the mean diff. test	0.058611	0.679168	0.299266	0.205474
p-value of the sign test	0.000069	0.014841	0.021305	0.000697
Observations	2470	2419	1631	1699

The results show the same pattern as with the MCSD-managed portfolios, but the statistically significant changes are much smaller. As compared with the MCSD managed portfolios, Chow's test algorithm produced only two thirds of the excess returns in Tel-Aviv and half of the excess returns in Frankfurt. In order to determine the best portfolio management, we calculated the statistics for the excess returns using Chow's test in lieu of the regular MCSD and compared them as shown in Table 3.

Table 3: Chow Test vs Standard MCSD-Managed Portfolios

	Tel-Aviv	New York	London	Frankfurt
$\bar{r}_p^{Chow} - \bar{r}_p^{MCSD}$	-0.000100	-0.000045	0.000025	-0.000221
p-value of the mean diff. test	0.672852	0.585092	0.464774	0.817302
p-value of the sign test	0.358609	0.572597	0.284505	0.623767
Observations	2470	2419	1631	1699

It seems that in three of the four markets, the portfolios managed according to Chow's test resulted in worse performances than those portfolios managed by the standard MCSD even when we used the best combination of test parameters. The results confirm what was evident in Table 2 i.e., that in most cases MCSD with an integrated Chow test reduces the average daily excess results although not always statistically significantly.

5.3 AMCSD

In the AMCSD procedure, only one parameter needs to be valued, i.e., the utility set restriction factor ϵ. Increasing this parameter confines the utility set that we are taking into account and increases the number of dominance relations pairs. In some recent work by Levy, Leshno, and Leibovitch (2010), a value of 0.3 was obtained. In the present paper we use the values of 0.1, 0.2, 0.3 and 0.4 to see how portfolio performance changes. It seems that the optimal value of the ϵ parameter is 0.4. In most cases, the mean excess returns are increasing monotonically and become more significant when ϵ rises. In Table 4 we present the AMCSD results of excess returns for the initial portfolio and in Table 5 we exhibit the results for the AMCSD portfolio vs the MCSD-managed portfolio.

Table 4: AMCSD-Managed Portfolios

For ϵ=0.4	Tel-Aviv	New York	London	Frankfurt
$\bar{r}_p^{AMCSD} - \bar{r}_p^I$	0.000619	0.000100	0.000252	0.000794
p-value of the mean diff. test	0.044458	0.401202	0.279602	0.118175
p-value of the sign test	0.045498	0.086559	0.022446	0.000741
Observations	2470	2419	1631	1699

Table 5: AMCSD- vs MCSD- Portfolios

	Tel-Aviv	New York	London	Frankfurt
$\bar{r}_p^{AMCSD} - \bar{r}_p^{MCSD}$	0.000252	0.000137	0.000172	0.000377
p-value of the mean diff. test	0.153745	0.243020	0.199042	0.182856
p-value of the sign test	0.018193	0.001225	0.006194	0.076160
Observations	2470	2419	1631	1699

The results clearly show that AMCSD can produce better portfolio returns in all markets and that those changes are statistically significant (at least, according to the sign test). The managed portfolios in Tel-Aviv, New York, London, and Frankfurt exchanges produce average excess daily returns of 0.0619%, 0.01%, 0.0252%, and 0.0794% , which amounts to annual mean returns of 15.475%, 2.5%, 6.3% and 19.85%. Moreover, when AMCSD portfolio management is used instead of MCSD we observe significant improvements in all four markets.

5.4 Changing the Initial Portfolio

As a test for robustness, we used the various MCSD procedures on the 1/N portfolio as the initial portfolio. Every asset in the portfolio is equally weighted from all the assets in the specific exchange. The results are not reported here and are available from the authors upon request. These results are somewhat astonishing since in all the markets and for all the procedures, the improvements were significantly lower than when the index portfolio was used as the initial portfolio. These results raise the following questions: Does this indicate that the 1/N portfolio is more efficient that the market index portfolio? This is quite possible since MCSD has far less room for improvement. Although these results to some extent contradict the general conclusions of De Miguel et. al. (2009) that 1/N naive portfolios are inefficient, we reiterate that the improvements provide portfolios that are marginally stochastic dominant. We have shown that improving performance strongly depends upon the initial portfolio and more specifically whether it is located near a local (or even global) optimum if such optimum exists.

5.5 The Market Effect

If we examine the mean excess return in the various exchanges, a pattern seems to prevail in all methods. The best results are obtained in the Tel-Aviv and Frankfurt exchanges followed by London and then New York. One possible explanation for this pattern is that the level of market competition and efficiency can affect the results of the managing algorithm. Namely, more efficient markets like New York and London exhibit fast price adjustments, and automatic trading systems perform poorly.

6 Conclusion

In this paper we used three different, yet interconnected, methods to manage portfolios. As shown, the standard MCSD procedure provides quite good results at least in the less efficient markets. Using Chow's test in MCSD resulted in poorer portfolio improvement probably due to the test power which ignores assets with growth potential. It may be possible to improve the test by deriving its optimal parameters by using 10 test points instead of 20 and locating them based on quantiles. Finally, we found evidence that using AMCSD improves the performance of the portfolio, beyond the standard MCSD. The reason is that if forced to satisfy "bizarre" concave utility functions, we ignore assets with improving returns.

A Framework of Human Resource Management Practices in Vietnam

Tran Kim Dung
University of Economics Hochiminh City (UEH), Vietnam
tkd@ueh.edu.vn

Truong Thi Lan Anh
Institute of Management and Technology Promotion (IMT)
Ho Chi Minh, Vietnam

The study presented a framework of human resource management (HRM) practices and explores their scales in the context of Vietnam. The study investigates the relationships between HRM practices and business performance. Data were collected from 388 companies, using a questionnaire survey. The research showed that HRM practices in Vietnam can be measured through seven dimensions with tested construct validity. Except four traditional functions of HRM such as recruitment-selection, training- development, performance appraisal, and compensation, HRM practices in Vietnamese context involve three more advanced functions: two traditional soft practices including leading change and motivation, and one contemporary hard practice as talent management. This result implies that HRM practices in Vietnam are following the world trend in HRM practices. It indicates that HRM practices in Vietnam are beyond traditional functions of HR department and closer to the change agent role and hand-in-hand with line managers in talent management. Another finding is about the important role of HRM practices the firm's business performance. Particularly, HRM practices can explain 43% of variation in business performance.

Keywords: HRM practices, business performance, Vietnam.

Introduction

Researches into Human resource management (HRM) practices have been increased in recent years as the trend of HR transformation is diffused from developed countries to developing countries.

Traditionally, HRM practices just focused on which distinguished HRM from other functions in a firm. The most common practices mentioned in many studies in HRM are recruitment and selection, training and development, performance appraisal, compensation and benefits, work relations, employment law and compliance, etc. (Ying Zhu, 2005). These practices carry both hard and soft functions of HRM which normally belong to the accountability of HR department.

The common vision of 64 thought leaders in the book edited by Losey et al. (2005) is that HR in the 21^{st} century would be integrated into the basic organizational processes. Traditional HRM functions are not enough for the changing role of HRM today. HR department needs to work in partnering with line managers. In returns, line managers also need to take direct responsibility of HRM under their supervision. Thus, contemporary HRM practices, in both hard and soft ones, should be introduced to meet the requirements of this changing role.

With the journey of Vietnam in joining in the World Trade Organization (WTO) and Trans-Pacific Strategic Economic Partnership Agreement (TPP), a lot of changes had been taken in the practices of HRM in Vietnamese firms. HRM becomes responsibilities of not only HRM department but all line managers. This paper aims at providing discussion on a new framework of HRM practices in Vietnam after nearly 30 years of economic reform and open-door policy.

The main objectives of this research are:

1. To conceptualize a holistic framework of HRM practices which reflects the trend of evolution in HRM
2. To identify the dimensions of HRM practices currently implemented in Vietnam, based on this framework
3. To examine the role of these HRM practices in Vietnamese firm's business performance.

Before achieving these objectives, definition of HRM and HRM practices which fit Vietnamese context was reckoned. Previous studies about HRM practices and its relationship with firm performance, including those in Vietnam, were reviewed.

Literature review

Concept of Human resource management

Due to the importance of HRM, there have been so many researches on HRM. Variety of definitions of HRM cause diversity in HRM practices.

Guest (1987) focused more on policy when considered human resource management as a set of policies which are designed to maximize organizational integration, employee commitment, flexibility and quality of work. With more systematic view, Wright and McMahan (1992) defined strategic human resource management as the pattern of planned human resource deployments and activities intended to enable an organization to achieve its goals. The real challenge for the human resource manager is how to attract, motivate and retain good people (Oyesola, 2011). According to Amstrong (2009, p.4), human resource management is a strategic integrated and coherent approach to the employment, development, and well being of the people working in organization. In addition, Stone (2008) reckoned that human resource management involves the productive use of people in achieving organization's strategic objectives and the satisfaction of individual employee needs. These definitions indicate two concerns in HRM: a) What have been involved in HRM; and b) Objectives of HRM. A summary is in Table 1.

Table 1: Two concerns in HRM definitions

Authors	What have been involved in HRM	Objectives of HRM
Guest (1987)	A set of policies	Maximize organizational integration, employee commitment, flexibility and quality of work.
Wright and McMahan (1992)	The pattern of planned human resource deployments and activities	To enable an organization to achieve its goals
Stone (2008)	The productive use of people	Achieving the organization's strategic objectives and the satisfaction of individual employee needs
Amstrong (2009)	A strategic integrated and coherent approach	Employment, development, and well being of the people working in organization

As in other developing countries, many managers in Vietnamese firms just focus on developing market and reducing costs rather than developing their people and improving their satisfaction. They do not pay sufficient attention in HRM, neither understands the contribution of HRM to the organization's performance and sustainable development. Thus they would think HRM merely belongs to HR department's responsibility or they should just follow the government policies. Normally CEO just sends those who lack of capabilities in business, in technology, in marketing, in finance, etc. to HR department. Line managers tend to blame HR department at these shortages.

Some managers mistakenly think that personnel management is applied in organization which is micro level while HRM is applied in managing people at the macro level such as in provinces or country. To facilitate the right understanding and practicing of HRM in Vietnamese context, the first aspect of definition of HRM should indicates that HRM is not only activities, actions, programs but managers' philosophies and policies related to people. The second aspect is that objectives of HRM should emphasize mutual benefits of organization and its employees. The third aspect should mention about the HRM's objects of study and scope of impact in the organization.

In a Vietnamese context, human resource management comprises a set of philosophy, policies, procedures and actions related to attracting, training and development and remaining people to achieve the organization's objectives and employee satisfaction.

Functions of HRM and practices

HRM involves acquisition, development, reward and motivation, maintenance and departure of an organization's human resources with key activities: job analysis, human resource planning, recruitment, selection, performance appraisal, human resource development, career planning and development, employee motivation, remuneration, benefit, employee relations (Stone, 2008). According to Fombrun et al. (1984), the human resource cycle in Michigan's human resource management model comprises four functions of HRM which are selection, performance appraisal, development, and rewards. This group is the core of HRM functions, although the names of practices in this group were quite diversified.

- **Selection**: matching people to jobs, may have other name in research: Attracting, placement
- **Appraisal** of performance
- **Rewards:** emphasizing the real importance of pay and other forms of compensation in achieving results may have other name in research such as compensation, rewards, benefits
- **Development** of skilled individuals, may have other name in research: training, personal/organizational development, career development

From a viewpoint of practitioners, SHRM[1] reported HRM practices nowadays involve compensation & benefits, business leadership & strategy, diversity, employee relations, ethics & corporate, social responsibility, organizational & employee development, talent management, technology. Meanwhile, according to CIPD[2], three top current priorities for HR functions in 2014 were employee engagement, managing change and cultural transformation, and managing performance.

Theoretical framework of HRM practices

In general, with respect to the HRM model by Michigan university, there are three key questions that HRM has to deliver the answers to the firm: How to attract the right HR? How to increase their productivity and develop their competencies? How to recognize and reward for retaining competent and high performers?

That was why many researches applied all four functions into HRM practices as in Joseph and Dai (2009), Bhanugopan et al. (2013), or in the review of Aggarwal & Bhargava (2008), etc. These practices indicated that there was an emphasis on "technical", in other word "hard" side of HRM functions. In addition, less mentioned were some other "hard" practices such as promotion, job design, etc. Normally, HR department is the "owner" of this hard group. Depending on research purposes, characteristics of regional or industrial culture, some studies mentioned some further hard practices such as promotion (Singh, 2004; Tessema and Soeters, 2006; Katou, 2008), job design (Singh, 2004; Katou, 2008), employee relations (Ying Zhu, 2005), etc.

Besides, HRM practices also cover the "human" side of HRM functions such as teamwork, communication, employee involvement, motivation, etc. They can be considered as the "soft" HRM practices. Teamwork and communication used to be recognized Le Chien Thang and Truong Quang (2005) and (Katou, 2008), while employee involvement was studied in Singh (2004), and motivation in Šikýr (2013).

Among hard and soft groups, some HRM practices used to be applied for long time as basis for any HRM system. They can be called "traditional" HRM practices. With the shift of human resource management responsibility to line managers, specially, the development of a new role of HRM as a business partner, to support globalization and internalization, HR department today is expected to be able to connect its work inside the organization to customers, investors, and community leaders outside.

---

[1] http://www.shrm.org/about/foundation/products/pages/shrmfoundationepgs.aspx

[2] http:www. www. cipd.co.uk/hroutlook

The collaboration between HR department and line managers will enhance business leadership and strategy, as well as focus more on customers, i.e. HR from the out-side in (Ulrich et al., 2009).

Boundary of HRM practices between HR department and line managers becomes blurred. However, there is a need to distinguish the accountability between these two groups in order to avoid overlapping and to provide clear goals and key performance indicators for the two groups. Only those practices led by HR department such as employee engagement, organization design, talent management, cultural transformation, retention, etc. are considered as HRM functions. We called them "Contemporary HRM practices" to distinguish them from those 'traditional' ones.

Learning from both academic and practical points of view, HRM practices can be classified into four groups (see Figure 1):

- Traditional HRM hard group: job analysis, work design, recruitment and selection, placement, training and development, performance appraisal, compensation and benefits, employment law and compliance, etc.
- Traditional HRM soft group: motivation, teamwork, employee involvement, leading change, etc.
- Contemporary hard group: organization design, staff retention, talent management, etc.
- Contemporary soft group: employee engagement, cultural transformation, etc.

Contemporary HRM practices, both hard and soft, are still emerging and expected to increase in the future. However, as this is an evolution of HRM, boundaries among the four groups of HRM practices are not discrete. The soft practices can work well only when the hard practices are already implemented. The contemporary ones need to base on traditional ones to develop. In other words, contemporary HRM practices cannot be implemented unless the traditional ones are effectively operated.

Thus, in this research, firstly four traditional dimensions of hard HRM practices were selected from literature review with respect to Vietnamese context: *Recruitment and selection, Training and development, Compensation and rewards.*

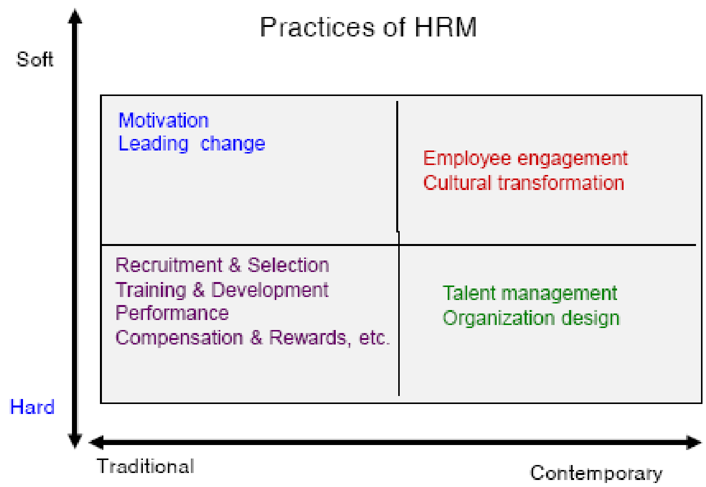

Figure 1: A framework of HRM practices

The fact that Vietnam has participated in WTO and TPP causes fierce competition even in domestic market. Improving productivity and business effectiveness become the keys for survival of Vietnamese firms. This situation forces managers in these firms to change their mindset and practices in order to motivate their people, attract and retain talents. Talent management becomes hot topic. Practitioners start to recognize the huge contribution of HRM to the business performance. The war for talents becomes more serious. Thus *talent management* is examined as a practice of HRM in this research as it was mentioned in a research of Šikýr (2013).

As a common situation in central planned economies, many managers focus on mandating rather than motivating. When moving to market orientation, managers have recognized the value of employee motivation. In addition, Vietnamese economy has not gone through the economic recession which has lasted since 2011. During economic recession, managers have to encourage people, not mandate them. Thus *motivation* is examined as a dimension of contemporary HRM practices in this research. Motivation was mentioned in recent researches such as Stone (2008), Šikýr (2013).

Vietnam comes from a central planed economy to a market oriented economy. This context has required firms to change accordingly. However, change management has been ignored for long time. Many managers do not want to change. Many HR policies in terms of salary and welfares are still being directed by the central government. Leading change was mentioned in research of Milkovich & Boudreau (2004) and discussion on "HR as change agent" by Ulrich et al. (2009). Thus, *leading change* is examined as dimension of contemporary HRM practices in this research.

However, organization design and employee engagement have not been chosen yet to put in our research model in Vietnam. The reason is about its rareness in Vietnamese firms. They might concern to some CEOs but they do not know how to assign these practices to which department. Cultural transformation relates across functions and reflects the mindset of CEO. It is expected to be more complicated in study. So it is suggested to be researched in a separate study.

In summary, HRM practices in Viet Nam can involve 7 dimensions. This research focused on the four traditional hard dimensions of HRM practices, which are quite popular in Vietnam, and two traditional HRM soft dimensions which are emerging in Vietnamese firms, including leading change and motivation. The research also added talent management as contemporary HRM hard dimension in the model (see Table 2). Contemporary HRM soft practices are not included in this research according the explanation in the paragraph above.

Table 2: Key concepts in the research model

Construct	Definitions	Literature
Recruitment & selection	The process of seeking and attracting a pool of qualified applicants for job vacancies through selection techniques and policy.	Fombrun et al (1984), Tran Kim Dung (2015)
Training & development	Build individual capability and knowledge to meet current and strategic requirements of the organization and personal career development.	Fombrun et al (1984), Tran Kim Dung (2015)
Performance appraisal	A system to record, fairly evaluate employee performance, with an aim to improving individual performance and hence achieving firm's objectives.	Fombrun et al (1984), Tran Kim Dung (2015)
Compensation & rewards	A system of payment to carry equality among job requirements, employee competencies, and individual and organizational performance and local market.	Fombrun et al (1984), Tran Kim Dung (2015)
Motivation	Policies and action plans to make employees feel happy and inspired in their jobs, desire to make efforts to give best contributions to the organization.	Robbins, S. (1986), Stone (2008), Šikýr (2013).
Leading change	Act as a role model leader, maximizing dynamic and positive force for stimulating creativity, diversity, learning and growth.	Ulrich et al. (2009), Milkovich & Boudreau (2004),CIPD (2015), Tran Kim Dung (2015)
Talent management	A system to ensure that the organization has the right resources, capability and talents to achieve its immediate and strategic objectives.	CIPD (2015), Šikýr (2013).
Business performance	The extent to which a firm increases sales, profits, market development and customer satisfaction	Singh (2004), Santos et al. (2007)

Relationships between HRM practices and firm's business performance

Effective HRM practices bring positive HR outcomes such as high competencies, satisfaction, high responsibility and commitment with the organization. Satisfied employees will make customers satisfied. As a result, business performance of the firm will be better.

Therefore, relationship between HRM and firm performance have been tested in many researches, with diversified respondents and in various contexts such as Fey at al. (2000) in Russia, Park, et al (2003) in Japan; Singh (2004) in India, Joseph and Dai (2006) in Abidjan, Absar et al (2010) in Bangladesh, Duke and Udono (2012) in Nigeria, Šikýř (2013) in Czech, Arshad et al. (2014) in Pakistan, etc.

In Vietnam, researches also showed that effective HRM practices can lead to higher organizational performance. Previous studies were conducted in different types of ownership and industries such as Le Chien Thang and Truong Quang (2005), Ying and Zhu (2007), Long Pham (2011), Nguyen Minh Ngoc and Ngo Van Tuan (2012).

As a result, our main hypotheses of this research are:

Hypothesis H1: The HRM practices are interrelated seven dimensional constructs.

Hypothesis H2: The HRM practices affect positively on firm's business performance.

Methodology

This research applied mixed methods to explore the current HRM practices and its importance in Vietnamese firms.

- Preliminary research was conducted with qualitative method to explore the current HRM practices in Vietnam and its contribution to business performance of Vietnamese firms. 9 managers and 12 employees were interviewed for reviewing those HRM practices in Vietnamese firms. The results were used for developing final measurement scales of all factors in the research model and then transferring to the survey questionnaire in the main research.
- Main research was conducted quantitatively via a survey of 388 firms. Respondents were managers and HR specialists working for firms in Ho Chi Minh city, Vietnam.

This research developed a set of valid and reliable instruments to measure 7 practices of HRM. Based on the definitions and conceptualizations in the literature and practices in Vietnamese firms, we develop measurement items for all these 7 dimensions of HRMP. All items were measured by a Likert seven-point scale, ranging from 1 (strongly disagree) to 7 (strongly agree).

SEM is effective when testing latent constructs that are being measured with multiple items (Luna-Arocas & Camps, 2008.). Thus, SEM method was applied in this research to measure multi-dimensional HRM practices.

Sample and data collection

In the main survey, the data was collected by self-directed questionnaire through face-to-face contact. Convenient sampling method was applied. Data includes 635 valid responses from 388 firms, in different industries, with response rate of approximately 43 percent. Mean scores of those responses from the same firm was calculated for the firm's score, i.e. aggregated score.

Description of the sample is summarized Table 3 below.

Table 3: Sample characteristics

Type	*Characteristic*	*Statistics*
Ownership	Private	42.3%
	SOE	23.0%
	FDI	19.2%
	Joint stock and others	15.4%
Size	less 300	69.3%
	301-1000	12.1%
	>1000 employees	18.6%
Time established	less 5 years	25.8%
	5-10 years	27.8%
	more than 10 years	46.4%

Measurement

Based on the current review of HRM practices in theories and previous study in Vietnam, and in deft – interviewing, this concept comprises 7 components, including recruitment and selection, training and development, performance management, compensation, leading change, motivation, and talent management. Each latent variable is measured by 3 observable variables (see Table 4).

The firm's business performance is measured by 4 observable variables: Revenue, profit, customer satisfaction, and market development. The responses were about perceived performance.

Data analysis methods

The measurement model was firstly tested on the complete data set using exploratory factor analysis employing SPSS 20.0. The data exhibited the univariate Kurtoses and Skewnesses within the range of [-1, +1]. Thus, maximum likelihood method was used to determine the underlying factor structures (Muthen and Kaplan, 1985).

Then, confirmatory factor analysis was employed using AMOS 20 to further investigate the latent structure of the factors and testing the measurement model. It tests the construct validity with uni-dimensionality, reliability, convergent validity, discriminant validity, and predictive validity (Garver and Mentzer, 1999). These methods will help to confirm dimensions of HRM practices with their respective measurement scales. In order to test hypotheses, we tested the research model via structural equation modeling (SEM) using AMOS 20.

Data analysis and results

Measurement validation

The measurement of HRM practices produces model fit with: $\chi^2_{[182]} = 342.144$; p=0.000; GFI= 0.923; TLI=0.964; CFI=0.969; RMSEA=0.048. In addition, all factor loadings were high > 0.586 and significant ($p < 0.001$). These findings indicate that the scales measuring the seven dimensions of HRM practices were uni-dimensional. Within-method convergent validity was achieved based on the standard by Steenkamp and van Trijp (1991).

The results supported that the scales of 7 dimensions of HRM practices, including recruitment and selection, training and development, performance appraisal, compensation and rewards, leading change, motivation, and talent management are relevant to Vietnamese context.

Business performance is a multi-dimensional construct which have two dimensions, finance performance and market development, with four observed items. Scale of business performance produced model fit with: $\chi^2_{[1]}= 1.736$; p=0.000; GFI= 0.998; TLI=0.994; CFI=0.999; RMSEA=0.044.

See Table 4 for CFA item loadings, composite reliability, and average variance extracted of the scales validated.

Table 4: Mean, standard deviation, and standardized CFA factor loading of items

	Mean	Std. Deviation	Standardized loadings
HRM practices: Composite reliability Pc = **0.9317;** Average variance extracted VE=**0.6627**			
1. ***Recruitment***: Composite reliability Pc = 0.7594 Average variance extracted VE=0.5174			
Selection criteria are standardized according to job requirements	4.75	1.425	0.586
Recruitment process is relevant	4.6	1.387	0.815
There is a good collaboration between line managers and HR department in selection process	4.5	1.436	0.735
2. ***Training & development***: Composite reliability Pc = 0.8735; Average variance extracted VE=0.6983			
Training design and implementation align with the firm's strategic objectives	4.94	1.433	0.755
Employees are provided with training of knowledge and skills to carry out their tasks	4.34	1.575	0.839
Employees are provided with high quality training programs	4.44	1.544	0.907
3. ***Performance appraisal***: Composite reliability Pc =0.8211 Average variance extracted VE=0.6064			
Employees receive sufficient feedback and counseling based on their performance	4.48	1.326	0.688
The performance appraisal system in this firm focus on enhance employee performance	4.46	1.416	0.798
The performance appraisal system in this firm is fair and accurate	4.23	1.408	0.843

4. ***Compensation***: Composite reliability Pc = 0.8773 Average variance extracted VE=0.7046			
Payment in this firm is fair	4.55	1.511	0.825
Compensation in this firm is based on job requirements and employees' competencies	4.7	1.521	0.878
Employee income reflects performance results	4.58	1.605	0.815
5. ***Leading change***: Composite reliability Pc = 0.8313; Average variance extracted VE=0.6219			
Encourage to improve performance frequently	4.63	1.245	0.754
Change efforts are encouraged	4.81	1.367	0.83
Opportunities to apply improvement initiatives for improvement are opened to all employees	4.69	1.366	0.781
6. ***Motivation***: Composite reliability Pc = 0.8846 Average variance extracted VE=0.7187			
There are programs that make employees feel motivated in their jobs	4.3	1.257	0.83
Care of employee moods in the workplace is a priority	4.37	1.322	0.856
Motivation programs in this firm have good effects	4.47	1.375	0.858
7. ***Talent management***: Composite reliability Pc = 0.8816; Average variance extracted VE = 0.7129			
Programs to attract talents work well	4.23	1.46	0.814
Programs to remain talent work well	4.31	1.435	0.866
Programs to develop talent work well	4.4	1.442	0.851
Business performance: Composite reliability Pc =0.7660; Average variance extracted VE = 0.6245			
1. ***Financial performance***: Composite reliability Pc = 0.8845; Average variance extracted VE = 0.7936			
Achieve revenue target	4.86	1.411	0.83
Achieve profit target	4.97	1.401	0.95
2. ***Market development***: Composite reliability Pc =0.7405; Average variance extracted VE = 0.5893			
Market development	4.77	1.273	0.82
Customer satisfaction	4.86	1.207	0.71
Valid N (list wise)	388		

Relationships analysis and results

Measurement model produced model fit with: $\chi^2_{[202]}$= 354.693; df=202; p=0.000; GFI= 0.927; TLI=0.966; CFI=0.972; RMSEA=0.044. All composite reliability (Pc) ranged 0.740 to 0.932; Variance extracted (VE) ranged from 0.517 to 0.793. Factor loading ranged from 0.765 to 0.889. All correlations had estimate r ranged from 0.405 to 0.809; and $p< 0.000$, proving the discriminant validity of the constructs. The correlations between constructs, together with their standard errors, indicate that they were significantly different from unity, thus, supporting the construct discriminant validity (Steenkamp and van Trijp, 1991).

Therefore, hypothesis H1 is accepted. The HRM practices are interrelated seven dimensional constructs. In other words, HRM practices compose of seven dimensions.

Research model produced model fit with: $\chi^2_{[222]}$= 407.743; df=222; p=0.000; GFI= 0.917; TLI=0.962; CFI=0.967; RMSEA=0.046 (see Figure 2). A positive relationship between HRM practices and business performance was found (0.65) with $p < 0.001$. The results hence indicate that HRM practices are key factors predicting business performance of firms. HRM practices can explain 43 percent of the variance of business performance.

The squared multiple correlations for all variables ranged from 0.428 to 0.838.

Therefore, hypothesis H2 is accepted. These HRM practices affect positively on business performance of Vietnamese firms.

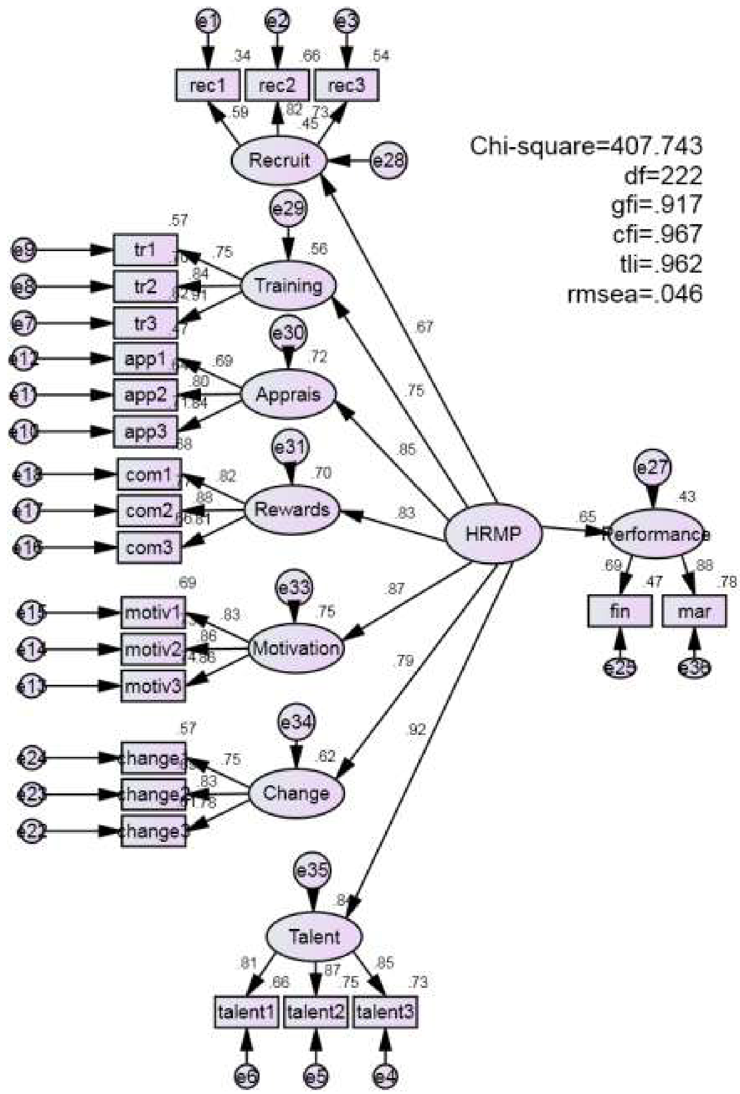

Figure 2: Impact of HRM practices to firm's business performance

Discussion and implications

Discussion

Construct validity for the practices of HRM was confirmed with 7 dimensions of HRM practices which include hard and soft dimensions, as well as traditional and contemporary HRM practices:

- Traditional hard dimensions of HRM practices: recruitment and selection, training and development, performance appraisal, and compensation and rewards. These practices comply with many previous studies in this field. It shows that Vietnamese firms nowadays apply all key functions of HRM. It is an improvement in comparison to the study by Ying Zhu (2005) in which HRM practices in Vietnamese firms depended much on the level of government, labor union, and foreign capital involvement. The improvement is on proactive HRM starting from how to recruit and select the right people to how to retain them by development and compensation.
- Traditional soft dimensions of HRM practices: motivation and leading change. These practices require insight understandings of employees, cross-functional collaboration about the business. They are big challenges to HR department. They also require a big change in mindset of line managers about their role and responsibility in HRM
- Contemporary HRM hard practices: talent management. These practices reflect a change in managers' mindset on the important role of talents to firm performance. Vietnamese firms today invest more in attracting, developing and retaining talents.

Benchmarking with some previous studies in Vietnam which represent for traditional approach and contemporary approach to HRM practices, it is indicated that those studies of all types of firms have reflected the trend of contemporary HRM practices in Vietnamese firms. Except in Long Pham (2011), equitized SOEs in Vietnam is still based on the government control, so only traditional HRM practices could be recognized (see Table 5).

Our research approaches to HRM practices in order to provide clearer concepts about HRM practices based on classifying them into hard vs. soft and traditional vs. contemporary groups of HRM practices, and to update the situation in Vietnam and attempts to close the gaps in these researches. Particularly:

- Research by Le Chien Thang and Truong Quang (2005) recognized some emerging HRM practices such as communication (belong to factor Information exchange) and retention management. However, an important function of HRM which is recruitment-selection was not examined. In addition, seniority-based compensation which was loaded in factor Group orientation is not appropriate in concept. And up to now, after ten years, many changes have been observed in Vietnam, with the participation into WTO and TPP recently.
- Among other studies in Vietnam about this topic then, Ying and Zhu (2007) qualitatively analyzed seven manufacturing firms in Vietnam to recognize work relations, employment relations, and employee involvement as key dimensions of HRM practices. It was just exploratory understanding the implementation of HRM practices, not yet statistically examined. Beside traditional hard HRM practices, one soft dimension of traditional practices, i.e. employee involvement, was recognized.
- Paper by Long Pham (2011) was still conceptual, not yet statistically testing, about HRM practices in equitized state-owned enterprises (SOEs) in Vietnam. Only traditional HRM hard functions were mentioned such as HR planning, recruitment and selection, compensation, training, performance appraisal.
- Research by Nguyen Minh Ngoc and Ngo Van Tuan (2012) which focused on 200 small and medium enterprises (SMEs) in Hanoi mentioned three traditional HRM hard dimensions of practices, including training, performance appraisal, and incentive compensation. No contemporary practices were discussed.

Table 5: Benchmarking among researches into HRM practices in Vietnam

	Le Chien Thang and Truong Quang (2005)	**Ying Zhu (2005)**	**Long Pham (2011)**	**Nguyen Minh Ngoc and Ngo Van Tuan (2012)**	**This research (Tran Kim Dung and Truong T. Lan Anh, 2015)**
Type of research	Quantitative Survey of 137 firms	Qualitative Case study with 7 cases	Conceptual	Quantitative Survey 200 firms	Quantitative Survey of 388 firms
Scope of research	Cross-sector, all types of ownership	Manufacturing SOEs, Join-ventures, FDIs	Equitized SOEs (i.e. run as joint-stock corporations)	Cross-sector, SME	Cross-sector, all types of ownership
Traditional hard dimensions of HRM practices	2 dimensions Training & development, Performance management,	3 dimensions Work relations, Employment relations, Employee involvement	4 dimensions HR planning, Recruitment and selection, Compensation, Training, Performance appraisal	3 dimensions Training, Performance appraisal, Incentive compensation	4 dimensions Recruitment & selection, Training & development, Performance appraisal, Compensation
Traditional soft dimensions of HRM practices	Information exchange, Group orientation,	No	No	No	Leading change, Motivation,
Contemporary HRM practices	Retention management (hard dimension)	No	No	No	Talent management (hard dimension)
Impact of HRM practices on firm's business performance	Yes HRM practices can explain 45% of variation in business performance.	Yes, but not statistically confirmed	Yes, but only with financial performance, and not statistically confirmed	Yes HRM practices can explain 42% of variation in business performance.	Yes, HRM practices can explain 43% of variation in business performance.

With a new framework of HRM practices, in comparison to previous studies in Vietnam, in different situations of economic changes, it is still true that HRM practices have significant impact to firm's business performance. This proves that people must be the vital key to firm success.

Implications

First, a framework of four groups of HRM practices suggested in this paper implies a need to design appropriate training programs to both HR professionals and line managers in order to effectively carry out them.

Second, the confirmatory results of HRM practices measurement model imply that HRM practices in Vietnam are following the world trend in HRM practices. Traditional hard practices are not enough for HRM in Vietnamese firms. It indicates that HRM practices in Vietnam are beyond traditional functions of HR department and closer to the change agent role and hand-in-hand with line managers in talent management. Such traditional HRM soft practices as motivation and leading change, and the contemporary HRM hard practices as talent management are practically appropriate to Vietnamese context.

Ten years after the research by Le Chien Thang and Truong Quang (2005), there are profound changes in Vietnamese economy with its participation in WTO and TPP that requires transformations in both mindset and practices of managers. Our research finds out that the emergence of traditional HRM soft practices and contemporary HRM hard practices is inevitable. Managers across functions should be aware of this trend and well prepared in terms of competencies to implement these practices.

A roadmap of HRM practices evolution can be learned from this research is from traditional hard group first, then traditional soft group, then contemporary hard group, and finally contemporary soft group (see figure 3). It would be more feasible when soft HRM practices are developed based on a well-designed system of hard HRM practices, and contemporary practices based on traditional practices. They are not mutually exclusive but reciprocal.

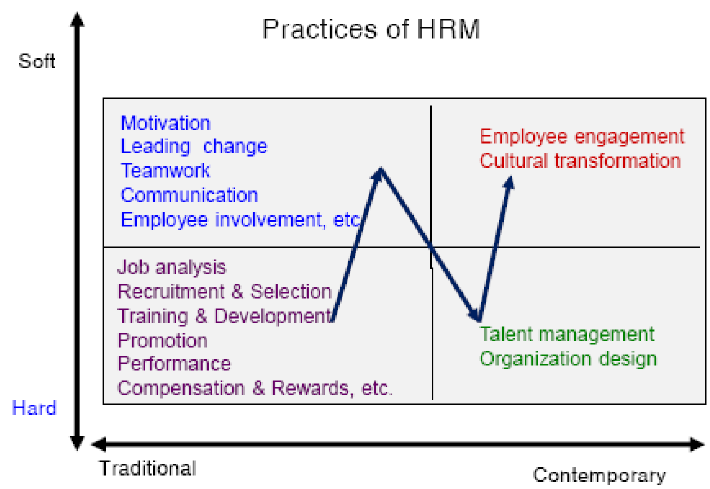

Figure 3: A suggested roadmap for HRM practices evolution in Vietnamese firms

Thirdly, investing in such contemporary HRM practice as Talent management will lead to better business performance. However, this practice challenges both HR department and line managers in a need to more collaboration with each other and to improve their human-related competencies.

Conclusions

HRM practices in Vietnam compose of seven dimensions with tested construct validity. Beside the four traditional hard dimensions of HRM such as recruitment and selection, training and development, performance appraisal, and compensation and rewards, HRM practices in Vietnamese context also involve two traditional soft dimensions such as leading change and motivation. The contemporary hard dimension which is significant in Vietnamese context is talent management. These HRM practices are recognized to have significant impact on business performance.

Contributions of the study

Firstly, this research suggests relevant concepts of HRM practices to Vietnamese firms. These concepts are presented in a framework which encourages right awareness about the changing role of HRM in the managerial circles. The framework of HRM practices in this study supports the concept of human resource management. HRM should be conceived and applied correctly in Vietnamese firms to replace the old concept of personnel management which still exist in many SOEs and SMEs in Vietnam.

Secondly, the research contributes to HRM field of study with valid measurement scales of HRM practices that would be significant to HR managers in Vietnamese context.

Thirdly, the research also contribute to theory a framework of HRM practices which helps recognize traditional vs. contemporary, and hard vs. soft groups. Based on this, firms in such developing countries as Vietnam can learn how to set a roadmap to upgrade their HRM functions following the world trend. CEOs can benchmark and envision the evolution process of HRM practices in their organizations. Accordingly, they can determine and distinguish responsibility of HR department and line managers in implementing HRM practices.

Forth, this research has confirmed the influences of HRM practices on firm's business performance. The significant role of HRM practices in leading firm performance is inevitable. The key is which specific HRM practices should be conducted in particular period of Vietnamese economy in order to bring in the most effective performance.

Limitations and directions for future research

This study has a number of limitations.

First, a sample is implemented by convenient method and we investigated only firms in Ho Chi Minh city, Vietnam. The model needs further replication in other places in Vietnam and critical evaluation to provide useful insights.

Secondly, this research did not measure organizational design, employee engagement, and cultural transformation as reviewed in our literature of contemporary HRM practices. In next few years, following the roadmap of HRM practices' evolution, these factors will become more popular in Vietnamese firms. So they should be tested in further research.

Thirdly, business performance was measured in perceived scales through an attitude survey. In such an environment of insufficient information about firm performance as in Vietnam, except those big ones on stock market, it is still impossible to access fact data about firm performance. So it just reflected managers' perceptions, not actual firm performance such as objective indicators.

Based on theories of the affective priming effect, implicit attitudes and conceptual fluency, this article has researched the persuasive effect of language styles of signboards in scenic spots on uncivilized behavior of tourists and probed into the influence of the matching methods between background color valence and language styles of signboards in scenic spots. The result indicates: (1) the language style of signboards exerts a distinct persuasive influence on tourists. (2) When the language style matches the background color valence, the persuasive effect becomes more effective. (3) Conceptual fluency forms the intermediate variable of the persuasive effect of in matching language style and background color valence. This article provides theories and guidance to enhance moral education and the intervening effect of signboards for uncivilized behavior.

Keywords: Color valence, Affective priming, Language style, Conceptual fluency, Persuasive effect.

1. Introduction

Tourism is nonresident and temporary, which leads to a lack of responsibility restriction and a weakened moral sense [1] and forms a significant factor of uncivilized behavior related to tourism. Cognitive psychologists have found that human behavior can be reached through internal motivation and purpose in a subconscious way [2]. As a message conveying social norms, signboards in scenic spots can have an impact involving warnings, reminders, requests, announcements, etc. to intervene with tourists' uncivilized behavior. However, in-depth research into the persuasive effect of signboards on tourists' uncivilized behavior is lacking.

Signboards bear differences in terms of language style and background color which offer an important clue for tourists' cognition and moral education. This article has conducted research on the persuasive effect of signboards on tourists through stimulated situational experimentation and further studied persuasive educational effects of the connection between language style and background color valence on tourist behavior, providing a theoretical basis and guidance for tourists' uncivilized behavior.

2. Paper review and research hypothesis

2.1 Influence of the persuasive effect of language style on tourists.

The standard focal point of this theory is that signal words described on signboards for tourism are mandatory social norms and behavior standards the majority agree or disagree with under a specific culture, which is attributed to an "ought-to-be" level [23] of social norms based on the theory. Signal words can be divided into two main sentence patterns: declarative sentences and imperative sentences. The declarative sentence is used to speak with a euphemistic and indirect mood, closed with a period. Compared to the declarative sentence style featuring certainty, the imperative sentence has a stronger negative meaning which is less acceptable to the public. Tourists' civilized behavior can be reached by different language-style signboards in scenic spots and generate the same result towards the pursuit of conscious civilized behavior. Tourists value their subjective feelings when accepting persuasive messages and prefer positive hints. In other words, they prefer the persuasion of a positive declarative sentence to that of a negative imperative sentence. Therefore, this study puts forward a hypothesis as follows:

H1: Declarative style sign wordage generates a more persuasive effect than imperative style sign wordage.

2.2 Interaction effect between language style of sign wordage and color valence of signboards.

Colors not only entail aesthetics, but also form a non-lexical stimulus which easily goes unnoticed and affects people's cognition and behavior [3]. Several studies have shown that colors exert effects on emotions, cognition and behavior [14] in relationships between men and women [7, 8], achievements [9], athletics [10], marketing and branding [11-13]. On the basis of the theory of color symbolism [4], people associate specific messages, concepts and experiences with specific colors. They are endowed with specific symbolic meanings to express different emotions and satisfy different psychological functions [6]. Under the Western mindset, red is associated with danger and mistakes (e.g. traffic lights and warning signs) [15]. Research done by Bock and others has also shown that red has a negative valence and confirmed that using red to deter people from undesirable behavior will backfire [17]. However, some research still indicates a positive effect for red. For instance, preschool children have a preference for red [18]. Maier and others owe individual red preference to different individual psychological circumstances which means under positive circumstances, people prefer red whereas under negative circumstance their preference will be totally the opposite [19]. Elliot and Niesta have proven that red has a positive influence on relationships between men and women: a red background will make women more attractive to men [20] and also make men more romantically attractive in women's eyes [21]. Red holds a respectable and traditional standing in the minds of Chinese because of folk magic of exorcising evil spirits and warding off bad luck. It is a joyous color representing luck and auspicious omens [22]. "Chinese red" has become the understanding and memory that people of other countries have for China. Therefore, under the Chinese circumstance, red has a positive psychological valence. Blue, standing for a typically cold color, has negative psychological effect, as opposed to red in terms of color and psychology.

Based on the priming effect, individuals will be affected by previous information when processing current information [24]. Emotions generate a priming effect and this individual emotional state is regarded as a prepared or starting state which influences individual cognitive actions. To be specific, individuals first process stimuli which have a certain emotional valence (prime stimulus), then process a subsequent stimulus (target stimulus). Generally, among stimuli of the same valence, people process target stimuli faster and more accurately [25]. Applying words consistent with the valence of a target stimulus as a priming stimulus will promote the processing of the target stimulus [26], but pictures have even higher levels than words as far as emotional arousal is concerned, thus have a more obvious priming effect [28]. Joyful images will be evaluated positively by respondents whereas angry images more negatively [27]. Elliot and Niesta (2007) conducted an intelligence test based on different background colors and proposed that social cognition should include color stimulus in stimulus materials with a priming effect [6]. Research done by Bock and others further proves that relatively abstract stimulus materials such as background colors do produce priming effects [17].

Background colors of tourist signboards are a kind of stimulus material and different language styles of signal words are the target stimulus. When thinking about tourist signboards, tourists can process colors and language styles of the same valence more quickly and accurately. Therefore, this study comes up with hypotheses as follows:

H2: When language styles match background colors of signboards in terms of valence, the signboards can have better persuasive effects.

H2a：Compared to signboards of declarative sentences with a blue background, signboards of declarative sentences with a red background have a stronger persuasive effect.

H2b: Imperative sentence style signboards with a blue background have a stronger persuasive effect then that of a red background.

2.3 Intermediate effect of fluency

Fluency is a subjective experience individuals have towards the difficulty levels of processing information of which conceptual fluency is a semantic analysis and semantic association between the target stimulus and the rendered scenario. The stronger the semantic association is, the higher the conceptual fluency will be, and psychological representation of target stimulus can be reached more easily. When the background color valence of signboards matches the semantic association of the language style on signboards, i.e. when a red background is paired with declarative sentences and a blue background is paired with imperative sentences tourists can experience conceptual fluency while processing information to inspire their positive affective state so as to influence the cognitive and persuasive effect in a positive way. Therefore, this study proposes a hypothesis as follows:

H3: When background color valence matches the language styles of signboards, tourists will experience conceptual fluency during information processing.

On the basis of above analyses, this conceptual modal of the study can be demonstrated in Fig. 1

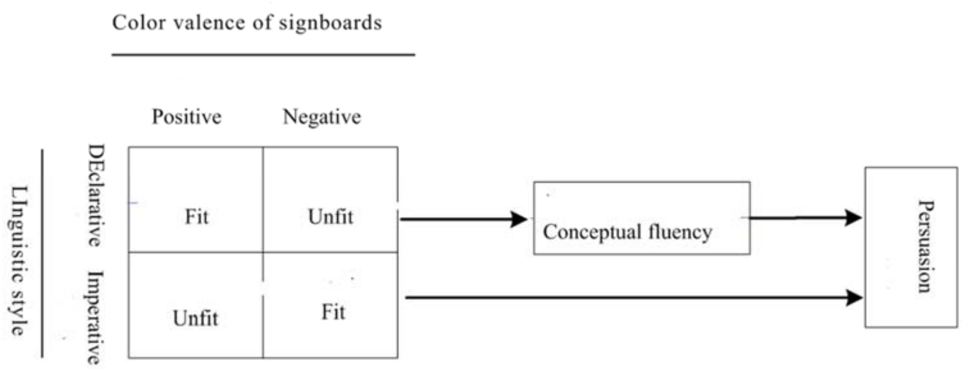

Fig.1 The concept model of the research

3. Research design

3.1 Analysis on psychological color valence

Colors convey different meanings when combined with different beliefs, customs and values of different nationalities, reflecting a unique experience of recording colors in different nationalities [33.] This study chooses tourists as its respondents, exploring tourist experiences and their emotional reaction associated with the 2 basic colors of red and blue and aims to identify the psychological valence of the 2 basic colors.

This study invited four tour guides to give out and retrieve 101 effective questionnaires when tourists were having a break. A professor majoring in psychology and 2 Ph.D. students collaborated together to arrange and summarize the words associated with the colors. Firstly, they independently screened color associated words related to psychological functioning and valence. Secondly, through discussions and combining synonyms or near-synonyms of associated words, they confirmed together that frequencies of red-and blue-associated words are respectively 210 and 251. Ultimately, they used the analysis of word frequency in a ROST content mining system to identity high-frequency words associated with red and blue and their cumulative association frequencies are respectively 84.8% and 77.7%. The research shows that, in rare cases, red is associated with danger and revolutions that have negative implications. Mostly, red is an affective and happy expression characterized by enthusiasm, jubilation, warmth, happiness, etc., which means red has positive psychological valence. Blue conveys a rational and negative emotion featuring vast, tranquility, melancholy, sophistication, etc indicating a negative psychological valence. The result of the analysis of variance ($F(1, 80) = 38.95$, $p<0.001$) signifies red and blue bear distinct differences in psychological valence.

3.2 Lab materials producing and measuring variables

According to common uncivilized behavior listed on the official website of the National Tourism Administration, the top one is “littering, spitting, blowing noses and spitting gum out in public places, no flushing after using the a toilet, lack of hygiene and leaving dirty marks”. Top 2 is smoking in nonsmoking areas which pollutes public space and impairs others’ health”. Based on that, the research experiment chose content and language style of signboards in scenic spots as follows:

(1) “If you spit on the ground, you're shooting your demeanor away.” (Declarative) and “No spitting” (Imperative)

(2)We hope you will not pick the flowers or walk on the grass for plants also have life and can feel. (Declarative) and “No picking flowers or walking on the grass” (Imperative)

(3) “I am an environmental protector and you are an emissary for your people.”(Declarative) and “No littering” (imperative)

Behavioral intent is based on the research of De Bock (2013) and “I am willing to accept the public behavior on tourist signboards”, “I am willing to abide by the public behavior on signboards while traveling”, and “I am willing to remind others to abide by the public behaviors on signboards while traveling” were extracted for measuring. Conceptual fluency was measured based on the methods of Schiffman and others. All the scales passed the reliability and validity tests.

4. Experiment Results

The study conducted hypothesis testing through 2 (signboard color: red vs. blue) by 2 (language style of sign wordage: declarative vs. imperative) between-subject design. 120 tourists from Chengdu scenic spots were invited to the official experiment. Steps were taken, including respondents grouping and guiding, experiment controlled tests, measuring cognitive and emotional responses, etc. SPSS 16.0 was also adopted to analyze and process the information.

（1）Analysis on the influence of the 2 language styles of sign wordage on persuasive effect.

Results of variance analysis on the influence of language style on persuasive effect show that respondents reading declarative sign wordage ($M_{\text{behavioral intention}}$=5.69) have a more positive behavioral intent ($F_{\text{behavioral intention}}(1,109)=25.87$, $p<0.001$）than that reading imperative sign wordage ($M_{\text{behavioral intention}}$=4.95), signifying that the language style of sign wordage described on signboards in scenic spots distinctly affects the persuasive effect on tourists, thereby supporting the hypothesis H1.

（2）Analysis on the persuasive effect of the matching between language style and background color valence of signboards on tourists.

Results stemming from variance analysis indicate that: in the declarative style, red signboards have better persuasive effect than blue on respondents, meaning a higher behavioral intent ($F_{\text{behavioral intention}}$ (1, 56) =10.26, p=0.002), among which respondents reading red signboards have a mean value of ($M_{\text{behavioral intention}}$ =5.98, $SD_{\text{behaviroal intention}}$=0.53), and respondents reading blue signboards have a mean value of ($M_{\text{behavioral intention}}$ =5.44, $SD_{\text{behaviroal intention}}$=0.71), thus supporting the hypothesis H2a. In the imperative style, blue signboards have a better persuasive effect than red on tourists, meaning a higher behavioral intent ($F_{\text{behavioral intention}}$ (1, 51) =15.91, $p<0.001$), among which respondents reading blue signboards have a mean value of ($M_{\text{behavioral intention}}$ =5.36, $SD_{\text{behaviroal intention}}$=0.76), and respondents reading red signboards have a mean value of $M_{\text{behavioral intention}}$ =4.56, $SD_{\text{behaviroal intention}}$=0.72), thus supporting hypothesis H2b.

In order to further study whether the psychological valence matching or mismatching between signboards colors and signal words language style can affect persuasive effects, this research introduces a dummy variable (1=valence matching between sign wordage language style and signboards color, 0=mismatching between sign wordage language style and signboards color) and adopts a one-way analysis of variance to conduct tests. Results obtained show that language style and background colors valence interact with each other reciprocally ($F_{behavioral\ intention}(1, 109)=18.14$, $p<0.001$＝ in terms of persuasive effects, i.e. when language style matches color valence, tourists have a higher acceptance of the persuasion, thus supporting hypothesis H2. Declarative sign wordage on red signboards and imperative sign wordage on blue signboards have different persuasive effects ($F_{behavioral\ intention}$ (1, 50) =11.82, p=0.001) and the result indicates that declarative signal words have better persuasive effect. Besides, signboard color valence itself does not affect persuasive effect significantly. ($F_{behavioral\ intention}$ (1, 109) =0.886, p=0.35)

（3）Test of intermediate effect of conceptual fluency

Referring to the cause and effect method put forward by Baron & Kennt, the study tested the intermediate effect of conceptual fluency and dealt with statistics with the help of dummy variables. The regression result (see Fig. 2) shows that conceptual fluency serves as an intermediate on the influence of the matching between language style and signboards color valence on a persuasive effect, thus supporting hypothesis H3.

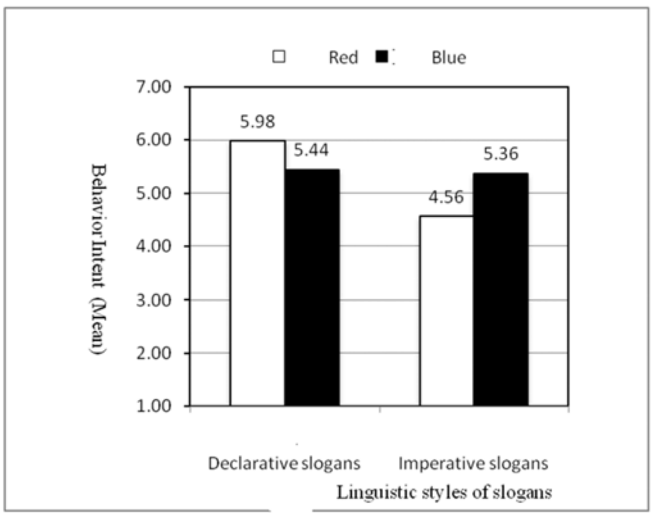

Fig.2 Interaction between linguistic style of slogans and color valence of signboards

5. Conclusion and discussion

5.1 Conclusion and discussion

（1）Under different cultural circumstances, different colors are associated with different psychological meanings. Different from Western cultural circumstances where red is associated with danger, mistakes and other negative meanings, in the color cognition experience of Chinese tourists, red and blue respectively have positive and negative psychological valence.

（2）Language style of sign wordage on signboards in scenic spots exerts significant influence on the persuasive effect. Researchers found that in contrast with the negative imperative style, the positive and euphemistic declarative style is more capable of arousing tourists' higher behavioral behavior. Imperative sign wordage directly mandates that people shall not behave immorally, which restricts people's freedom to some extent, reflecting a strong negative meaning. However, declarative signal words demonstrate positive information valence by encouraging people to enhance their morality.

（3）When language style matches the color valence of signboards, tourists are more willing to accept what is said on the signboards. This conclusion illustrates that background colors of signboards in scenic spots have an affective priming effect, people's morality is not a rational and deliberate reasoning process and color valence and other intuitive factors should be paid attention to.

（4）Conceptual fluency serves as an intermediate viable of the influence of the matching between language style and background color valence on the persuasive effect. Processing declarative sentences on red signboards makes tourists experience more conceptual fluency than that on blue signboards, thus bringing a stronger persuasive effect. Also, processing imperative sign wordage on blue signboards makes tourists experience more conceptual fluency than that on red signboards, thus bringing a stronger persuasive effect.

5.2 Management suggestions

Uncivilized tourist uncivilized behavior is a bad phenomenon of tourism, which not only endangers the ecological environments of tourist destinations, but also influences the quality of the experience of others. As an important means of spreading social norms, signboards in scenic spots have been given much attention by management departments of scenic spots. How to make tourists embrace social norms and behave in accordance with social norms are of much importance for tourist management practices. This study reveals that the matching between language style and background color valence of signboards impacts tourists' emotion, cognition and behavior through the formation of an implicit attitude. This study not only extends research on tourist behaviors, but deepens theories on uncivilized tourist behavior and also serves as a significant guide for tourist management departments to intervene in uncivilized behavior with proper signboards.

Moving toward Efficiency: The Study of Time-Varying Informational Efficiency in the Stock Exchange of Thailand

Sophana Buraprathep
Faculty of Commerce and Accountancy
Thammasat Universitty,
Thailand
sophanab@gmail.com

The application of random walk or general auto-regressive model to investigate time-varying degree of informational efficiency in the previous literatures has some drawbacks. To make improvements on model specification, this study proposes the stochastic AR(p) coefficient model that relates the dynamic behavior of degree of efficiency with time in three functional forms. Using daily returns from Thailand's stock market from April 30th, 1975 to September 19th, 2014, this study finds the statistically relationship between degree of efficiency and time, which is well described either by the linear or the logistic function. Furthermore, the results suggest that degree of informational efficiency in the stock market improves through time as indicated by the decreasing numbers of day to disseminate particular amount of information.

Keywords: Time-varying market efficiency, informational efficiency, stochastic AR(p) coefficient model, Kalman filter

1. Introduction

Market efficiency is one of the most important foundations of finance theories. Although the hypothesis of efficiency has been extensively studied for financial markets in developed and emerging countries, the literature in this area is still growing. New sample markets as well as new techniques or improvements are introduced in order to achieve correct and insightful understanding. In the early period of the study, Fama (1970) concentrated his interest on informational efficiency, classifying efficiency into three separate forms, namely, weak-, semi-strong- and strong-form. Among these three forms, the test for weak form efficiency is the most popular because it employs market price data which are readily available to investigators. Examples of such studies include Fama (1965), Lo and Mackinlay (1988), Worthinton and Higgs (2006), Kim and Shamsuddin (2008), etc. Most of the tests for weak-form efficiency are restrictive in that they focus on whether the markets are or are not efficient during a sample period. Nevertheless, Grossman and Stiglitz (1980) argued that the market could not be fully efficient so that it was worth the effort of informed investors to gather the necessary information.

It should be noted that market efficiency is informational. The market is considered fully efficient if all information is known instantaneously to all investors and is reflected in prices. Based on this definition, the market should be interpreted as being more efficient, or less inefficient, if it takes less time for information to flow to investors and to be fully reflected in the relevant asset prices. So, even though the market is inefficient for a period in time, it is interesting to ask whether the market is less inefficient or more efficient in the following period. From a theoretical perspective, Lo (2004) proposed the Adaptive Market Hypothesis (AMH) to show that market efficiency is an evolutionary process and can be improved through time. Briefly, AMH asserts that individuals have their own interest and can make mistakes. However, they will learn from their mistakes and adapt themselves to the changing environments. Competition as well as innovation also leads to the evolution of the market, which, in turn, improves the degree of efficiency. His study found that degree of efficiency in US market varied over time as indicated by AR(1) coefficient from rolling regression. These findings point to the fact that, despite inefficiency, the degree may be time-varying.

The question as to whether the degree of market efficiency is time varying has been addressed in the literatures. Emerson et al. (1997) found evidence of changing auto-regression (AR) coefficients from a regression of stock returns in Bulgarian stock market. This study is the pioneer in support of time-varying degree of efficiency. Their framework has been broadly accepted and extended by subsequent studies. For example, Zelewska-Mitura and Hall (2000) employed this approach to investigate whether stocks listed in different periods have different degrees of efficiency, Li (2003a) applied it to study time-varying efficiency of two stock exchanges in China, Li (2003b) extended the scope of study using data from A-share and B-share markets of each stock exchange, while Arouri et al. (2010) employed it to investigate degrees of efficiency in emerging markets before and after liberalization. Apart from Emerson et al (1970)'s framework, Khantavit et al. (2012) recently applied time-varying smoothed transition autoregressive model (time-varying STAR) to the study of evolving market efficiency in Thailand's stock market.

The approaches used by the abovementioned studies have drawbacks at least in three respects. Firstly, the rolling regression model applied by Lo (2004) is inappropriate because AR coefficient of the model is fixed in each estimation window. Thus, the series of constant coefficients shall not be able to represent the correct dynamic process of degree of efficiency. Secondly, the time-varying AR(p) model suggested by Emerson et al. (1997) imposes random walk specification to AR(p) coefficient. With normally distributed disturbance of the random walk process, the coefficient is allowed to be any value between minus and plus infinity as well as to revert to the high level even if it has a falling trend. The theoretical and empirical evidences suggest otherwise. Once the market becomes more efficient, as indicated by a decreasing in magnitude of AR(p) coefficient, it is less likely to become less efficient in the future. Lastly, the time-varying STAR model applied by Khanthavit et al. (2012) imposes deterministic specification to AR(p) coefficient. It is, therefore, unable to capture stochastic behavior of the coefficient, if it indeed exists.

This study proposes the stochastic AR(p) coefficient model to examine time-varying degree of informational efficiency in Thailand's stock market. The degree of efficiency is measured by tracking the amount of time, as implied by the size of AR(p) coefficient from the regression of market return, the market needs to disseminate information. Besides, this model makes important improvements on what has been applied in the past. Firstly, this stochastic model is more suitable to investigate the time-varying degree of efficiency than the constant parameter model applied by Lo (2004). Secondly, the proposed specification is in a general form, which capable of accommodating the specification of AR(p) coefficient even if it is a random walk, as proposed by Emerson et al. (1997), or deterministic, as proposed by Khanthavit et al. (2012), or even a constant. Finally, and most importantly, the model imposes functional relationship of AR(p) coefficient with time in order to align with the theoretical perspective that the AR(p) coefficient has a negative relationship with time and should move towards a long-run value, not necessarily zero, as time goes to infinity. The key contribution of this study is to propose some improvements on the model as well as to provide an insightful analysis of how Thailand's market efficiency improves over time based on correct specification of the degree of efficiency that the market must have as time passes.

The scope of this study is limited to informational efficiency in weak form. That is, all the information should be reflected in the current market price so that past prices cannot predict future prices and abnormal returns cannot be made consistently. The author uses daily data of logarithm returns on SET Index from April 30th, 1975, the establishment of the Stock Exchange of Thailand (SET), to September 19th, 2014, totally 9,682 observations. Kalman filtering technique is applied to estimate the unobserved stochastic AR(p) coefficient based on the regression of the market returns. The remaining of this paper is organized as follows; Section 2 discusses the time-varying coefficient models applied in the previous literatures and the model proposed by this study. Section 3 briefly discusses the methodology for model estimation.

Section 4 presents data and descriptive statistics. Next, the empirical results are reported and discussed in Section 5. Finally, Section 6 provides conclusions of the study.

2. Time-Varying Coefficient Models for Investigating Evolving Market Efficiency

2.1 The Existing Models

There are at least three specifications of time-varying coefficient models applied in previous studies to investigate changes in the degree of efficiency. The first one is rolling regression applied by Lo (2004), yet this specification assumes that AR coefficient is constant in each estimation window (the reader may refer to Lo (2004) for more details on model specification). The second one is a time-varying AR(p) model proposed by Emerson et al. (1997). The model is expressed as follows:

$$r_t = \beta_{0t} + \sum_{i=1}^{p} \beta_{it} r_{t-i} + \nu_t,\ \nu_t \sim N(0, \sigma_\nu^2) \tag{1}$$

$$\beta_{it} = \beta_{it-1} + \omega_t,\ \omega_t \sim N(0, \sigma_\omega^2) \tag{2}$$

where r_t denotes return at time *t*,

β_{0t} denotes arbitrary time-varying drift parameter,

β_{it} denotes time-varying auto-regression coefficient of i^{th} lag order of returns for $i = 1,\ldots,p$,

ν_t denotes white noise disturbance of return, $\nu_t \sim N(0, \sigma_\nu^2)$, and

ω_t denotes white noise disturbance of auto-regression coefficient, $\omega_t \sim N(0, \sigma_\omega^2)$,

AR coefficient, β_{it}, in this model is stochastic and its behavior is described by random walk process in eq. (2). β_{it} plays a key role in determining the degree of market efficiency because it implies how fast information is reflected in the asset prices. Especially when AR(1) specification is imposed, the coefficient β_{1t} can be applied with half-life (HL) measurement to estimate the numbers of days for information dissemination. Basically, HL is computed by dividing minus logarithm 2 by the logarithm of AR(1) coefficient, i.e. $h = \frac{-\log 2}{\log \beta_1}$. The lower AR(1) coefficient, the faster a half of a particular amount of information is relayed to the market.

Some studies provide arguments on using random walk process to describe dynamic behavior of β_{it}. For example, Rockinger and Urga (2000) suggested that the best predictor of the future value of a parameter is its present value. Hence, the random walk process seemed to be the most appropriate choice. In addition, Li (2003a) mentioned that the random walk process was flexible enough to nest two possibilities of β_{it} to be both constant and time-varying in one specification. He also argued that the coefficient will be forced to change, even if it is constant when assuming other processes rather than random walk.

However, the author argues that random walk specification of AR coefficient is inaccurate. This is mainly due to the assumption of Gaussian white noise disturbance term, ω_t. It is obvious that β_{it} will have no directional trend and is likely to have any value. Without any mechanism to relate β_{it} with time, it is allowed to bounce back to a higher level once it is close to the long-run value. In such a case, it would say that once the market becomes more efficient or less inefficient, the degree of efficiency could be deteriorated at any point of time in the future. Intuitively, when a market has achieved a certain level of efficiency, it shall not turn back to being less efficient.

Apart from random walk, Li (2003b) assumed that β_{it} followed general auto-regression of order one process (GAR(1)). He claimed that the specification of GAR(1) was parsimonious to either constant or time-varying degree of efficiency. Nevertheless, the author considers that this specification still has some flaws. This is because it does not incorporate a mechanism to impose a functional relationship between the coefficient and time, and again, it is allowed a reversion to a higher value.

The third specification is a time-varying STAR model proposed by Khanthavit et al. (2012). The model is expressed as follows;

$$\begin{aligned} r_t = &\{\rho_0^1 + \textstyle\sum_{i=1}^{p} \rho_i^1 r_{t-i}\} \\ &+\{(\rho_0^2 - \rho_0^1) + \textstyle\sum_{i=1}^{p} (\rho_i^2 - \rho_i^1) r_{t-i}\} G(s_t;\theta_1, c_1) \\ &+\ldots+\{(\rho_0^m - \rho_0^{m-1}) + \textstyle\sum_{i=1}^{p} (\rho_i^m - \rho_i^{m-1}) r_{t-i}\} G(s_t;\theta_{m-1}, c_{m-1}) + \varepsilon_t \end{aligned} \tag{3}$$

where r_t denotes return at time t,
ρ_i^k denotes coefficient of return at lag order i^{th} of the k^{th} autoregressive process, for $i = 1,\ldots,p$ and $k = 1,\ldots,m$,
ρ_0^k denotes intercept of the k^{th} autoregressive process,
$G(s_t;\theta_k, c_k)$ denotes the logistic function, where s_t denotes time variable, $\theta_k \geq 0$, and c_k is parameter of the logistic function, and
ε_t denotes random disturbance, $\varepsilon_t \sim N(0,\sigma^2)$

This model explains market returns via a combination of autoregressive processes. They are related by a monotonic function of time, $G(s_t;\theta_k, c_k)$, to accommodate a smooth transition between each AR(p) process. Their study allowed lag order p to be greater than one and applied π-Absorption Time (AT) measurement to measure improvement in the degree of efficiency. AT measures the period of time a market requires to disseminate (1-π%) of information. If π is set at 50%, AT measurement will yield the same result as HL measurement.

This approach facilitates the investigation of time-varying degree of efficiency, especially when returns processes are described by AR(p) where p > 1. The aggregate size of all AR(p) coefficients are taken into consideration via the general impulse response function of AT measurement in order to make an inference on the improvement of degree of efficiency. Nevertheless, specification of autoregressive process of this model is deterministic. Therefore, with a particular set of parameters, market return at each period can be specified with certainty.

2.2 The Proposed Stochastic AR(p) Coefficient Model

This study proposes the stochastic AR(p) coefficient model that improves drawbacks of the existing models discussed above. The model is formulated as follows:

$$r_t = \beta_0 + \sum_{i=1}^{p} \tilde{\beta}_{it} r_{t-i} + \nu_t \tag{4}$$

$$\tilde{\beta}_{it} = \alpha_0^i + \alpha_1^i f(t) + \sum_{j=1}^{m} \sum_{k=j+1}^{m+1} \alpha_k^i \beta_{it-j} + \omega_t^i \tag{5}$$

where r_t denotes logarithm return at time t,

β_0 denotes longterm mean rate of return,

$\tilde{\beta}_{it}$ denotes stochastic AR coefficient of the i^{th} lag order of returns for $i = 1,\ldots,p$,

ν_t denotes white noise disturbance, $\nu_t \sim N(0, \sigma_\nu^2)$,

α_0^i denotes drift term or long-term mean of $\tilde{\beta}_{it}$,

α_1^i denotes time coefficient,

α_k^i denotes coefficient of the j^{th} lag order of $\tilde{\beta}_{it}$ for $j = 1,\ldots,m$,

$f(t)$ denotes a functional relationship of $\tilde{\beta}_{it}$ with time, and

ω_t^i denotes white noise disturbance, $\omega_t^i \sim N(0, \sigma_\omega^2)$.

Similar to the previous studies, $\tilde{\beta}_{it}$ is related to the degree of market efficiency as its magnitude reflects how much time the market takes to relay information. In case AR(1) specification is imposed, such as in Rockinger and Urga (2000) and Arouri et al. (2012), the HL measurement can be applied. And in case lag order p is greater than one, such as in Khanthavit et al. (2012), AT measurement can be applied. Though, this model is opposite to Emerson et al. (1997) in several respects.

Firstly, mean rate of market returns, β_0, in this model is assumed to be constant. The author considers that the assumption of time-varying long term mean rate of return is not only unnecessary, but also inaccurate. It is unreasonable to say that mean rate of return changes over time when economic conditions in the long run remain unchanged. Moreover, if β_0 follows random walk, when the model is restricted so that all AR(p) coefficients, $\tilde{\beta}_{it}$, are dropped to zero, r_t will also collapse to random walk, which is inconsistent with theory of time series model in which returns are stationary.

Secondly, eq. (5) nests the specification of $\tilde{\beta}_{it}$ to be a constant, or random walk process, or auto-regressive process into one. For example, if parameters restrictions are imposed such that α_0^i and α_1^i equal zero, m and α_k^i equals to one, the reduced-form specification will facilitate a random walk process. Again, if α_0^i and α_1^i are restricted to zero, but the absolute value of α_k^i is less than one, the reduced-form will accommodate auto-regressive specification. In addition, if $\alpha_1^i$and α_k^i are simultaneously restricted to zero and σ_{ω}^{2} is very small, the reduced-form specification will facilitate a constant degree of market efficiency.

Thirdly, a functional relationship with time, $f(t)$, is imposed to describe dynamic behavior of $\tilde{\beta}_{it}$. With a particular set of parameter values, $\tilde{\beta}_{it}$ shall be decreased through time, as suggested by the hypothesis of improving efficiency. As the true relationship of $\tilde{\beta}_{it}$ with time is unknown, $f(t)$ in eq. (5) can be a constant, increasing function or decreasing function. This study, however, proposes three functional forms as follows;

$$f_1(t) = t \tag{6}$$

$$f_2(t) = \frac{1}{t} \tag{7}$$

$$f_3(t) = 1 - \frac{1}{1+e^{-\theta(t-\tau)}} \tag{8}$$

The function of time in the eq. (6) linearly relates the stochastic AR(p) coefficient with time variable t. In case degree of efficiency has relationship with time in this manner, parameter α_1^{l} should be significant and negative. On the other hand, eq. (7) relates AR coefficient with time in a non-linear manner. This function accommodates the possibility of rapid improvement in the degree of market efficiency. In case the relationship between degree of efficiency and time can be explained by this non-linear function, parameter α_1^{l} should be significant and positive. In addition, $\tilde{\beta}_{it}$ will dramatically drop to an insignificant value within a few sample periods.

In eq. (8), the author applies the logistic function proposed by Khanthavit et al. (2012) to relate $\tilde{\beta}_{it}$ with time. In opposite to the specification in eq. (7), this specification facilitates either gradual or rapid improvement of degree of efficiency, as indicated by the size of parameter θ that could be estimated from the regression of market returns. From casual observation, like that of the development of communication network trading systems, as well as empirical evidences, such as Li (2003a and 2003b) and Khanthavit et al. (2012), it is more likely that the degree of efficiency slowly improves through time.

Lastly, the specification in eq. (5) is general in that the number of lag order m is not specified. However, this study proposes lag order m equals to one to estimate the model. With this specification, the proposed process for $\tilde{\beta}_{it}$ can be absolutely compared with random walk or GAR(1) specification applied in the previous studies. If the estimated parameters in eq. (5) are statistically significant, they will be the evidences to support the argument that neither random walk nor GAR(1) is correctly specified.

3. Model Estimation

3.1 Kalman Filter

This study will apply Kalman filter technique to estimate the stochastic, unobserved parameter $\tilde{\beta}_{it}$. Briefly, Kalman filter is a recursive procedure for computing the optimal estimator of state, e.g. the unobserved variable, at time *t*, based on the measurement, e.g. the observed information, available up to and including time *t*. This recursive procedure consists of predicting and updating phases. In the predicting phase, the state and prediction error variance are estimated using the observed information from the previous period. Once the new information at time *t* is available, the estimated state is updated. New observation plays an important role to update the state in such the way that the lower the variance of new observation (relative to the variance of prediction error), the greater impact of new observation it has on the estimated state at the next period, and vice versa (the reader can refer to Harvey (1991) for more details).

To apply Kalman filter, a time series model is put in a state space form, consisting of measurement equation and transition equation. The stochastic AR(p) coefficient model in equation (4) and (5) can be put in state space form as follows:

$$r_t = \boldsymbol{R_t B_t} + \beta_0 + v_t \tag{9}$$
$$\boldsymbol{B_t} = \boldsymbol{A B_{t-1}} + \boldsymbol{D_t} + \boldsymbol{\omega_t} \tag{10}$$

where $\boldsymbol{R_t}$ denotes observation vector, e.g. $[r_{t-1} \quad \cdots \quad r_{t-p}]$

$\boldsymbol{B_t}$ denotes state vector or vector of stochastic AR(p) coefficient, e.g. $\left[\tilde{\beta}_{1t} \quad \cdots \quad \tilde{\beta}_{pt}\right]'$

$\boldsymbol{A}$ denotes transition matrix. This is a diagonal matrix which contains α_k^i on its main diagonal, and

$\boldsymbol{D_t}$ denotes a vector of drift term, α_0^i, and function of time, $\alpha_1^i f(t)$.

The estimation of unobserved state vector $\boldsymbol{B_t} = \left[\tilde{\beta}_{1t} \quad \cdots \quad \tilde{\beta}_{pt}\right]'$ depends on a set of unknown parameters of the model, $\psi = \{\beta_0, \alpha_0^i, \alpha_1^i, \alpha_k^i, \theta, \tau, \sigma_v^2, \sigma_\omega^2\}$. This calls for a maximum likelihood estimation to estimate these parameters. With assumptions of normally distributed error terms, and independence between the error terms and initial state vector, the likelihood function can be written in prediction error decomposition form as follows:

$$Log\ L = -\frac{1}{2} T log 2\pi - \frac{1}{2}\sum_{t=1}^{T} log|F_t| - \frac{1}{2}\sum_{t=1}^{T} v_t' F_t^{-1} v_t \tag{11}$$

Denote v_t as prediction error and denote F_t as prediction error covariance. Maximum likelihood estimation finds the value of unknown parameters in ψ so that log likelihood function in eq. (11) is maximized.

3.2 Lag Order Identification

As the number of lag order p of the stochastic AR(p) coefficient model is unknown, it is crucial to specify lag order properly since it has important implications on the correctness of model specification as well as the interpretation of the degree of efficiency. This study applies information criteria to identify the appropriate order of p in eq. (4) because it provides a measurement of goodness-of-fit of the statistical model given a set of observations. Two particular information criteria tests are going to be estimated; Akike information criterion (AIC) and Schwatz Bayesian criterion (SBIC). These tests are also applied in Khanthavit et al. (2012) to identify lag order of time-varying STAR model.

Based on the auto-regressive process with constant parameter, AIC and SBIC can be calculated as follows:

$$AIC = T \times ln(\textstyle\sum_{t=1}^{T} v_t^2) + 2(p+1) \tag{12}$$
$$SBIC = T \times \ln(\textstyle\sum_{t=1}^{T} v_t^2) + (p+1) \times ln(T) \tag{13}$$

where T denotes total number of observations and v_t denotes disturbance term of the auto-regressive process and p is numbers of lag orders. The model with the most appropriate lag order is the one that gives the lowest AIC or SBIC. In case estimations of AIC and SBIC lead to an inconsistent conclusion, the higher order of lag term will be chosen in order to be more conservative and avoidance of model misspecification. It should be noted that these tests are preliminary because the AR(p) coefficients are assumed to be constant under testing procedures, whereas they are stochastic in the proposed model.

3.3 Model Comparison

This study proposes three functional forms in eqs. (6) to (8) to relate the degree of market efficiency with time. Though, these three specifications of the stochastic AR(p) coefficient model are nested with the constant and random walk specifications, neither of them are nested to each other. Thus, traditional tests for parameter restriction and model comparison cannot be performed. This calls for an alternative statistical test to compare the proposed specifications with one another. In this study, the author will follow the test for model comparison suggested by Voung (1989) because it is able to provide directional information for choosing between non-nested models.

Briefly, Voung (1989)'s test for model comparison is based on Kullback-Leibler Information Criterion (KLIC), which measures the distance between the true unknown distribution and hypothesized model. The test can be applied to any given pair of competing models, whether or not they are nested, non-nested, or overlapping, and both, only one or neither of them are correctly specified. KLIC is computed from the expected value of the difference between log likelihood values of the true unknown model and the competing model. Given this expression, KLIC will always be positive. However, when comparing KLIC of two competing models; namely the null model and the alternative model, by subtracting one from another, it can be either positive or negative. Therefore, in order to make conclusion, Voung (1989) suggested the following test statistic:

$$V = \frac{\sqrt{n}\left(\frac{1}{n}\sum_{i=1}^{n} m_i\right)}{\sqrt{\frac{1}{n}\sum_{i=1}^{n}(m_i-\bar{m})^2}} = \sqrt{n}(\bar{m}/s_m), \quad m_i = \ln L_{i,0} - Ln\ L_{i,1} \tag{14}$$

where $\ln L_{i,0}$ denotes log likelihood value at the i^{th} observation, for $i = 1,\dots, n$, of the null model and $\ln L_{i,1}$ denotes the same for the alternative model. V statistic is compared with critical value at a conventional significant level from a standard normal distribution. If V is greater than the positive critical value, we reject the null hypothesis that both models are equivalent in favor of the null model. On the other hand, if V is lower than the negative critical value, we reject the null hypothesis that both models are equivalent in favor of the alternative model. If the absolute value of V is between minus and plus critical value, neither model is distinguished. In this study, the test statistic V will be compared with critical values at 99%, 95% and 90% for hypothesis testing.

4. Data and Descriptive Statistics

This study employs the daily closing price index of the Stock Exchange of Thailand (SET Index) obtained from the SETSMART database to represent the overall market returns. In fact, the Exchange provides SET Total Return Index (SET TRI) which can be used as a proper measurement of market performance as it is adjusted for changes in number of stocks resulting from corporate actions, e.g. right issuance, public offering, exercise of warrants, etc. However, the author proposes to use the SET Index to investigate evolving efficiency in Thailand's stock market based on the following two reasons. Firstly, the SET TRI series is available since January 2nd, 2002, while the SET Index series is available since April 30th, 1975, (the opening of the Exchange). The longer series of data, the more insightful it should provide on the changing degree of efficiency with respect to evolution of the stock market. Secondly, the SET Index and SET TRI are highly correlated, as evidenced by their correlation coefficient of 0.9906[1]. Therefore, estimated results using data from SET Index shall not be biased.

The samples cover the first official trading day from April 30th, 1975 to September 19th, 2014. Then, logarithm returns on SET Index is computed using $\ln(\frac{p_t}{p_{t-1}})$, where p_t denotes the daily closing index at time t. This logarithm returns, in total of 9,681 observations, is used for model estimation. The descriptive statistics of logarithm returns are summarized in Table 1.

[1] Sample period to estimate correlation is from January 2nd, 2002 to September 19th, 2014.

Table 1
Summary of Descriptive Statistics

Statistics	Mean	Standard deviation	Skewness	Kurtosis	JB (p-value)
SET Index	0.0003	0.0146	-0.1066	11.7664	1,547.60 (0.0000)

Table 2
Identification of Optimal Number of Lags Using AIC and SBIC

Numbers of lags	1	2	3	4	5
AIC	-54575.191	-54572.982	-54566.080	-54560.779	-54553.314
SBIC	-54560.835	-54551.448	-54537.368	-54524.891	-54510.248

Following the information reported in Table 1, logarithm returns is characterized as negative skewness and leptokurtosis, with a skewness of -0.10664 and kurtosis of 11.76642. These evidences of non-normality are affirmed by the Jarque-Bera (JB) normality test statistic, showing that the null hypothesis of normally distributed return series is rejected with 99% confidence interval. However, it should be noted that the application of Kalman filter shall not be affected by the non-normality of returns series. This is because Kalman filter is based on orthogonal projection theory so the classical assumption of Gaussian distribution is not required.

The results of AIC and SBIC tests are demonstrated in Table 2. They indicate that the model with only one lag order has the minimum AIC and SBIC. Although the results of these tests are derived from the estimation of classical time-invariant coefficient AR(p) model, the author proposes that it is applicable to the stochastic AR(p) coefficient model because the constant AR coefficient shall be considered as the average value of all stochastic AR(p) coefficients. Moreover, previous researchers such as Rockinger and Urga (2000), Arouri et al. (2012) also applied time-varying AR(1) coefficient model to describe return process in their studies. Therefore, this study specifies the stochastic AR(1) coefficient model to investigate time-varying degree of efficiency in Thailand's stock market.

5. Empirical Evidences

5.1 Estimation Results of the Stochastic AR(1) Coefficient Model

According to the indicative results from AIC and SBIC tests, the stochastic AR(1) coefficient model can be expressed as follows;

$$r_t = \beta_0 + \tilde{\beta}_{1t} r_{t-1} + \nu_t \tag{15}$$

$$\tilde{\beta}_{1t} = \alpha_0^1 + \alpha_1^1 f(t) + \alpha_2^1 \beta_{1t-1} + \omega_t \tag{16}$$

The proposed functions of time in eqs. (6) to (8) are substituted in $f(t)$ in eq. (16). Next, $\tilde{\beta}_{1t}$ is the smoothed estimate from the Kalman filter and other unknown parameters of the model are then derived from maximum likelihood estimation. Besides, when restriction is imposed such that α_0^l and α_1^l equal to zero, and α_2^l equals to one, the restricted model represents random walk specification applied in the previous studies. For purpose of comparison, this study estimates both restricted and unrestricted forms of the stochastic AR(1) coefficient model. The results are summarized in the following table.

Table 3
Estimation Results of Random Walk and Stochastic AR(1) Coefficient Model

Panel B				
LRT	-	1,854.7193***	1,815.0010***	1,856.6937***
df		3	3	5

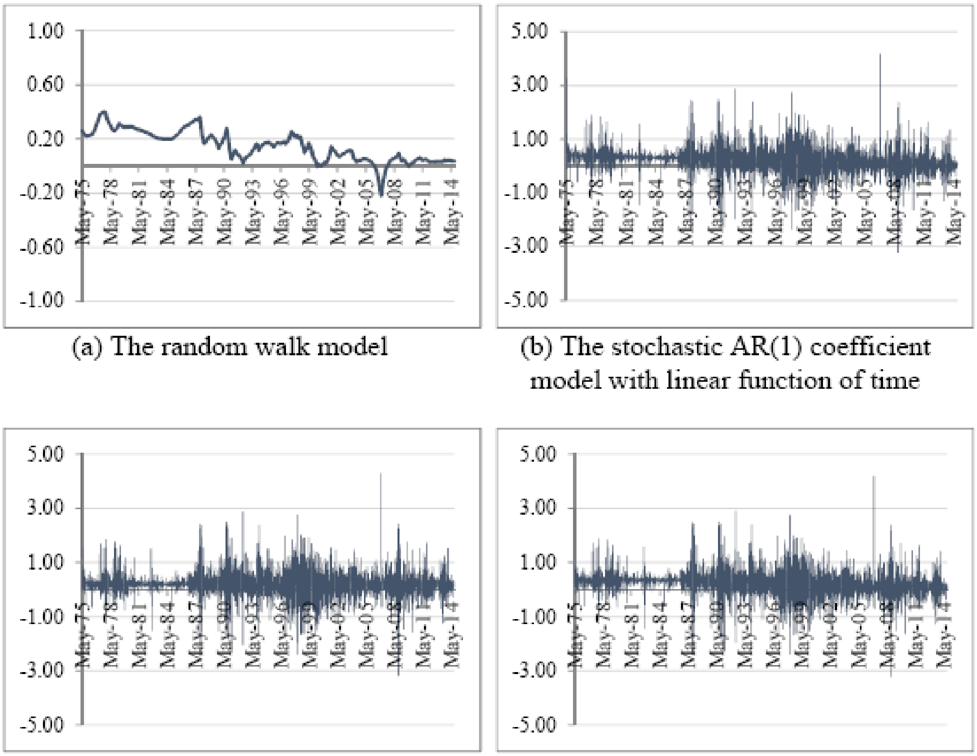
Note. Figure in parentless is t-statistic. *, ** and *** denote the estimated parameters are significant at 10%, 5% and 1% level, respectively. LRT denotes likelihood ratio test in which the random walk model is the restricted model and the stochastic AR(1) coefficient model is the unrestricted model. And df = $df_U - df_R$; where df_U and df_R represent numbers of free parameters of the unrestricted and restricted models, respectively.

Table 3 is separated into 2 Panels; Panel A presents the estimated coefficients together with the t-statistics, while Panel B presents likelihood ratio test (LRT) statistics. Several messages are presented in Panel A. Considering parameters in eq. (16); the results show that drift parameters, $\hat{\alpha}_0^1$, from two models are statistically significant. The estimated drift term in the model with linear function of time is equal to 0.3985, while it is 0.1837 in the model with inverse function of time. These figures represent a long-term mean value of the stochastic AR(1) coefficients, $\hat{\beta}_{1t}$. Suppose the dynamic process of $\hat{\beta}_{1t}$ is truly described by these two models, $\hat{\alpha}_0^1$ of each model will reflect the average number of day in which the information is disseminated to the stock market. However, this expression is subject to the test for model comparison, which will be discussed later in subsequent section.

Besides, coefficients of trend element, $\hat{\alpha}_1^1$, are statistically significantly different from zero in all three specifications. These evidences are very important because they indicate that the degree of market efficiency has a statistical relationship with time, which is consistent with the hypothesis of this study. The sign of $\hat{\alpha}_1^1$ is negative in the model with the linear function of time, while it is positive in the model with inverse and logistic functions of time. These results indicate that, in the long run, $\hat{\beta}_{1t}$ will behave in at least three manners; linearly decreasing, abruptly decreasing within a very short period of time, or S-shape decreasing. At the same time, they also imply how degree of efficiency in the stock market improves. In addition, parameter $\hat{\theta}$ in the model with logistic function of time is also important to explain how fast the degree of efficiency improves. A big positive value of $\hat{\theta}$ suggests a rapid improvement, while a small positive value suggests otherwise. In this study, $\hat{\theta}$ is equal to 9.5281 and is significantly different from zero. Nevertheless, its effect on $\hat{\beta}_{1t}$ is deprived by a small value of $\hat{\alpha}_1^1$, which equals to 0.2813. As a result, the magnitude of $\hat{\beta}_{1t}$ in the model with logistic function of time will gradually decrease throughout the sample period.

The estimated volatility $\hat{\sigma}_{\omega}$ is large vis-à-vis $\hat{\sigma}_{v}$ and is statistically significant. This indicates that $\hat{\beta}_{1t}$ is not constant, but rather time-varying and has a relationship with time as mentioned earlier. Nevertheless, except in the model with inverse function of time, this study finds no evidence of relationship between $\hat{\beta}_{1t}$ and its one-period lagged value. Lastly, LRT statistics are highly significant at 1% level, with the values of 1,854.7193, 1,815.0010, and 1,856.6937 for the stochastic AR(1) coefficient model with linear, inverse, and logistic function of time, respectively. The results suggest that the stochastic AR(1) coefficient model is significantly better than random walk model in terms of goodness-of-fit. The drift and trend terms are, therefore, meaningful to be incorporated into the model to explain the behavior of degree of market efficiency. Following these evidences, it shall be inferred that neither random walk nor GAR(1) specification applied in the previous studies is correctly specified.

Figure 1
The smoothed estimate of $\hat{\beta}_{1t}$



(a) The random walk model

(b) The stochastic AR(1) coefficient model with linear function of time

(c) The stochastic AR(1) coefficient model with inverse function of time

(d) The stochastic AR(1) coefficient model with logistic function of time

From Figures 1 (a) to (d), it can be seen that the smoothed estimate of $\hat{\beta}_{1t}$ from random walk model has a decreasing trend, while such a trend is not visually presented in the smoothed estimate of $\hat{\beta}_{1t}$ from the stochastic AR(1) coefficient model. Also, it is noticed that the absolute values of $\hat{\beta}_{1t}$ from random walk model are less than one, but some of $\hat{\beta}_{1t}$ from the stochastic AR(1) coefficient model are not. However, the arguments for these evidences can be explained in two folds. Firstly, coefficient $\hat{\alpha}_1^1$ are strongly statistically significant, which in turn indicate that values of $\hat{\beta}_{1t}$ from the stochastic AR(1) coefficient model are implicitly diminishing in the long-run.. Secondly and most importantly, the fluctuation pattern of $\hat{\beta}_{1t}$ is due to a Gaussian white noise property of the disturbance. However, the numbers of times that the absolute values of $\hat{\beta}_{1t}$ are greater than one is, on average, 2.78% of total observations. This is considerably small and shall be ignored.

Previously, Arouri et al. (2012) studied time-varying degree of efficiency in Thailand's stock market using a random walk model. Their results differ from the results of the stochastic AR(1) coefficient model in two respects. Firstly, Arouri et al. (2012) demonstrated that $\hat{\beta}_{1t}$ were very stable, while this study finds that $\hat{\beta}_{1t}$ are volatile, but decreasing with time. This is possibly due to the less frequency of data and shorter sampling period since Arouri et al. (2012) used monthly returns from January 1976 to March 2000. The different in model specification is also crucial. As discussed earlier, the random walk model is inferior to stochastic AR(1) coefficient model, hence, $\hat{\beta}_{1t}$ from the latter model shall be more accurate and well described the true process of time-varying degree of market efficiency in Thailand. Secondly, Arouri et al. (2012) asserted that Thailand's stock market was weak-form efficient, but did not indicate how much the degree of efficiency improved. In contrast, this study will demonstrate this improvement using the number of days for information dissemination in the stock market. The details will be discussed later.

5.2 Models Comparison

Table 4 below presents V statistics computed from each pair of models. Recall that a large negative value implies that the alternative model is preferred to the null model, while a large positive value implies otherwise. Comparing between the null random walk model and the alternative stochastic AR(1) coefficient model with three forms of function of time, the results show that all three specifications of the alternative stochastic AR(1) coefficient modes are favorable to the random walk model in describing the dynamic behavior of the degree of market efficiency. This is consistent to likelihood ratio test in Table 3, which indicates that the stochastic AR(1) coefficient model is better fitted to the data than random walk model.

inverse function of time	-10.1283***	3.3277***		
logistic function of time	-10.3673***	-0.6272	-3.2556***	

Note. *, ** and *** denote the estimated parameter is significant at 10%, 5% and 1% level.

When comparing the three specification of the stochastic AR(1) coefficient models with one another, the results show that the model with linear function of time is superior to that with inverse function of time, indicated by a significant and positive V statistic of 3.3277. In addition, the model with logistic function of time is also superior to that with inverse function of time, indicated by significant and negative V statistic of -3.2556. Finally, when comparing between the models with linear and logistic functions of time, the sign of V statistic suggests that the model with logistic function of time would be more superior, however, the value of the test statistic, e.g. -0.6272, is not statistically significant. As a result, it can only be inferred that neither of the models with linear nor logistic functions of time are distinguished.

This result is understandable. With particular set of parameters, the logistic function is able to accommodate the linear function of time, especially when the magnitude of $\hat{\alpha}_1^1$ is small as observed in this study. Accordingly, these two specifications are almost identical in terms of describing dynamic behavior of degree of market efficiency. Nevertheless, it should be noted that the model with linear specification has a drawback. When time increases to infinity, $\hat{\beta}_{1t}$ will possibly be a huge negative value. In such a case, it implies that once the degree of efficiency improves, it can deteriorate in the future because the higher value of $\hat{\beta}_{1t}$, the greater time to disseminate information to the market. Opposite to the model with logistic function of time, the magnitude of $\hat{\beta}_{1t}$ estimated from this specification will tend to decrease continuously in the long run.

Furthermore, the model with the logistic function of time is more intuitive than the model with the linear function of time when it is applied to explain time-varying degree of market efficiency. In this regard, it suggests that degree of market efficiency gradually and continuously improves. At the opening of the stock market, degree of efficiency is low as indicated by the big magnitude of $\hat{\beta}_{1t}$. Thereafter, the developments of the stock market, such as improvements in the trading system, enforcement of disclosure rules, establishment of derivatives exchanges, etc., will lead to improvement in degree of informational efficiency. Rather than abruptly happens, this process arises moderately because it takes time for market participants to accumulate experience, learn, and adapt themselves. This process is reflected in the characteristic of the slowly decreasing trend of $\hat{\beta}_{1t}$ proposed by this model. Once the market participants gain more knowledge, combined with better price discovery mechanisms, the degree of market efficiency will then be improved.

Consequently, this study would suggest that the stochastic AR(1) coefficient model with logistic function of time is the most appropriate model specification to explain the dynamic behavior of degree of efficiency in Thailand's stock market.

5.3 Numbers of Days for Information Dissemination

The magnitude of AR(p) coefficient can be related to the degree of market efficiency as it implies how much time the market takes to disseminate information. In this study, results from the statistical test suggest that AR(1) specification is appropriate, therefore, HL measurement can be applied to investigate how much time, in numbers of days, information is disseminated to the market. Based on discussion above, the author will employ the smoothed estimate of $\hat{\beta}_{1t}$ from the stochastic AR(1) coefficient model with logistic function of time. In order to illustrate whether the numbers of days for information dissemination decrease, the calculation will be done at three points of time.

The first point of time is when $t = 1$, which is the opening of the stock market. The second point of time is when $t = \hat{\tau}$, and the last point of time is when $t = 9{,}682$, which is the latest sample of this study. As for the second point of time, the author proposes using $t = \hat{\tau}$ instead of using t equal to half of total observations because $\hat{\tau}$ provides an indicative point of time where trend element of degree of efficiency decreases by a half. Therefore, the estimation of half-life measure at this point of time is more informative. From Table 3, the point of time corresponds to $\hat{t}$ = 0.5245 is at the 5079th observation (variable t in this study is scaled by dividing by total number of observation), or approximately 20 years after the opening of the stock market.

Previously, the studies that interested in measuring units of time to dissipate a piece of information throughout the market generally use a half of information as a benchmark, so called HL measurement. In this study, being enthusiastic to see the different results if the other magnitudes of information are applied, the author develops the measurements to gauge the unit of time in order to spread out 25%, 50% and 75% of information. The empirical results are tabulated in the Table 5 below.

Table 5
Numbers of Days for Information Dissemination

Time	**Numbers of days for the magnitudes of information are disseminated to the market**		
	One-fourth	**Half**	**Three-fourth**
$t = 1$	0.3574	0.8612	1.7223
$t = 5{,}079$	0.1100	0.2651	0.5301
$t = 9{,}682$	0.1035	0.2494	0.4988

The results illustrated above support that degree of informational efficiency in Thailand's stock market has been improved as indicated by the decreasing numbers of days that the market utilizes to relay either one-fourth, a half, or three-fourth of information. Particularly, the numbers of days to spread out three-fourth of information decrease from 1.7223 days at the opening of market to 0.5301 day and 0.4988 day at the points of time t = 5,079 and t = 9,682, respectively. Considering the utilization of time to dissipate a half of information, it is interesting that the market employs less than one day at all three points of time. At t = 1, the market uses 0.86112 day to disseminate a half of information. Then, the period of time declines to 0.2651 day and 0.2492 day at t = 5,079 and t = 9,682, respectively. Moreover, the dissemination speed is also improving. For example, at t = 1, the market requires additional 0.8162 day in order to relay further information from a half to three-fourth (1.7223 – 0.8612), while it needs additional 0.2494 day at t = 9,682 (0.4988 - 0.2494).

However, numbers of days for information dissemination at the latest observation are not much different from those at the second point of time, i.e. at t = 5,079. This could be explained that, for the given data, the stock market has been developed until it has reached the long run level of market efficiency to so that the number of day for information dissemination at the second and the latest points of time is very close to each other.

6. Conclusions

Efficient market hypothesis has been studied and tested in a numbers of literatures. This hypothesis is important in economic and financial theories since it is a foundation in developing asset pricing models, investment strategies, as well as risk assessment. Recently, research framework on this topic focuses on investigating the time-varying degree of market efficiency, particularly on informational efficiency of an emerging financial market.

This study proposes the stochastic AR(1) coefficient model and imposes relationship of degree of efficiency with time in order to correct the drawback of the model specification applied in the previous studies. Based on the sample from daily returns of the SET index from April 30th, 1975 to September 19th, 2014, this study finds that the degree of market efficiency has a statistically significant relationship with time, at least in three functional forms. This evidence leads to the conclusion that both the random walk and GAR(1) models are mis-specified. Further statistical test also shows that the stochastic AR(1) model with linear and logistic functions of time are the best two models in describing the dynamic behavior of degree of market efficiency in Thailand. Finally, the results of HL measurement indicate that number of day for information dissemination decreases through time.

This study not only is an evidence of improving degree of market efficiency, but also contributes to research methodology of the study in this topic. For one who is interested in time-varying degree of market efficiency, further study can be performed to expand the edge of knowledge on this field. One of the interesting results from this study is that behavior of degree of market efficiency in Thailand's stock market is highly volatile. It would be interesting to find out the determinants to explain such dynamic behavior.

We examine whether natural disaster losses vary under the tenure of a government with a different ideology. Using panel data for 123 countries over the period of 1975-2007, we find that right-wing governments experience fewer natural disaster losses, especially in non-OECD countries.

Keywords: Government ideology; Natural disasters

JEL Classification: P48; Q54

1. Introduction

Natural disasters are significantly associated with a destruction of physical and human capital in a country. The literature documents however that these natural disaster losses differ greatly across governments. For example, Kahn (2005) finds that countries with higher income, democratic institutions and stronger governments experience fewer natural disaster deaths. Toya and Skidmore (2007) find that nations with higher measures of development suffer less natural disaster losses.

In this paper, we contribute to the literature by examining the role of government ideology in mitigating the impacts of natural disasters. For example, it is possible that left-wing governments are more inclined to implement natural disaster prevention measures because these reforms usually imply that the government is increasing control in the economy. Keefer et al. (2012) argue that government regulation in the economy is critically important to mitigate the negative effects of natural disasters: governments who enforce natural disaster prevention standards experience fewer natural disaster losses.

In addition, it is also probable that right-wing governments may experience fewer consequences of natural disasters. Toya and Skidmore (2007) indicate that countries with higher growth rates allocate more resources to natural disaster prevention standards to lower natural disaster losses. Given that right-wing governments may associated with higher growth rates (Bjørnskov, 2005; 2008), they are more likely to implement natural disaster prevention measures to lower the negative effects of natural disasters. However, it against the partisan theory, advanced by Hibbs (1977), assumes that politicians are partisan, acting in accordance with their ideology. It typically presumes that the left wing (Democrats) pay more attention to promoting expansionary policies with have put more emphasis on increasing income and reducing unemployment.

In this paper we take a first step in that direction, examining the relationship between the impacts of natural disasters and the ideology of political party in huge samples countries. Despite theoretical salience and political relevance, we know of no previous attempt of this sort in historic agenda. More specifically, we test whether natural disaster losses vary under the tenure of a government with a different ideology employing panel data for 123 countries over the period of 1975-2007. Using two measures of government ideology, we find that right-wing governments experience fewer natural disaster losses, especially in non-OECD countries.

The remainder of this paper is organized as follows. In section 2, we describe the data and the model. Section 3 presents the empirical results, while the final section summarizes the major findings.

2. Data and Model

We collect annual data for a panel of 123 countries over the 1975-2007 period. The list of countries is reported in Table 1. We use three dependent variables to effective quantify all natural disaster losses. Our first dependent variable, death, represents the total number of "persons confirmed as dead and persons missing and presumed dead" caused by natural disaster. Our second measure of dependent variable, affected, is defined as the total number of "displaced or evacuated people" and "people requiring immediate assistance" caused by natural disaster. Our last measure of dependent variable, damages, includes all estimated economic damages (in US$) as a percentage of GDP caused by natural disaster. All this data is taken from EM-DAT (2011).

Our government ideology data comes from Beck et al. (2001) Database of Political Institutions. To ensure robustness, we use two measures of government ideology. On the first measure of government ideology (ideology1), we follow the general approach in Bjørnskov (2005) and code right-wing 1, centrist 0, and left-wing -1. On the second measure of government ideology (ideology2), we follow the methodology in Bjørnskov (2008), and assign right-wing 1, centrist 0, and left-wing -1, and weight single party ideologies with their proportion of seats in the parliament.

In choosing our control variables, we follow Toya and Skidmore (2007) and employ real per capita income (gdp), domestic credit/GDP (bank), (exports plus imports)/GDP (trade), total years of educational achievement aged 15 and over (education), government consumption/GDP (gov), where all variables are obtained from the World Bank (2011). We expect these measures of development to reduce natural disaster losses because nations with higher level of development allocate more resources to implementing natural disaster prevention standards (Toya and Skidmore, 2007).

We also follow Kahn (2005) and take into account the total number of natural disasters (disaster) that took place, drawn from EM-DAT (2011); and population size (population) based from World Bank (2011). Finally, we consider the effect of democracy (1 if the government is democratic, 0 otherwise) extracted from Cheibub et al. (2010). This is because democracies take strong actions to adequately provide public resources following a natural disaster and implement natural disaster prevention measures (Kahn, 2005; Keefer et al., 2012). All variables are logged, except for the dummy variable democracy. The descriptive statistics for all the variables are reported in Table 2.

In summary, our baseline model is expressed as follows:

$$y_{kit} = f\left(\text{ideology}_{it}, x_{it}, \varepsilon_{it}\right) \qquad (1)$$

where ykit is the dependent variable that represents the total number of death, affected, or damages caused by natural disaster k that took place in country i during year t. The variable ideology includes two measures of government ideology variables (ideology1 or ideology2); corresponds to a vector of control variables as discussed above; is the disturbance term. We estimate three set of regressions since we have three alternative dependent variables. Given the nonnegative count and discrete structure of the dependent variables death and affected, we estimate a Poisson regression model. For the dependent variable damages, we estimate a system GMM model to make use of the time series variation in the data and to account for possible endogeneity in our model.

3. Results

We provide the Poisson regression estimates for the dependent variables death and affected in columns 1-4 of Table 1. As can be seen, the variables ideology1 and ideology2 are negative and statistically significant at the 5% level, suggesting that right-wing governments experience fewer natural disaster deaths. We also find that less people are affected from natural disasters under the tenure of a right-wing government. The size is larger with the ideology2 since party's proportion of seats in the parliament is considered.

Next, it is important to account for possible heterogeneity in our sample. For example, Cohen and Werker (2008) argue that developing countries "may choose to invest very low amounts in disaster prevention (p. 805)." We therefore re-estimate the Poisson regression model differentiating between 30 OECD countries and 93 non-OECD countries. In columns 5-8 of Table 1 we include only non-OECD countries, whereas in columns 9-12 the sample is restricted to OECD countries.

As before, we find that right-wing governments have lower natural disaster losses (death and affected) in non-OECD countries. While the results indicate that less people are affected from natural disasters under the tenure of a right-wing government, we find no evidence that government ideology matters in protecting the general public from natural disaster death in OECD countries.

Further, we present the GMM regression estimates for the dependent variable damages in Table 2. The variables ideology1 and ideology2 are negative and statistically significant at the 5% level, indicating that right-wing government experience lower economic damages caused by natural disasters. We also find that right-wing governments suffer less natural disaster damages in non-OECD countries. However, this effect is statistically insignificant at conventional levels in OECD countries. In summary, we find strong evidence that right-wing governments experience fewer natural disaster losses, particularly in non-OECD countries.

We provide the results of Sargan and Arellano-Bond tests at the bottom of Table 2. The Sargan test of over-identification restrictions tests the validity of the instruments. As can be seen, the Sargan test cannot reject the null hypothesis (p-value > 0.10) in all equations, suggesting that the instrumental variables are valid in the estimation. Next, the Arellano-Bond test of second-order autocorrelation tests the estimated residuals does not produce second-order serial correlation. The Arellano-Bond test cannot reject the null hypothesis (p-value > 0.10) in all equations, indicating that the estimated residuals do not produce second-order serial correlation, and, thus, the estimators are consistent in all specifications.

Turning to control variables, most results are broadly in line with those of Kahn (2005), and Toya and Skidmore (2007). Countries with higher national income, government consumption and educational achievement experience fewer deaths and less people are affected but suffer more economic damages from natural disasters. Perhaps not surprisingly, nations with larger population and higher natural disasters endure more natural disaster losses, while trade openness reduces the negative consequences of natural disasters. Finally, it appears that the level of democracy and more developed financial system have a limited effect on mitigating the consequences of natural disasters.

4. Conclusion

We examine the effect of government ideology on natural disaster losses for 123 countries over the 1975-2007 period. Using two measures of government ideology, we find that right-wing governments experience fewer natural disaster losses, especially in non-OECD countries. We emphasize that government ideology matters in mitigating the consequences of natural disasters. We introduce this fundamental evidence for further research.

This study examines the effect of asset diversification on bank performance (profitability, cost efficiency, and asset quality). Given the uniqueness and rapid growth of Islamic banking, whether and how the prevailing diversification in conventional banks influences the performance of Islamic banks that have become increasingly diversified is necessary to be examined. A review of banks in Indonesia, Malaysia, and Pakistan from 2006 to 2012 indicates that diversification generally has a negative effect on the performance of conventional banks, whereas a minimal effect on that of Islamic banks. Considering bank size, diversification is found to positively affect the profitability of large banks (greater than bottom 25%), and this positive effect is more pronounced among Islamic banks. Moreover, diversification has a positive effect on the cost efficiency of large conventional banks (top 25%), whereas a negative and no effect on the cost efficiency of small and medium banks, respectively. Furthermore, diversification has a positive effect on asset quality of large Islamic banks (top 25%). By contrast, diversification has a negative effect on asset quality of conventional banks. However, this negative effect is weak for large conventional banks (top 25%).

Keywords: diversification; bank performance; Islamic banking; panel data.

1. Introduction

Existing literature has extensively explored the relationship between diversification and bank performance. The ability of Islamic banks to survive the recent global financial crisis has been recognized as well. However, no research to date has examined the effect of diversification from traditional (loans) to non-traditional assets, which is widely considered as value-reducing and conducive to the recent crisis, on profitability, cost efficiency, and asset quality of Islamic banks in Asian countries with a dual banking system. To address these research gaps, this study is conducted.

Muslims constitute approximately 1.6 billion or 23% of the global population (DeSilver 2013). With the Muslim population ranking as the second largest religious group and continually growing, financial services that are acceptable with Islam are increasing in demand, resulting in the rapid growth of Islamic banking. The emergence of Islamic banking also represents the growing population of wealthy Muslims. Most Islamic countries in the Middle East, for example, have become an important commercial and distribution center and the hub of many countries because of their abundance in oil. Given the growing world demand for oil, the revenue from oil sales has been a main income source for Middle East. With their accumulation of money from oil trading, rich Muslims demand financial services to meet their religious requirements to help manage and invest their oil revenues. In fact, with the ongoing trend of global financial market integration, Islamic banking is no longer limited to countries that have a large population of Muslims. Islamic banking has become popular outside the Muslim world, which is best exemplified by the recent widespread issuance of Sukuk (i.e., an Islamic financial certificate equivalent to the Western bond) in non-Islamic countries (The Economist 2014). Islamic banking or finance is not only expanding rapidly, but is also becoming globalized.

Islamic banks operate based on the Islamic law that has highly religious regulations, emphasizes on fair trade and non-payment of interest, prohibits gambling, and does not allow moral value speculations. The performance of Islamic banks or banking systems remains to be seen because Islamic banking has a relatively short history compared with that of conventional banking (Masruki et al., 2011). Nevertheless, the capability of Islamic banks to adapt with the recent global financial crisis prompts the examination of their unique features that allow them to achieve financial stability regardless of the crisis. In addition to compliance of the Islamic law, Islamic banks, for example, are generally less diversified than conventional banks. Therefore, Islamic banks are immune to the recent crisis that is triggered by over-diversification prevailing in conventional banks.

Given the emergence of Islamic banking, examining whether and how diversification, which is the product of bank deregulation and is long prevailing in conventional banks, affects the performance of Islamic banks that are becoming increasingly diversified is essential. This study examines the effect of asset diversification on the performance (profitability, cost efficiency, and asset quality) of Islamic banks in three Asian countries that practice dual banking systems. Conventional banks in the same countries are also included for comparison. The ultimate goal is to provide policy implications for Islamic banks that are becoming globalized and facing increasingly high competition against conventional banks with the so-called Islamic windows.

Existing literature mostly concludes that diversification causes a decrease in value because the benefit from the accompanied economy of scope is outweighed by the loss brought about by the accompanied diseconomies and increased risks associated with intensified agency problems. Given that conventional banks are generally more diversified than Islamic banks, such that the marginal cost of diversification likely outweighs the marginal benefit, this study initially hypothesizes that diversification negatively affects bank performance of conventional banks as opposed to that of Islamic banks. In addition, Islamic banks are generally less diversified, thus they have a higher potential to reap risk diversification benefits than conventional banks. With the compliance of Islamic banks with the Sharia law that should mitigate the negative effect of diversification on bank performance, this study posits that any positive effect of diversification on bank performance is stronger for Islamic banks than for conventional banks. Furthermore, given that large banks have better capacity and higher capability than small banks to engage in diversification, any positive effect of diversification on bank performance is assumed in this study among large banks and not among small banks. This phenomenon is more pronounced for Islamic banks than conventional banks because of the low level of diversification of Islamic banks compared with that of conventional banks.

Using data from 1,233 banks in three Islamic countries (Indonesia, Malaysia, and Pakistan) from 2006 to 2012 as the study sample, this study shows that diversification is a determinant of bank performance. Results based on the entire sample specifically indicate that diversification generally has a negative effect on the performance of conventional banks, whereas minimal effect on Islamic banks. However, with the consideration of bank size, diversification has a positive effect on profitability of large banks (outside bottom 25% range), and this positive effect is more pronounced among Islamic banks. In addition, diversification does not add to the cost efficiency of both Islamic and conventional banks, whether they are small or medium-sized banks. However, diversification has a positive effect on the cost efficiency of large conventional banks (in top 25%) only. Furthermore, diversification has a positive effect on the asset quality of large Islamic banks (top 25%). By contrast, diversification generally has a negative effect on the asset quality of conventional banks, but this negative effect is weaker for large conventional banks (top 25%). Overall, the results suggest that diversification remains valuable, especially for Islamic banks. Moreover, gains are obtained and fewer losses are incurred from diversification, if the bank, regardless of bank type, is a large bank. Hence, the results highlight the importance of considering bank size in examining the effect of diversification on bank performance because bank size contributes in modifying the effect of diversification on bank performance.

The remainder of the paper is structured as follows. Literature review on the background of Islamic banking and bank diversification that leads to hypotheses is first provided, followed by description of methodology and an analysis of the empirical results. The final section concludes the paper.

2. Literature Review

2.1. *Commercial Banks*

The role of commercial banks (hereafter called as conventional banks) is initially to serve as mere financial intermediaries that channel funds from depositors to borrowers. With the availability of lending and borrowing services through conventional banks, lenders, and borrowers can save costs associated with searching, performing transactions, evaluating liquidity risk, and monitoring. The profits of conventional banks are mainly from net interests spreading between borrowing and deposit rates, aside from those provided by other financial services such as fees for letters of credit and for account maintenance.

However, conventional banks face challenges of financial innovations that resulted in low funding costs decades ago. These banks subsequently began to engage in off-balance-sheet income activities such as creating derivative instruments to secure cost advantages and generate profits. This phenomenon became more pronounced in the latter part of the last century when banking regulations successively relaxed worldwide. For example, in 1999 when the Grammm–Leach–Bliley Act (GLBA), also known as the Financial Service Modernization Act of the US, was enacted, financial holding companies (FHCs) were permitted to engage in any financial activity. The biggest benefits of the GLBA are revenue efficiencies and scale and scope economies as a result of the so-called “universal banking” that is performed by cross-selling business products such as commercial loans and securities. Despite these appealing benefits, FHCs do not consider GLBA as advantageous as they expected, and instead they observed that the act worsens bank performance. For example, any positive effect of GLBA on the performance of FHCs can be attributed to the continual effort of Section 20 subsidiaries, prior to the enactment of GLBA, to exploit the synergies between investment and commercial banking not because of GLBA alone (Yeager et al. 2007). In addition, Stiroh and Rumble (2006) indicated that risk-adjusted returns decline with the increasing diversification of the income activities of banks. Furthermore, Laeven and Levine (2007) found that financial conglomerates (i.e., financial firms engaging in pure commercial and investment banking activities) have intensified agency problems that resulted in bank diversification discounts.

2.2. *Islamic Banks*

The establishment of Islamic banks can be attributed to the ever-growing worldwide demand for oil during the last century. Given that major oil producers are located in the

Muslim-populated Middle East, the increase in oil demand results in an increase in oil price and revenue, allowing oil producers in Muslim countries to accumulate huge wealth. The subsequent assets attained by these oil producers will necessitate financial institutions that can manage them. The Islamic banking system was then created to meet the needs of these wealthy Muslims and of the increasing number of Petrodollar investors. Therefore, the Islamic banking system has a key role in financial intermediation and resource allocation in the Islamic world.

Islamic banks provide lending and borrowing financial services that comply with the Sharia law and concur with the core philosophy of Islam. The basic principle of Islamic banking is that money has no intrinsic value and should be regarded as a unit of account only rather than a commodity. Islamic law similarly prohibits the charging of interests (riba) on loans or deposits (i.e., investment deposits). Moreover, an Islamic bank shares its net profit/loss with its depositors, and they are not permitted to invest in high-risk financial products to comply with the Islamic law. However, Islamic law allows the generation of wealth by trading and investing in financial products that are linked to real assets (Hopeneret al., 2011; Derigs and Mzrzban, 2008). Some researchers promote the Islamic banking system by arguing that the principles of Islamic finance, the concept of profit-and-loss sharing, a multitude of financing modes that are similar to the universal banking system, and financing that is closely linked to real-sector activities are deemed conducive to attaining bank stability in the future (Ahmed, 2009; Ahmed, 2010; Kayed and Hassan 2011).

Islamic and conventional banks differ in many ways. According to Masruki et al. (2011), Islamic banks have more stable bank operations though less profitable, as opposed to conventional banks. In addition, the higher profitability of conventional banks can be attributed to higher transaction fees charged and more channels of external financing than those of Islamic banks. Moreover, conventional banks have a pre-fixed rate payment of interest, whereas Islamic banks are based on profit sharing. Furthermore, liquidity in Islamic banks is higher because of their lower variety of loans or financial products than conventional banks. Lastly, Islamic banks are generally less cost-efficient compared with conventional banks; however, they have higher asset quality, capitalization, and intermediation ratio (Srairi 2010; Beck et al. 2013). In fact, any differences between Islamic and conventional banks can be attributed to the strict compliance of Islamic banks with the Sharia law on lending and investing.

Despite the previously mentioned unique features and differences, Islamic banking has failed to receive much attention prior to the 2008 global financial crisis when Islamic banks were observed to have been minimally affected by the crisis. The global crisis that originated from the US subprime mortgage crisis tested the foundation of the banking industry and caused economic recession worldwide. Most conventional banks were severely affected by the crisis, whereas Islamic banks remained intact. Specifically, the total value of Islamic financial assets grew by 29% in 2008, whereas that of conventional banks generally experienced a sharp decline (Tabash & Dhankar 2014). In addition, Islamic banks subsequently experienced a rapid asset and credit growth (Hasan and Dridi 2010). Existing literature has provided ample evidence indicating that Islamic banks outperformed conventional banks during the crisis through the use of rigorous approaches. One of the observations was the higher resilience of Islamic banks than conventional banks during the crisis (IMF 2010; Zaheer and Farooq 2014). Miniaoui and Gohou (2013) proved the superior performance of Islamic banks over that of conventional banks after comparing Islamic and conventional banks in the United Arab Emirates (UAE) from 1995 to 2010. Hidayat and Abduh (2012) examined the performance of both bank types in the Middle East Bahrain from 2005 to 2010 and determined that the financial crisis has no significant effect on Islamic banks during the global crisis.

The higher resilience and good performance of Islamic banks compared with those of conventional banks during the crisis prompted a growing body of research on whether these achievements can be attributed to the unique features of Islamic banking. Beck et al. (2013), for example, identified higher asset quality and capitalization as factors contributing to the superior performance of Islamic banks compared with that of conventional banks during the crisis. However, these financial characteristics, among other qualities that explain why Islamic banks performed better during the crisis, can be ultimately attributed to the compliance of Islamic banks with Islamic law. Given the previously mentioned and other unique qualities of Islamic banking, it has played an increasingly important role in today's global financial market (Masruki et al.,2011; Čihák and Hesse 2010; Liang, 2009; Hasan and Dridi 2010).

Despite the emergence of Islamic banking, some challenges persist. For example, the Muslim population is relatively young, with their average age of 35 (Pew Research Center, 2013). Since young generation is generally more open, they are more likely to utilize international conventional banks than old generations, resulting in the apparent edge of conventional banks in the modern times. In fact, with the growth of Islamic finance, large international non-Islamic banks, such as HSBC Direct, Standard Chartered Bank, Deutsche Bank, and Citigroup, have started offering Islamic investors with specialized financial products and services (i.e., Islamic window). Although these conventional banks can only provide simple financial services tailored to Muslims, as opposed to fully-fledged Islamic banks, they have established more Islamic subsidiaries to expand the scale and scope of their services, with their increased experiences and relaxed domestic government regulations. The competitiveness of conventional banks threatens the sustainability of Islamic banks. Hence, whether Islamic banks will eventually be disregarded by the Islamic world is worrisome. In addition, current Islamic banks are below the standards of Muslims because they are not only insufficiently inclined to Islam, but also more regulated, inefficient, and not as diversified as compared with conventional banks (Siddiqi 2002). Thus, Muslims demand Islamic banks to be similar to conventional banks, particularly with respect to diversification. Considering the competitiveness of conventional banks and the dissatisfaction of Muslims with Islamic banks, exploring whether and how the diversification prevailing in conventional banks and being sought for by Muslims is relevant for Islamic banks. This investigation is important because diversification can negatively affect bank performance, as evidenced by conventional banks during the crisis. Although Islamic banks indicate much room for improvement, some of the features of conventional banks that are preferred by Muslims should be reconsidered. The high level of diversification prevailing in conventional banks is particularly a subject of scrutiny and may need to be eschewed in transitioning to an increasingly diversified banking system. Over-diversification as a result of bank deregulation is considered a major culprit in the global crisis because of the complex financial products permitted and developed under such circumstances, which present high risks but were not captured by capital requirements and effective monitoring prior to the crisis. In fact, recent studies that explore bank failure during the financial crisis similarly concluded that any bank failure during the said period was primarily due to high investments in innovative financial products, such as commercial real estate loans that were assigned a small asset risk weight prior to the onset of the crisis (Altunbas et al., 2011; Berger et al., 2012; Cole and White 2012). Other studies further provided evidence indicating that diversification from traditional to non-traditional banking activities increases bank risks and bank failure probabilities during the crisis. Lepetit et al. (2008), for example, found that diversification into non-interest income results in elevated bank risks for European banks as opposed to traditional banks. Using US banks as the study sample, Stiroh (2004) determined that non-interest income, particularly trading revenue, leads to less risk-adjusted profits because non-interest income activities have minimal risk diversification benefits, and the total risk will likely increase with diversification. Demirgüç-Kunt and Huizinga (2010) further confirmed the limited risk diversification benefit of non-interest income activities and concluded that relying too much on non-interest income activities for profit generation led to bank failure in the US during the crisis. DeYoung and Torna (2013) examined non-traditional income sources across hundreds of US depository institutions between 2008 and 2010 and found that asset-based non-traditional banking activities have a positive effect on the probability of bank failure during the crisis.

In sum, bank deregulation and the resulting emergence of financial engineering and various financial products with non-interest income and intractable high risks are considered major factors contributing to bank failures during the crisis. The identification of factors further highlights the differences between conventional and Islamic banks. The latter do not engage in financial engineering and selling of financial products that are implicitly highly risky. Compared with the majority of conventional banks that suffered from the global financial crisis, Islamic banks generally survived the crisis smoothly because of their low level of diversification (Chatti et al. 2013). Hence, in transition to more advanced and westernized banking system, Islamic banks should preserve their unique features without becoming over-westernized to prosper without committing the mistake of conventional banks prior to the crisis. In particular, given the established relationship between

diversification and bank failure, Islamic banks should learn from the experiences of conventional banks and moderately engage in diversification in expanding their business.
Existing literature has documented the relation of diversification to bank performance. However, results indicating the effect of diversification on bank performance remain ambiguous and dependent on several factors such as the countries of interest, bank size and type, and diversification level (e.g., Čihák and Hesse 2010, Vallascas et al. 2012, Molyneux and Yip 2013). In addition, prior studies virtually used income diversity as a measure for bank diversification (Molyneux and Yip 2013). . Although Chatti et al. (2013) investigated the effect of asset/liability diversification on bank performance, the measure they used for asset diversification was the Herfindahl–Hirschman Index. Though asset diversification has been found to be negatively related to risks (Liang and Rhoades 1991), the link between "asset diversity" and Islamic bank performance remains unexplored. Furthermore, all prior studies on the subject used static models in examining the effect of diversification on bank performance. That is, they fail to consider the dynamic process of attaining bank performance and the endogeneity problem. Although recent studies have begun to investigate the effect of diversification on the performance of Islamic banks, they were unable to consider performance measures other than profitability and financial stability (Čihák and Hesse 2010; Chatti et al. 2013; Molyneux and Yip 2013). Therefore, this study aims to fill the research gap by examining whether and how asset diversification contributes to the performance of Islamic banks as opposed to conventional banks using the dynamic panel data approach that addresses the endogeneity problem. Given that Islamic banks are generally less diversified compared with conventional banks, whether the higher level of diversification sought by Muslims will worsen the performance of Islamic banks, such as in the case of conventional banks during the crisis, should be investigated.

2.3. *Hypothesis development*

As mentioned in this section, the effect of diversification on bank performance has been debated in existing literature. Diversification may not necessarily yield risk reduction benefits for banks as assumed. A group of studies has shown that banks tend to underperform with increased diversification. Gamra and Plihon (2011), for example, found a negative effect of diversification on bank performance in emerging markets because of the costs incurred from diversification in the form of aggravated agency problems that exceeded the gains. Using Italian banks as the study sample, Acharya et al. (2006) found that loan portfolio diversification tends to increase risk and decrease return because diversification results in diseconomies caused by factors such as adverse selection and ineffective monitoring. Laeven and Levine (2007) provided evidence from 43 countries, which indicated the presence of diversification discount. Specifically, financial conglomerates that engage in multiple activities face more severe agency problems; thus, they are outperformed by banks that specialize in specific activities. Mercieca et al. (2007)

determined a negative effect of income diversification on the performance of European small banks. DeYoung and Roland (2001) found that bank performance tend to worsen with increasing income diversity because earnings become more volatile under such circumstances.

By contrast, another group of studies, though only a few, revealed the positive effect of diversification on bank performance. Using the US banks as the study sample, Saunders et al. (2014) found that banks that diversify from the interest income to non-interest income activities have higher profitability and lower insolvency risk than other banks. In addition, using Italian banks as the study sample, Vallascas et al. (2012) observed the benefits obtained by banks from diversification across unrelated income groups rather than that within narrow income activities. In fact, such a positive effect of diversification on bank performance is particularly found in Islamic banks. A survey of Islamic countries practicing a dual banking system by Molyneux and Yip (2013) revealed that income diversification (e.g., trading income, commission, and fee income) has a positive effect on bank performance, as measured by ROA and ROE, which is more pronounced for Islamic banks than for conventional banks. This finding can be attributed to the low diversification of Islamic banks and their higher potential to reap the benefits of diversification compared with conventional banks. Chatti et al. (2013) examined eight Islamic banks in Malaysia and found that despite low efficiency, an increase in portfolio diversity can improve the performance of Islamic banks. Čihák and Hesse (2010) found that income diversity tends to have a positive effect on z-score (a proxy of bank stability) of large Islamic banks as opposed to that of small banks where no such effect was observed. Shahimi et al. (2006) investigated Malaysian Islamic banks and found that diversification from traditional debt financing to other non-traditional activities, such as fee income, tends to decrease bank risk and increase bank size.

Based on the empirical evidence described previously, the net effect of diversification on bank performance remains ambiguous and dependent on two opposing effects and bank types. However, with conventional banks as generally more diversified, the marginal benefit of diversification is likely smaller than its marginal cost. That is, any positive effect of diversification is likely overwhelmed by the negative effect. Thus, the net effect of diversification on bank performance should be negative for conventional banks as opposed to Islamic banks. The following hypothesis is therefore formulated.

Hypothesis 1: Asset diversification has a negative effect on the performance of conventional banks as opposed to Islamic banks in the Islamic world with similar openness level of banking environment.

Prior research that investigated on the effect of diversification on bank performance mostly focused on conventional banks. As mentioned previously, Laeven and Levine (2007) found a diversification discount based on multi-country sample. However, Islamic banks were excluded from their sample because of their unique accounting standards compared with conventional banks. In contrast to conventional banks, the net effect of diversification on bank performance should be non-negative or even positive for Islamic banks. The underlying reason is because all Islamic banks have to comply with the Sharia law. Therefore, any diseconomies and agency problems associated with diversification should be less severe for Islamic banks. More specifically, the feature of risk-sharing ensures the mitigation of any increase in risk associated with diversification. The requirement of financial transactions connected with real economic activities further reduces any positive effect of diversification on bank risk. The non-exploitative nature of Islamic banking ensures that diversification will not aggravate any agency problems. Finally, agency problems and diseconomies associated with diversification will further be under control with the prohibition of criminal behavior such as speculative financial transactions and risky investments.

Existing literature has provided evidence indicating that any positive effect of diversification on bank performance is more likely to be observed by Islamic banks as opposed to conventional banks (Molyneux and Yip 2013; Saunders et al. 2014; Chatti et al. 2013; Čihák and Hesse 2010; Shahimi et al. 2006). Molyneux and Yip (2013), for example, found that risk-adjusted returns are higher as the share of non-traditional or non-financing income increases and this positive effect is more pronounced for Islamic banks than for conventional banks. Given that conventional banks are generally more diversified, any potential gain from diversification will likely be dominated by the negative effect of diversification emerging from the accompanied diseconomies and agency problems. Therefore, the net effect of diversification is negative for conventional banks. By contrast, in addition to the compliance with the Sharia law that helps minimize the negative effect of diversification on bank performance, Islamic banks are typically less diversified. Therefore, their marginal benefit of diversification likely overweighs the marginal cost. As a result, Islamic banks are more likely to reap benefits from diversification than conventional banks (Molyneux and Yip 2013). Despite minimal research on the effect of asset diversification on bank performance, given the risk reduction associated with the compliance with the Sharia law and the low level of diversification of Islamic banks, asset diversification, similar to income diversification, should have a positive effect on the bank performance of Islamic banks. The following hypothesis is therefore formulated.

Hypothesis 2: Any positive effect of asset diversification on bank performance is more pronounced for Islamic banks than for conventional banks.

Although results are mixed, prior studies have shown that bank size matters in determining the effect of diversification on bank performance. The consensus is that large banks can afford to diversify their income activities and reap the risk diversification benefits as opposed to small banks. Mercieca et al. (2007), for example, found the negative effect of income diversification on the performance of European small banks compared with large banks because small banks are inexperienced and not sufficiently specialized such that diversification results in more losses than gains. However, the capability to engage in diversification does not guarantee better performance of large banks. Demsetz and Strahan

(1997) found that large bank holding companies (BHCs) are better diversified than small BHCs, but the total risk of large BHCs is similar to that of small BHCs, which suggests that diversification plays a minimal role in reducing bank risk of large banks because of other factors. In fact, given the documented positive relationship between bank size and diversification (Demsetz and Strahan 1997; Deng et al. 2007), any minimal effect of diversification on bank performance of large banks can be attributed to the potential negative effect of bank size on bank performance. This relationship is attributed to the likelihood that as banks increase in size and capability of diversifying their income activities or portfolios, agency problems will likely worsen, and the expected negative effect of diversification on bank risk is offset or overwhelmed by the positive effect of bank size on risk because of increased agency costs (Laeven and Levine 2007).

The negative effect of bank size on bank performance has been documented in prior research. Demirgüç-Kunt and Huizinga (2013), for example, showed that stock returns are discounted when banks are exceedingly large. Other studies further provided empirical evidence indicating the negative relationship between bank size and profitability among conventional banks, which can be attributed to increased costs associated with bureaucracy, agency problems, and management diseconomies as bank size increases (e.g. Stiroh and Rumble, 2006; Demirgüç-Kunt and Huizinga 1999).

However, another group of studies indicated the possible non-negative effect of bank size on bank performance. Given the documented positive relationship between bank size and bank efficiency (Altunbaş et al. 2001; Delis and Papanikolaou 2009) and that between bank efficiency and bank performance (Beccalli et al. 2006), large banks should achieve better performance by gaining efficiency. Any positive effect of diversification on bank performance is subsequently strengthened as the accompanied bank size increases. Thus, diversification has a positive effect on the bank performance of large banks. In addition, regarding financial stability, Čihák and Hesse (2010) found that large conventional banks are more financially stable than small ones. By contrast, large Islamic banks are less financially stable compared with their small counterparts and large conventional banks because large Islamic banks are less capable of credit and liquidity risk management. Nevertheless, financial stability is found to increase with income diversity of large Islamic banks, which indicates that a higher level of income diversification can offset the negative effect of bank size on financial stability, rendering diversification valuable for large Islamic banks (Čihák and Hesse 2010). That is, diversification helps improve financial stability of large Islamic banks, despite the negative relationship between bank size and financial stability for such banks. This positive effect of diversification on financial stability of large Islamic banks should carry over to other bank performance measures such as profitability, cost efficiency, and asset quality because reduced risk and increased financial stability accompanied by higher diversification can ensure better operating conditions. Large Islamic banks are therefore expected to be more profitable, more efficient, and have better asset quality under such circumstances than small Islamic banks.

In sum, given that large banks are more capable of engaging in diversification and likely to be more efficient than small banks, diversification should have a positive effect on the bank performance of large banks. In addition, given the observed positive effect of diversification on financial stability of large Islamic banks alone, any positive effect of diversification on bank performance should be more pronounced for large Islamic banks than for large conventional banks. The following hypothesis is therefore formulated.
Hypothesis 3: Diversification has a positive effect on bank performance of large banks as opposed to that of small banks; and this positive effect is particularly more observed among large Islamic banks than among large conventional banks.

3. Methodology

3.1. *Data*

Annual data on the financial variables of banks in Malaysia, Pakistan, and Indonesia are gathered through Bankscope. The sample period is from 2006 to 2012. Banks covered in this study include Islamic and conventional banks, and the latter include depository institutions, investment banks, savings banks, and cooperative banks. Table 1 lists the number of conventional and Islamic banks for each of the three countries.

The selection of these three countries is mainly based on the following reasons. First, Malaysia is a typical Islamic country with the largest Islamic financial assets in Asia. Specifically, Malaysia accounted for 10% of the world's Islamic banking assets and ranked third in 2012. Malaysia also ranked first in terms of equity, Sukuk (Islamic version of bond), and fund management markets in 2009 (PricewaterhouseCoopers 2010). With an open financial environment and as the world's largest Islamic bond market in Asia, Malaysia is recognized as the future center for Islamic finance (Sy 2007; Gelbard et al. 2014). In addition, other Islamic countries in Asia, such as Indonesia and Pakistan, have the potential to develop because of their large and rapidly growing population. According to the Pew Research Center (2011), Indonesia has the second largest Muslim population in 2010and is expected to surpass Indonesia and become the world's largest Muslim country in 2030. Second, conventional and Islamic banks co-exist in the three countries identified, indicating a similar level of openness in terms of banking environment.

Following Laeven and Levine (2007) and LeBaron and Speidell (1987), we first used the chop-shop approach to obtain excess value of return on asset (ROA) to measure profitability as one of the bank performance measures in this study.

ROA is adjusted according to the relative weights of lending and non-lending activities of banks. A new variable named Adjust_ROA is created subsequently.

$$\text{Adjust\_ROA}_{j} = \alpha_j P_1 + (1 - \alpha_j) P_2 \qquad (1)$$

, where α_j is net loans divided by total earning assets for bank j based on the balance sheet. P_1 and P_2 are ROA for pure commercial and investment banks, respectively. The values of P_1 and P_2 are obtained by calculating the mean values of the ROA of both pure commercial and investment banks, respectively, where pure commercial (investment) banks are defined as banks with the ratio of loans to total earning assets as greater than 0.9 (less than 0.1) (Appendix).

We then created another variable, namely, excess value of ROA (EV_ROA) to measure diversification discount or premium by subtracting Adjust_ROA from Actual_ROA. The equation is as follows:

$$\begin{aligned} EV\_ROA &= Actual\_ROA_j - Adjust\_ROA_j \\ &= Actual\_ROA_j - [\alpha_j P_1 + (1-\alpha_j)P_2] \end{aligned} \quad (2)$$

This measure of bank performance differs from that of Laeven and Levine (2007) who used Tobin's Q (i.e., the sum of the market value of common equity plus the book value of preferred shares divided by the book value of total assets). Given the limited data on market value of banks, this study follows the work of Tsai et al. (2009) by using ROA to measure bank performance and to derive excess value.

According to ECB (2010), bank performance measures should not be limited to ROA or ROE. Bank performance should also cover other measures such as cost efficiency and asset quality. Hence, to provide a better insight into the research question, in addition to EV_ROA, we use three other variables as dependent variables: ROA, cost to income ratio (CTI, an inverse proxy for bank (cost) efficiency), and loan loss reserve divided by gross loans (LLR_GL, an inverse proxy for asset quality or bank stability) (Beck et al. 2013; Vander Vennet 2002).

According to Laeven and Levine (2007), asset-based and income-based diversity measures can be used to determine the level of diversification from lending to non-lending activities. Considering that most of the ratios derived from the income statements are greater than 1, which renders such ratios as unqualified for the income-based measure, we use the asset-based diversity (AD) measure in the present study. The asset-based measure is less problematic compared with the income-based measure (Laeven and Levine 2007).

The asset-based diversity measure for a given bank is calculated as follows:

$$\text{Asset diversity (AD)} = 1 - \left|\frac{(Net\ loans - Other\ earning\ assets)}{Total\ earning\ assets}\right| \quad (3)$$

, where other earning assets include underwritten securities and investments whereas other two variables are as defined above. The value of the AD variable is between zero and one, inclusive. Higher values indicate higher asset diversity.

The selection of other control variables follows prior studies, including the ratio of deposits to liabilities (DL), the ratio of equity to asset (EA), growth in assets (GIA), and log of total assets (TA). DL, EA, GIA, and log(TA) are used to control the effect of bank intermediation, financial leverage, bank growth opportunity, and bank size on bank performance, respectively. , All these variables (except for AD) are winsorized at 1% and 99% levels to remove outliers from the sample.

Other dummy variables are created to distinguish between bank types and between countries. D_type is specifically a dummy variable that returns a value of one, if a given bank is a conventional bank, and zero otherwise. The conventional banks in this study include the following banks: commercial banks defined by Bankscope, savings banks, cooperative banks, and investment banks. Islamic banks are defined by Bankscope as well. C_ID is a dummy variable that returns a value of one, if a given country is Indonesia, and zero otherwise. The C_MY is a dummy variable that returns a value of one, if a given country is Malaysia, and zero otherwise. Although the three countries in this study are Islamic countries and practice Islamic banking, discrepancies are observed among them. For example, the driving forces behind Islamic banking system development for these countries are different. Specifically, the development of an Islamic financial system in Indonesia is driven by market force, whereas the Islamic financial systems in Malaysia and Pakistan are driven by government initiatives. In addition, despite the de jure dual banking system, all banks in Pakistan are de facto Islamized (KPMG 2007). Hence, country dummy variables are included to capture and control for country-specific effects.

Table 2 presents a summary statistics of the variables used in this study. A total of 495 conventional banks and 70 Islamic banks are used as the study sample. All statistics for AD are lower for Islamic banks than for conventional banks, indicating lower asset diversity of Islamic banks than that of conventional banks. The mean and median values of EV_ROA are lower for Islamic banks than for conventional banks, indicating lower profitability of Islamic banks than that of conventional banks. The mean and median values of CTI are higher for Islamic banks than for conventional banks, indicating lower cost efficiency of Islamic banks than that of conventional banks. The mean and median values of LLR_GL are lower for Islamic banks than for conventional banks, indicating higher asset quality of Islamic banks than that of conventional banks. Results concur with those in prior studies (e.g., Beck et al. 2013; Srairi 2010). As for other control variables, the mean and median values of EA, log(TA), and log (TOI) are lower for Islamic banks than for conventional banks, indicating higher financial leverage and smaller bank size for Islamic banks than for conventional banks. The mean and median values of DL and GIA are higher for Islamic banks than for conventional banks, indicating higher level of bank intermediation and greater bank growth opportunity for Islamic banks than for conventional banks.

3.2. *The model*

We examine the effect of asset diversification on bank performance (EV_ROA, ROA, CTI, LLR_GL) by estimating the econometric model similar to that used by Laeven and Levine (2007) and Beck et al. (2013). Specifically, we regress the bank performance variable on asset diversity (AD) and its interaction variable AD×D_type as well as other control variables to examine whether and how the effect of AD on bank performance differs between Islamic banks and conventional banks. As the data vary across banks and over time, the panel data model is used. Moreover, since past bank performance likely influences future performance, we estimate the dynamic panel model for bank performance to reflect such adjustment process as opposed to the static model used in all of prior studies. Different specifications of the following one-step difference and system generalized method of moment (GMM) dynamic panel model that is adjusted for heteroskedasticity are estimated to obtain robust estimators.

$$\begin{aligned} BP_{i,t} = {} & \beta_0 BP_{i,t-1} + \beta_1 AD_{i,t} + \beta_2 AD_{i,t} \times D\_Type_{i,t} + \beta_3 C\_ID_{i,t} + \beta_4 C\_MY_{i,t} \\ & + \beta_5 DL_{i,t} + \beta_6 EA_{i,t} + \beta_7 GIA_{i,t} + \beta_8 \log(TA)_{i,t} \\ & + \sum_{t=2006}^{2011} \gamma_t YEAR_t + \mu_i + \nu_{i,t} \end{aligned} \tag{4}$$

BP refers to bank performance measured by EV_ROA, ROA, CTI, or LLR_GL. AD, D_Type, C_ID, C_MY, DL, EA, GIA, and TA are as defined above. YEAR is the dummy variable that returns a value of one if a given year is t. YEAR is included to capture year-specific effects.   denotes the unobservable firm-specific effect for bank i;   is the remainder disturbance for bank i and year t.

Using this framework, our focus is on the coefficient of AD, which measures the effect of asset diversification on bank performance. When BP is captured by EV_ROA or ROA, this coefficient indicates whether there is any diversification premium or discount. In general, based on model 1, the effect of asset diversification on bank performance is measured as β_1+β_2 D_type, which equals β_1 if a given bank is an Islamic bank (D_type = 0) and β_1+β_2 if a given bank is a conventional bank (D_type = 1). According to H1, when bank performance is measured by EV_ROA or ROA (i.e., proxy of profitability), □2 is expected to be negative. By contrast, when bank performance is measured by CTI or LLR_GL (i.e., inverse proxies of cost efficiency and asset quality, respectively), □2 is expected to be positive. For H2, when bank performance is measured by EV_ROA or ROA, □1 is expected to be positive. By contrast, when bank performance is measured by CTI or LLR_GL, □1 is expected to be negative.

Given that bank size may play a role in determining the effect of diversification on bank performance (Mercieca et al. 2007), model 1 is reestimated using sample partitions classified based on bank size. Specifically, the entire sample is grouped into three partitions based on total assets for each year, i.e., bottom 25%, middle 50%, and top 25%. Alternatively, to provide more insight into the potential role of bank size in determining the effect of diversification on bank performance, model 1 is modified in a way to facilitate comparison of the effect of diversification on bank performance between banks with different size for each bank type. To this end, the following model is estimated:

$$\begin{aligned} BP_{i,t} &= \beta_0 BP_{i,t-1} + \beta_1 AD_{i,t} + \beta_2 AD_{i,t} \times Q1_{i,t} + \beta_3 AD_{i,t} \times Q4_{i,t} \\ &+ \beta_4 C\_ID_{i,t} + \beta_5 C\_MY_{i,t} + \beta_6 DL_{i,t} + \beta_7 EA_{i,t} + \beta_8 GIA_{i,t} + \beta_9 \log(TA)_{i,t} \\ &+ \sum_{t=2006}^{2011} \gamma_t YEAR_t + \mu_i + \nu_{i,t} \end{aligned} \tag{5}$$

All variables are as defined as for model 1 except for Q1 and Q4, which are dummy variables that indicate the bottom 25% and the top 25% ranges of total assets for a given year. Q1 (Q4) returns a value of one if total assets are in the bottom (top) 25% range and zero otherwise. When total assets are in the middle 50% range, Q1 and Q2 take on the value of zero.

Based on model 2, the effect of diversification on bank performance is measured as β_1+β_2 Q1+β_3 Q4, which equals □1 + □2 , □1, and □1 + □3 when total assets are in the bottom 25%, middle 50%, and top 25%, respectively. According to H3, when bank performance is measured by EV_ROA or ROA, the coefficient of AD is smaller when total assets are in the bottom 25% than that when total assets are in the top 25%. That is, □2 is expected to be lower than □3. By contrast, when bank performance is measured by CTI or LLR_GL (i.e., inverse proxies of bank performance), □2 is expected to be higher than □3. Since financial variables are likely codetermined, all independent variables are treated as endogenous except dummy variables (C_ID, C_MY, D_Type, Q1, and Q4), which are treated as exogenous. All available lags of the dependent variable BP and independent variables other than dummy variables are used as instruments for the transformed equation. The aforementioned dummy variables and year dummy variables are used as standard instrument variables.

4. Empirical Results

Table 3 presents the results of the effect of asset diversification (AD) on bank performances based on the entire sample. In Columns 1 and 2 where EV_ROA and ROA are used to measure bank performance and where the coefficient of AD is insignificant and that of AD D_type is significantly negative, the effect of AD on EV_ROA and ROA is measured as -3.279 D_type and -3.132 D_type, respectively. Results indicate that AD has a negative effect on EV_ROA and ROA of conventional banks, whereas no effect was observed among Islamic banks. In Column 3, the coefficients of AD and AD D_type are shown as insignificant, indicating no effect of AD on cost efficiency for both bank types. In Column 4, the coefficient of AD is shown as significantly positive, whereas the AD D_type is insignificant, indicating that AD has a negative effect on asset quality for both bank types, given that LLR_GL is an inverse proxy of asset quality. Overall, results in Table 3 indicate that AD has a negative effect on bank performance, particularly of conventional banks. That is, a diversification discount generally exists for conventional banks, concurring with the findings of Laeven and Levine (2007) and Tsai et al. (2009). Results further supported the view that agency problems emerging from financial conglomerates increase in severity when the level of diversification is higher, such that the net effect of diversification on bank performance is negative (Laeven and Levine 2007). These results support H1.

As mentioned previously, the effect of diversification on bank performance may depend on bank size (Mercieca et al. 2007), we re-estimate the model using sample partitions classified based on bank size, (i.e., bottom 25%, middle 50%, and top 25%). Results are presented in Table 4, where Panel A shows the effect of AD on EV_ROA and ROA and Panel B shows the effect of AD on CTI and LLR_GL.

In Panel A, the coefficients of AD and its interaction variable, AD×D_Type, are insignificant, as shown in Column 1, where banks with bank sizes at the bottom 25% range are examined, indicating that diversification has no effect on EV_ROA for both bank types with bank sizes within this range. In Column 2, findings from the examination of banks with bank sizes at the middle 50% range are presented. The coefficient of AD is significantly positive and that of AD×D_Type is significantly negative. Specifically, the effect of AD on EV_ROA is measured as 5.071-1.750 D_type, which is 3.321 if D_type has a value of one (i.e., a given bank is a conventional bank) and 5.071 otherwise (i.e., a given bank is an Islamic bank). Results indicate that for banks with sizes at the middle 50% range, AD has a positive effect on EV_ROA, and this positive effect is more pronounced for Islamic banks than for conventional banks. Column 3 shows the results of the examination of banks with bank sizes at the top 25% range. The coefficient of AD for these banks is significantly positive, whereas that of AD×D_Type is insignificant. AD therefore has a positive effect on EV_ROA for both bank types with bank sizes at the top 25% range. When the dependent variable is ROA, a similar pattern is observed. AD has no effect on ROA when the bank size is at the bottom 25% range (Column 4). In Column 5, the effect of AD on ROA is indicated as 3.515-1.626 D_type, which is 1.889 if D_type has a value of one (i.e., a given bank is a conventional bank) and 3.515 otherwise (i.e., a given bank is an Islamic bank), for banks with bank sizes at the middle 50% range. This result indicates that for banks at the middle 50% size range, AD has a positive effect on ROA, and this positive effect is more pronounced for Islamic banks than for conventional banks. When bank size is at the top 25% range, the coefficients of AD and AD×D_Types are insignificant, and no effect of AD on ROA for both bank types under such circumstance is observed (Column 6). In sum, results in Panel A of Table 4 strongly indicate that diversification has a positive effect on EV_ROA and ROA for medium or large-sized (i.e., outside the bottom 25% range) banks. In addition, this positive effect is stronger for Islamic banks than for conventional banks with bank sizes at the middle 50% range. Results further indicate that bank size is important in determining the effect of diversification on EV_ROA and ROA.

In Panel B, where bank performance is measured by CTI and LLR_GL, the coefficients of AD and AD×D_Type are insignificant in all columns, indicating that diversification has no effect on CTI and LLR_GL for both bank types, regardless of bank size.

To provide a better insight into the research question, we re-estimate the model using a slightly different approach. Instead of conducting estimations using samples classified based on bank size, we estimate the model for each bank type by including additional variables that interact AD with dummy variables that indicate bank size at the bottom 25% and top 25% ranges (i.e., Q1 and Q4, respectively). Results are presented in Table 5. Columns 1 and 2 present the results on the effect of AD on EV_ROA of Islamic and conventional banks, respectively. The effect of AD on EV_ROA of Islamic banks is measured as 1.697 – 1.501 Q1, which equals 0.196 if bank size is at the bottom 25% range (i.e., Q1 = 1) and 1.697 otherwise (i.e., Q1 = 0) (Column 1). This finding indicates that AD has a positive effect on EV_ROA of Islamic banks, and this positive effect is stronger for those with bank sizes beyond the bottom 25% range. By contrast, the coefficients of AD, as well as its interaction variables AD Q1 and AD Q4, are insignificant in Column 2, indicating that AD has no effect on EV_ROA of conventional banks, regardless of bank size. In Columns 3 and 4 where ROA is used as the proxy of bank performance, the effect of AD on ROA of Islamic banks is measured as -1.277 Q1, which equals -1.277, if bank size is at the bottom 25% range, (i.e., Q1 = 1) and zero otherwise (i.e., Q1 = 0). These figures indicate that AD has a negative effect on ROA of Islamic banks with bank sizes at the bottom 25% range, whereas no effect on ROA of those with bank sizes outside this range. By contrast, the coefficients of AD, as well as its interaction variables AD Q1 and AD Q4, are insignificant, as shown in Column 4, indicating that AD has no effect on ROA of conventional banks, regardless of bank size, and concurring with the observation listed in Column 2.

In sum, when bank performance is measured by EV_ROA or ROA, results strongly indicate that AD has no effect on the performance of conventional banks, regardless of bank size. By contrast, AD has a positive effect on bank performance or a diversification premium exists for Islamic banks, and this positive effect or diversification premium is more pronounced for large banks (outside the bottom 25% range). Hence, results suggest that Islamic banks should be sufficiently large to obtain immense benefits from diversification. These results support H3.

The effect of AD on CTI and LLR_GL is more revealed in the results in Table 5 than those in Table 4. The effect of AD on CTI of Islamic banks, specifically, is measured as 19.674 Q1 in Column 5, which equals 19.674 if bank size is at the bottom 25% range and zero otherwise. That is, given that CTI is an inverse proxy of cost efficiency, results indicate that AD has a negative effect on cost efficiency of Islamic banks with bank sizes at the bottom 25% range, whereas AD has no effect on cost efficiency for banks with bank sizes outside this range. For conventional banks, the effect of AD on CTI is measured as 46.435 Q1 – 30.812 Q4, which equals 46.435, 0, and -30.812 when bank sizes are at the bottom 25%, middle 50%, and top 25% ranges, respectively (Column 6). That is, given that LLR_GL is an inverse proxy of asset quality, AD has a negative effect, no effect, and positive effect on cost efficiency for banks with bank sizes at the bottom 25%, middle 50%, and top 25% ranges, respectively.

In Columns 7 and 8, the effect of AD on LLR_GL is indicated by the listed results. The effect of AD on LLR_GL of Islamic banks is measured as -7.069 Q4 in Column 7, which is equal to -7.069 if bank size is in top 25% (i.e., Q4 = 1) and zero otherwise (i.e., Q4 = 0). Given that LLR_GL is an inverse proxy of asset quality, AD has a positive effect on asset quality of Islamic banks with bank sizes at the top 25% range, whereas AD has no effect on those with bank sizes outside this range. In Column 8, the effect of AD on LLR_GL of conventional banks is measured as 7.291 – 3.243 Q4, which equals 4.048 if the bank size is at the top 25% range (i.3., Q4 = 1) and 7.291 otherwise (i.e., Q4 = 0). That is, AD has a negative effect on asset quality of conventional banks, and this negative effect is weaker for banks with bank sizes at the top 25% range.

Based on results in Columns 5 to 8, any positive effect of AD on cost efficiency and asset quality occurs when the bank size is at the top 25% range. In addition, any negative effect of AD on cost efficiency and asset quality occurs when the bank size is small (i.e., at the bottom 25% range and outside the top 25% range, respectively. For large conventional and Islamic banks (at the top 25% range), they tend to gain cost efficiency and asset quality, respectively, from asset diversification. The results highlight the importance of bank size in determining the effect of AD on cost efficiency and asset quality, concurring with the results in Columns 1 to 4 on the effect of AD on profitability.

The study results suggest that Islamic banks tend to benefit from asset diversification in terms of profitability and asset quality when they have large bank sizes. However, diversification does not add to the cost efficiency of Islamic banks, especially when the bank size is at the bottom 25% range in which a negative effect is observed. For conventional banks, diversification does not appear to add to profitability and asset quality. However, diversification can improve cost efficiency and has a weak negative effect on the asset quality of conventional banks when the bank size is large (i.e., at the top 25% range). In sum, banks should be sufficiently large to benefit from diversification. Furthermore, conventional banks seem to enjoy less performance gain from diversification as opposed to Islamic banks. In particular, this study provides evidence indicating the presence of diversification discount for conventional banks, consistent with the finding of Laeven and Levine (2007) and Tsai et al. (2009).

5. Concluding Remarks

This study examines the effect of asset diversification on bank performance in three Asian Islamic countries that have a dual banking system. With the data obtained from banks in Indonesia, Malaysia, and Pakistan, from 2006 to 2012, asset diversification is found to have a role in determining bank performance. Diversification, specifically, has a negative effect on profitability and asset quality of conventional banks, whereas no effect on cost efficiency and weak negative effect on asset quality of Islamic banks. In considering the bank size, the results reveal a positive effect of diversification on profitability of large banks (i.e., banks with sizes outside the bottom 25% range). This positive effect is stronger for Islamic banks than for conventional banks. In addition, diversification has a positive effect on the cost efficiency of conventional banks with bank sizes at the top 25% range, whereas no positive effect on the cost efficiency of Islamic banks. Furthermore, diversification has a positive effect on the asset quality of Islamic banks with bank sizes at the top 25% range. By contrast, diversification has a negative effect on the asset quality of conventional banks. However, this negative effect is weaker for conventional banks with bank sizes at the top 25% range. The results overall suggest that diversification remains to be valuable, especially for Islamic banks. Moreover, this study is the first to provide evidence indicating that size is important in examining the effect of diversification on bank performance. Any gain from diversification appears to occur and any loss from diversification appears to be smaller for large banks, regardless of bank type. That is, with diversification, the larger the bank is, the more gain or the lesser loss is attained.

The findings of this study provide implications for researchers, practitioners, and policy makers. For researchers, results suggest that diversification affects bank performance. Islamic banks have diversification premium, whereas conventional banks have diversification discount. In addition, size matters in determining the effect of diversification on bank performance. Hence, future studies should consider the type and size of banks to accurately identify the effect of diversification on bank performance. For practitioners, given that any gain from diversification is larger and any loss is smaller for large banks, Islamic banks are not recommended to engage in high diversification levels unless their bank sizes are sufficiently large. By contrast, while large conventional banks gain cost efficiency from diversification, diversification generally adds nothing to profitability and asset quality. These banks should moderately engage in diversification because, unlike Islamic banks, diversification will cause more harm than good for conventional banks. For policy makers, since conventional banks generally fail to gain from diversification, authorities should implement policies that will reduce the level of bank diversification to improve the performance of conventional banks. Meanwhile, policies or measures should be implemented to encourage Islamic banks to diversify their assets for better performance. These policies or measures will more likely work if Islamic banks will be sufficiently large to gain from diversification.

Appendix

Following Laeven and Levine (2007), banks are classified into pure commercial banks and pure investment banks based on the following asset-based measure:

$$\text{Loans to total earning assets} \quad (\text{LEA}) = \frac{\text{Net loans}}{\text{Total earning assets}} \qquad \text{(A1)}$$

, where total earning assets includes loans, securities assets, operating mutual funds, etc. The value of this variable is between zero and one, inclusive. A higher ratio means that a bank focuses on deposit-taking and loan-making such that it is closer to a commercial bank whereas a lower ratio means that a bank is closer to an investment bank. Banks are classified as pure commercial banks and pure investment banks if their LEA is greater than 0.9 and less than 0.1, respectively.

Table 1 Numbers of conventional banks and Islamic banks across countries

	Malaysia	Indonesia	Pakistan	Total
Conventional banks	56	80	31	167
Islamic banks	17	4	9	30
Total	73	84	40	179

Notes: This table presents descriptive statistics for variables used in the study, including mean, minimum value (Min), three quartiles with p25, p50, p75 indicating the first, second (median), and third quartiles, respectively), maximum value (Max), standard deviation (sd), and number of observations (N). Excess value of ROA (EV_ROA) is actual ROA minus adjusted ROA. Cost efficiency (CTI) is the ratio of operation cost to operation income. Asset quality (LLR_GL) is the ratio of loan loss reserve to gross loans. Asset diversity (AD) is 1-|(net loans-other earning asset)/total earning asset. Control variables include: DL (deposits/liabilities), EA (equity/assets), GIA (growth in assets), Log(TA) (Log (total assets)), Log(TOI) (Log (total operating income)).

This paper studies the role of order flow in information dissemination around macroeconomic announcements.We find that,in the EBS trading platforms of EUR/USD and USD/JPY, a moderate fraction of information is revealed through order flows, and rates of information flow differ among sequential trading periods over a 24-hour trading day. In particular, trades taken place in the overlapping trading hours of London and New York are most informative than those in the other trading periods. The release of announcements actually does not alter the intraday pattern of trade informativenessacross different trading periods. The information content of trades even declines on days after the announcement release, which is consistent with Tetlock (2010), suggesting public announcements resolve asymmetric information.

1. Introduction

Trading activities play an important role in the process of information incorporation into prices in the foreign exchange (FX) market (Lyons, 2001; Berger et al., 2008).We study whether rates of information dissemination differ among sequential trading periods over a 24-hour trading day, and whether rates of information flow differ between announcement and nonannouncement days. Examining how news is impounded into prices via order flowsaround the release of macroeconomic announcements in theFX market under asymmetric information, we use the actual trading data of EUR/USD and USD/JPY from the Electronic Broking Services (EBS). We use the approach proposed by Hasbrouck (1991) to decompose the variance of changes in the efficient price into trade-correlated and -uncorrelated components.

Recent studies provide evidenceof asymmetric information in the FX market(Lyons, 1995; Perraudin and Vitale, 1996; Payne, 2003; Menkhoff and Schmeling, 2010).Evans and Lyons (2002) report that order flows explain about 6o percentof exchange rate movement. Moreover, Evans and Lyons (2008)explore how information in macroeconomic news is incorporated into exchange rates via the channel of order flow.Love and Payne (2008)find announcement-relevant information is transmitted into exchange ratesdirectly or indirectly through order flow.

Informed traders prefer to trade in certain trading periods. Barclay and Hendershott (2003) study the effectsof trading after hours on the amount and timing of price discovery over the 24-hour tradingdayby examining the amount of private information revealed through trades in different periods, andfindthat prices are more efficient and more information is revealed per hourduring the trading day than after hours, however, individual trades containmore private information after hours than during the day. In the FX market, Wang and Yang (2011)show price discovery efficacy varies with trading regions, after dividing the 24 trading hours into four sub-markets, namely Asian, European, London and New York overlapping trading hour (London+NY) and US markets, and the London+NYmarket dominates the price discovery over the 24-hour day.

Furthermore, Jiang, Likitapiwat and Mclnish (2012) extendthe analysis of Barclay and Hendershott (2003)by examining whether earning announcementsaffect price discovery across different trading periods, and find that more information is revealed through order flow in the trading period with releases of earning news made in the period.

Previous studies have shown that new information istransmitted into prices before announcements. Huberman and Schwert (1985) find that 85% of the announcementsareanticipated by all traders and impounded into asset prices before the announcement date. Alternatively, Bhattacharya et al. (2000) indicatethat informed traders react to news before its release. However, Meulbreok (1992) shows that about half of price changes before announcements occurs due to informed trading, and the other half comes from public anticipation about the forthcoming news.

Exchange rate volatility rises after news releases since asset prices will not completely respond to macro announcements in the short run(Ederington and Lee, 1993; Bauwens, Omrane and Giot, 2005; Rime, Sarno, and Soji, 2010, among others), and the increased volatility may relate to investors' heterogeneity in news interpretation skills. Lyons (1995) and Evans and Lyons (2002) also suggest that customers'order flows provide dealers more information about fundamental value of the exchange rate, and this information advantage is particularly pronounced during the period of public information releases.

Priorresearch indicates that there exists abnormal trading volume and higher spread around news announcements (e.g., Libby, Mathieu, and Robb, 2002; Pronk, 2006; Graham, Koski, Loewenstein, 2006). Jiang et al. (2012) find that trading volume is positively correlated with the efficacy of price discovery, and infer that abnormal trading volume can come from informed traders who possess private information, whereas a negative relation between price discovery efficacy and spread may result from market friction.

Following Barclay and Hendershott (2003), weusethe approach of Hasbrouck (1991)to study the informativeness of trades in the FX market by distinguishing the variance of changes in exchange rate into trade-related and -unrelated components. Examining the content of private information contained in order flow across four sequent trading periods, including Asian, European, London+NYand UStrading periods, we findthat order flows significantly contain price-relevant information in the FX market. We compare the fractions of the fraction of variance attributed to order flows across four trading periods, and discover that trades in London+NYperiod are most informative than those inother periods.

Considering the release of macroeconomic announcements in the U.S., Japan, and Europe area, we studywhether information dissemination process differs on days with and without announcements. The results show that role of order flow in conveying informationremains the same between days with and without announcements.

Our results indicate that the informationcontent of order flows decreasesin Asian, European and U.S. trading periods before certain forthcoming announcements.Huberman and Schwert (1985) and Meulbreok (1992) point out thattraders would have anticipated the forthcoming news, and the forecasting of announcements will reduce the dispersion in opinionsabout the future exchange rate.However, we find that the informativeness of order flow improves in the overlapping trading period of London+NYC before the release of announcement.

Foster and Viswanathan (1996) suggest that heterogeneously informed traders may wait to preserve their informational advantage as long as possible rather than trade immediately after news announcements.We furtherexamine whether trade informativenesschanges after the announcement, and find that trades contain less information on days after the announcement. The results imply that public announcements resolve asymmetric information among tradersright after the release of announcement, which is consistent with Tetlock (2010).

Overall, we demonstratethat order flow plays an important role in the flow ofinformation on days with and without announcements.We further identify that trades in the London+NYperiod are most informative than those in Asian, European and U.S. periods. The informativeness of trades is also associated with trading volume and effective spread significantly.

The remainder of the paper is organized as follows. Section 2 introduces the structure of the FX market, the EBS trading data, and lists macroeconomic announcements released in the U.S., Europe and Japan we consider in the analysis. Section 3demonstrates the vector autocorrelation model used in Hasbrouck (1991) for the measurement of trade informativeness. Section 4 discussesthe empirical results. Section 5 concludes.

2. Data

2.1 FX trading data

FX trading starts in Asia, then moves on to Europe and New York, and ends in the United States over a 24-hour day. BIS (2013) addresses that FX markets are the most liquid financial markets, as the daily average turnover of the global FX marketsachieved $5.3 trillion in April 2013, and the spot transactions increases from $1.5 trillion in April 2010 to $2 trillion in April 2013.

The two primary global electronic broking systems for FX trading are EBS and Reuters D2000-2 (or D3000). Ito and Hashimoto (2006)alsoreveal that the market share (in absolute value) for trading of EUR/USD and USD/JPY in the EBS is the largestamong all electronic trading systems, which may be attributed to the acquisition of Minex, which was developed by the Tokyo Bank in 1995 and provided a significant market share in Asia.

We use the trading data of EUR/USD and USD/JPY provided by the EBS, covering the period of January 1, 2008 through December 31, 2012 for EUR/USD and the period from January 1, 2009 through December 31, 2012 for USD/JPY, due to the limitation of macroeconomic announcement data. For each trade, the EBS screen provides the best quoted prices for trades larger than 10 million, which contains the following detailed information: (1) date and time; (2) quote or deal indication; (3) bid/ask quotes price or executed price; (4) trading volume, and (5) the trading direction (buy or sell). Although the fast execution speed and disclosure in the EBS system lead to higher transparency, the information shown on EBS screens only includes the best bid and ask quotes, and the deal prices done on the bid side, or on the ask side.

To study the intraday pattern of trade informativeness, we separate 24 trading hours into four trading periods, following Wang and Yang (2011). The four sequential trading periods includeAsian trading, European trading,the overlapping trading hours in London and New York, and U.S. trading periods. We consider the Daylight Saving Time (DST) shift in the Europe and the U.S.when we deal with the intraday data. Table 1 reports the GMT hours and corresponding local time of three major markets in three panels which are split into the Normal Time (winter), DST (summer), and the period when New York is under the Summer Time, but London is not.[1]

Table 1 summarizes the Greenwich Mean Time (GMT) and corresponding local time of three major financial markets in the FX trading: Japan, London and New York.Panels A, B and C of Table 1 display the local time of three major markets in winter, summer and the period when New York is under the Summer Time, respectively.

The first trading period(in winter time)is the Asian trading period from 23 GMT to the end of 6 GMT the next day. The second period is the European trading period between 7

[1]Daylight Saving Time in 2008 is from March 9 to November 2 in the United States (US); from March 30 to October 26 in the United Kingdom (UK); in 2009, from March 8 to November 1 in the US; from March 29 to October 25 in the UK; in 2010, from March 14 to November 7 in the US; from March 28 to October 31 in the United Kingdom; in 2011, from March 13 to November 6 in the United States; from March 27 to October 30 in the UK; in 2012, from March 11 to November 4 in the US; from March 25 to October 28 in the UK.

GMT and 13 GMT. The third period is the overlapping hours of London afternoon session and New York morning session, covering the period between 13 GMT and 14 GMT, and is labelled as London+NY. The last trading period is the UStrading period that runs from 15 GMT to 22 GMT, as shown in Table 1.

Panels B and C of Table 1, respectively, summarize the hours for each trading period in summer time. We exclude all trading data on weekends and holidays from our sample, and delete observations with a larger bid quote price than the corresponding ask quote price, as suggested by Ito and Hashimoto (2006).

Tables 3 and 4 report summary statisticsof the trading activities of EUR/USD and USD/JPY market, respectively, for the four trading periods: Asian, European, London+NY and U.S. periods. We report per-hour trade numbers and per-hour trading dollar volume for each trading period.[2] Effective spread is calculatedby $2\left|\log(p_{it}/q_{it})\right|$, where $p_{it}$and q_{it}denote trading price and the mid-quote price at the end of period $i$on day$t$.

Wefind that numbers of trades, trading dollar volume and effective spread differ between days with and without announcements. Tables 3 and 4 display that numbersof trades and trading dollar volumein European and London+NYperiods are higher on announcement days in the EUR/USD market.Similarly, in the USD/JPY market, the number of trades and trading volume increase on U.S. announcement days for the four trading periods, suggesting that investors react to the arrival of information at the release of announcement.

As forthe trading cost,we find thateffective spreadsincrease in European and Asian, European, and London+NYperiods in both EUR/USD and USD/JPY markets on announcement days. Consistent with Libby, Mathieu and Robb (2002), we show that spreads are relatively wider as announcements are released.

[2] Since the trading hours of the four markets are different from each other. A market may have a larger number of trade and trading volume simply because of its long trading hours. We thus compare per-hour number of trade and trading volume.

2.2 Data of macroeconomic announcements

The macroeconomic announcement data used in the paper comesfrom the Econoday. Thedata archive of Econoday provides the median of professional forecasts for the macroeconomic indicator to be announced. The consensus forecasts are the medians of surveymade on Friday in the week prior to the announcement release day.

Table 2 lists the announcements we consider in the analysis. There are 32 US macroeconomic announcements, 15 Japanese macroeconomic announcements(during the 2008-2012 period), and 28 European macroeconomic announcements (during the 2009-2012 period). Most of U.S.announcements areannounced at 8:30 EST, most of Japanese announcements are announced at 8:50 JST, but the release time of European announcements varies over time.

3. Empirical Models

3.1Vector autoregressivemodel

Following Hasbrouck (1991, 1996) and Payne (2003), we measure the informativeness of trades by estimating a vector autoregressive model (VAR) of quote-midpoint revision and signed order flow. We denote $z_t = [r_{it} o_{it}]$, where r_{it} is calculated by $\log(qm_{i,t}) - \log(qm_{i,t\text{-}1})$, where $qm_{i,t}$is the midpoint of ask and bid quotes at time t, in trading period i, and$o_{i,t}$is defined as a 3×1 vector of the trade variablesat time$t$, which includes (i) a trade sign indicator (+1 for a buy order, and -1 for a sell order), (ii) signed trading volume, and (iii) the signed squareof trading volume. The VAR we estimate for four markets is as follows:

$$z_t = A_1 z_{t\text{-}1} + A_2 z_{t\text{-}2} + \ldots + A_k z_{t\text{-}k} + \nu_t, \quad (1)$$

whereA_j (j = 1, …, k) are coefficient matrices, k is the maximum lag length, and $\nu_t$is a vector of serially uncorrelated disturbances with the covariance matrix Ω.

Based on Hasbrouck (1991), we identify the trade informativeness under the assumption that the public information set includes the trade and quote history. We can calculate impulse responses recursively from Eq. (4) as follows.

$$E[z_t|v_t] = v_t, \tag{2}$$

$$E[z_{t+1}|v_t] = A_1 v_t = \Phi_1 v_t, \text{ and} \tag{3}$$

$$E[z_{t+2}|v_t] = (A_1^2 + A_1)\, v_t = \Phi_2\, v_t, \tag{4}$$

where Φ_i is the impulse coefficient matrix. We can also calculate the accumulated impulse responses Ψ_i by:

$$E[z_t|v_t] = v_t. \tag{5}$$

$$E[z_t + z_{t+1}|v_t] = (I + \Phi_1)\, v_t = \Psi_1. \tag{6}$$

$$E[z_t + z_{t+1} + z_{t+2}|v_t] = (I + \Phi_1 + \Phi_2)\, v_t = \Psi_2. \tag{7}$$

$$E[z_t + z_{t+1} + \ldots|v_t] = \Psi_{\infty,z} v_t. \tag{8}$$

The accumulated impulse response function measures the long-run impact of an innovation on the cumulative (quote-midpoint) return, and it can be used to measure the information content of the innovation. As noted in Hasbrouck (1996), although microstructure effects may motive transient effects on the cumulative return, any persistent long-term impact will reflect new information about fundamental value of a asset.

We also follow Hasbrouck (1991) to compute an alternative summary measure of the information contained in the order flow. As noted earlier, the left-hand side of Eq. (11) represents the impact of the innovation on the price net of any transient microstructure effects. The variance of this term approximately adds up to the return variance per unit time, provided that the return calculated over an interval long enough that transient price effects can be ignored. To measure the variance of this term, we can use the variance of the random walk component implicit in the price. Indicate this random walk component as w_t, and we can represent its variance as follows:

$$\sigma_w^2 = Var(w_t) = Var(E[r_t + r_{t+1} + \cdots | v_t]) = \Psi_{\infty,r}\, \Omega\, (\Psi_{\infty,r})' \tag{9}$$

With a diagonal Ω, we can decompose the variance of the random walk as:

$$\sigma_w^2 = \sigma_{w,r}^2 + \sigma_{w,o}^2, \tag{10}$$

The two variances on the right-hand side of Eq. (13) denote an incremental contribution to the variance of random walk component, relative to $r_t$and o_t. That is, that $\sigma^2_{w,r}$ is the incremental contribution from quote revision innovations, and $\sigma^2_{w,o}$ is the component of the variance explained by order flow. To measure the trade informativenessfrom the VAR model, we follow Hasbrouck (1996) and Payne (2003) to calculate the following variance component:

$$IS = \sigma^2_{w,o} \Big/ (\sigma^2_{w,r} + \sigma^2_{w,o}), \tag{11}$$

where*IS*reflects the trade informativeness or information content of trades, σ^2_{w,o_p} is the proxy to gauge the effect of private information, and $\sigma^2_{w,r} + \sigma^2_{w,o}$ refers to the variation of caused by the total information.

Overall, the VAR approach allows us to measure the dynamic relations among returns and order flows across the four markets. The variance decomposition offers a measure of the contribution of quote and order innovations to the total price innovation. Therefore, we can use the VAR approach to find the proportion of private information to total information, and use the ratio to measure the contribution to price discovery of each trading segment or market.

3.2 Regression analysis

To examine how the price discovery ability from trade-relative information shockin different periods changes on days with macroeconomic announcements, we use the linear regression model to examine the relationships between information contents, which is estimated by VAR.In this study, we usedummy variables to measure news effects, which equal 1 when the U.S.,European or Japanesemacroeconomic announcement are made on the day, and nonannouncement days refer to days without any U.S., Europeanor Japanese macroeconomic announcement.

Further, we add effective spread and trading volume into our model to make sure the results are robust which is as follows.

$$IS_{i,t} = \sum_{j=1}^{4} \beta_j MKT_{j,i,t} + \sum_{j=1}^{4} \sum_{m=-\kappa}^{\kappa} \lambda_{m,j} \times MKT_{j,i,t} \times USNEWS_{t+m} + \sum_{j=1}^{4} \sum_{m=-\kappa}^{\kappa} \gamma_{m,j} \times MKT_{j,i,t} \times EUNEWS_{t+m} + \tag{12}$$

$$\sum_{j=1}^{4} \sum_{m=-\kappa}^{\kappa} \sigma_{m,j} \times MKT_{j,i,t} \times BOTHEWS_{t+m} + \theta \times Volume_{i,t} + \delta \times SPREAD_{i,t} + \varepsilon_{i,t}$$

where $IS(VAR)_{i,t}$ is the information share from order flow of period$i$ on day t. $MKT_{j,i,,t}$ is a dummy variable for the j-th market, where j =1, 2, 3, 4, indicating Asian, Europe, London-New York and the U.S. markets, respectively. $MKT_{j,i,t}$ equals 1 for the j-th market, and 0 otherwise. $USNEWS_{t+m}$ is a dummy variable which equals 1 if only US announcements are released on day $t+m$, where m =-2, -1, 1, 2, indicating one day before, two days before, one day after, two days after the announcements day, respectively; $EUNEWS_t$ equals 1 if only European (Japanese) announcements are released on day t. $BOTHNEWS_t$equals 1 if U.S. announcements and European (Japanese) announcements are released on day t. We also consider the effect of announcements on the days before and after announcement by including the dummy variables for one to five days prior to the announcement day andone to five days after the announcement day into the regression model.H_Volume_{it}refers to per-hour trading volume of period i on day$t$; and, RE_Spread_{it}denotes the relative effective spread of the corresponding market on day t which equals to2× $|\log(p_{it}/q_{it})|$, where $p_{it}$is the trading price and $q_{it}$is the quote price at the close of period$i$ on day$t$.

4. Empirical Results

We calculate the ratios of private information to total information to investigate the role of order flow in information content related to private information shocks, and further compare the price discovery efficacyamong Asian, European, London+NY and U.S.trading periods on days with and without macroeconomic announcements. Furthermore, we examine whether information is incorporated into exchange rate before the release of macro announcements by informed trading. Moreover, to learn how news isrevealed into prices after announcements, we study whether information is still transmitted by trade-related channel after the announcement is known to all traders. Finally, as a robustness check, we add volume and effective spread into our analysis to examine the effect of news on price discoveryefficacy.

4.1 Informativeness of trades in different trading periods

Tables 5 and 6 report the trade informativenessover Asian, European, London+NY and U.S.periods for EUR/USD and USD/JPY, respectively. Panel A of Table 5 presentsthat the informationcontent of order flow forthe four trading periodsbased on the entire sample. We find that the ratio of private information to total informationcontained in order flows is 30% averagelyover the four trading periods, and the fraction of private information contained in order flow in the period of London+NYis significantly higher than those of other trading periods. Thus, Wang and Yang's (2011) finding that trading in London+NYsegment dominates price discovery in FX marketmay be attributed to the possibility that more informed trades occur during that period.

We observe thatannouncementssignificantly relate to the price discovery over the four periods in the EUR/USD market, as shown in Panels B, C, D, E of Table 5. Evans and Lyons (2008)demonstrate that there is still about 30% or more of information which is indirectly incorporated into exchange ratesthrough order flows on days with U.S. or European macroeconomic announcements. Hence, we conclude that order flow is an important channel of information incorporation. Moreover, our results show thatorder flow in the trading period ofLondon+NYcontains morefraction of private informationthan the trading periods of Asian, European and U.S. segments on days with and without announcements.

Table 6 showsthat ratios of private information to total information contained in order flow over the four trading periods on days with or without announcement in the USD/JPY market. Similarly, we find a high portion of information is transmitted into exchange rate throughorder flow, according to the estimation results of the entire sample. We find that about 30%to 40% of private information contained in order flow on days with public announcementreleases.

Table 6 also displaysthe information content oftradesin the period of London+NYis highest among the four trading periods on days with or without announcements. Moreover, we find a higher fraction of information content of order flowin the Asian trading period than in the European and U.S.periods on days with U.S. announcements only. This means that more informed traders enter the market to exploit information advantage during Asian period on days with U.S. announcements.

4.2 Trade informativenessaround the release day of macroeconomic announcement

Huberman and Schwert (1985) find that 85% of the announcementsisanticipated by all traders and impounded into asset prices before the announcement date.Moreover, Tetlock (2010) further deomonstratesthat public news will make traders have the same opinion about the asset valueafter information is known to all traders. If the prediction of Huberman and Schwert (1985)andTetlock (2010)holds in the EBS trading system, we expect that trade informativeness which is attributed to informed trading will decrease around announcements, if news releases will eliminate belief heterogeneity among dealers.

This paper uses regression analysis to analyze how trade informativeness differ on days around the release of announcement, in that we can investigate whether news announcements will resolve asymmetric information, and new information may be directly impounded into exchange rates instead of through order flows submitted by informed traders. The changes in trader-related information content across four trading periods for EUR/USD are shown in Table 7. In Asian period, Table 7 indicates that information content in order flowsdecreaseson three days beforeU.S. announcement only and both of U.S. and European announcements. Therefore, consistent with Huberman and Schwert (1985) and Meulbreok (1992), traders in Asian period will anticipate the releases of the U.S. announcement only and both of U.S. and European announcements, and the degree ofinformation asymmetry declines on days before the announcement release.

Also, Table 7 points out that information shares from trades decrease on four days after U.S. announcement only and both of U.S. and European announcements in Asian, which supports the suggestion of Tetlock (2010), public news resolves the information asymmetry of the market. However, we further find that the information content of order flows increases on two and three days before European announcement only. Meulbreok (1992) and Bhattacharya et al. (2000) indicate that part of information is revealed into price through informed traders before news is released. Hence, the increases in information content of order flow would imply that there is a higher ratio of information incorporated into prices through informed traders on days before the day with European announcement only.

We do not find informativeness of trades significantly decreases on days before news release during the European tradeingperiod. But, Table 7 also presents that the information contentof trades significantly decreasesone day and three, four and five days afterthe day with the U.S. announcementsonly and the day with both the U.S. and European announcements.

There is no any significantly decrease in informationcontent of order flow around days with news releases in London+NYC period. We even find that information content increases on three days before the day withboth U.S. and European announcements.Consistent with the finding for Asian and London+NYC periods, we find that trade informativeness increases on days with announcements, and the informativeness of trades in the U.S. period also increases four days before European announcements only. We also consider effective spread and trading volume in the regression model. Table 7 shows that less information is revealedthrough order flow when the spread is wider. Trade informativeness is positively related to trading volume.

Table 8 reports the estimation results for the USD/JPY market. Trade informativenessis reduced three days before the day with both U.S. and Japanese announcements. Similarly, trades carries less information on days after the announcement day. For the European trading period, trade informativenessdecreases three days before and four daysbeforethe day with both Japanese and U.S. announcements. For the U.S. trading period, Table 8 indicates that trade informativenessdecreases on days before and after the announcement. We find that the fraction of information carried by trade is relatively smaller five days before the day with the U.S.announcements only. Moreover, trade informativenessdecreases three days after the U.S announcement.

Overall, the results of Tables 7 and 8 are consistent with Huberman and Schwert (1985) and Tetlock (2010), showing the release of announcement resolvesasymmetric information as the informativeness of trades declines after the announcement day. We further find the informativeness of trade decreases on days before the announcement in Europe only, on days before the announcement in Japan only, and on days before the day with both U.S. and European (Japanese) announcements, consistent with Meulbreok (1992) and Bhattacharya et al. (2000).

5. Conclusions

We study the impact of trade-related information shocks around days with and without macroeconomic announcements, and address howprice-relevant information is revealed through the channel of order flowin the FX market.Our result is consistent with Evans and Lyons (2002) and Evans and Lyons (2008),showing a high portion of private information is transmitted into asset prices via order flows, even on days of announcement releases.

Examining the difference of informativeness of order flow across sequential trading periods: Asian, European, the overlapping trading period of London and New York (London+NY), and U.S. trading periods, we identify the intraday pattern of informativeness of order flow. Comparing therelative amount of public and private informationcontent in order flow for each trading period, we find that order flow in overlapping trading hours of London and New York is more informative than those in the other three trading periods.

Furthermore, we further study the change of information content before and after the announcement. Examining news effects before and after the announcement day, wefind thatinformativeness of order flow is reduced on days afterthe announcement. However, a higher ratio of private information is revealed through order flowbefore the announcement day.

The purpose of this paper is to investigate the effect of foreign institutional trading activity on stock liquidity. Three dimensions of foreign institutional trading activity are associated with stock liquidity, institutional holdings, institutional herding and institutional aggressive/ passive trading. We apply dynamic panel generalized method of moments (GMM) estimation to deal with the two possibility sources of endogeneity: unobservable heterogeneity as well as dynamic relation between past stock liquidity and current foreign trading activity. We investigate whether foreign institutional trading activity facilitates stock liquidity using the GMM estimator based on a panel dataset of the Taiwan listed stocks monthly data between 2001 and 2012. Although foreign institutional holdings decrease stock liquidity, their net purchase does provide stock liquidity. Foreign institutional herding to buy provides stock liquidity; while their herding to sell deteriorates stock liquidity. Both aggressive and passive trading activities facilitate price impacts as measured by Amihud (2002). On the other side, their trading narrows the quoted spread as with higher stock returns and deteriorates liquidity as stock returns decrease.

Keywords: stock liquidity, foreign institutional trading, herding, passive trading, aggressive trading, endogeneity, dynamic panel GMM estimation.

1. Introduction

Financial liberalization to remove the foreign investment ceilings on common stocks in 2003 facilitates foreign institutional investors' participating in Taiwan stock market. Statistics from Taiwan Financial Supervisory Commission indicate that foreign institutional holding as a proportion of total market capitalization in Taiwan stock market increases from 6.99% in 2002 to 26.03% in 2012. Academic researchers and practitioners have devoted considerable efforts in analyzing the increasing impacts of foreign institutional holdings on stock liquidity (e.g. Rhee and Wang, 2009). It is expected that increased foreign institutional participation would reduce information asymmetry and increase stock liquidity. This study intends to investigate whether foreign institutional trading in Taiwan stock market facilitates stock liquidity.

The effects of foreign institutional participation are two-faced. Foreign institutional investments are recognized as benefits to local economies in that their trading lowers the cost of capital and enhances the firm value (e.g., Bekaert and Harvey, 2000; Ferreira and Matos, 2008). Alternatively, foreign investors may destablize local capital markets (Tesar and Werner, 1995; French and Poterba, 1991). It is noteworthy that previous literature was more about the impacts of foreign institutional trading on stock returns, but we know little about their impacts on stock liquidity in an emerging market like Taiwan. On the other side, the empirical studies by Chordia et al. (2000) and Kamara et al. (2008) found that institutional investing is critical to commonality in liquidity. Liang and Wei (2012) found that stocks with increased foreign institutional ownership subsequently experience higher liquidity. However, in an emerging market, Indonesia, Rhee and Wang (2009) found that foreign holdings had a negative impact on future liquidity, as measured by the bid-ask spread, depth and price sensitivity. One explanation to this negative impact contributes to information asymmetry. In emerging markets, the information asymmetry may be amplified due to foreign investors' participation in local firms. The company becomes "foreign" to local investors, which reduces liquidity. Empirical evidences regarding the impacts of foreign institutional holdings on stock liquidity are still in dispute and this paper will identify how foreign investors impact stock liquidity in Taiwan.

The other mechanisms through which stocks become more liquid are foreign institutional trading activities. Chen et al. (2008) proved that foreign institutional investors participating in Taiwan stock market do herd towards some particular stocks. Lai and Huong (2010) proposed that due to information advantages, foreign institutional herding lead individual investors to follow their trading so that stock liquidity improves. This raises our interests to investigate whether foreign institutional herding behavior in Taiwan affects stock liquidity. On the other side, Boehmer and Kelley (2009) classified foreign institutional trading into aggressive and passive strategies. If foreign institutional investors are better informed about the firms' fundamentals or about impending order flow, they need liquidity to trade in the appropriate direction and are identified as aggressive traders. Alternatively, if foreign institutional investors are able to recognize uninformed sellers as stock prices drop, they can gain by providing liquidity, which is identified as passive trading (e.g. Chan and Lakonishok, 1993; Boehmer and Kelly, 2009).

In sum, institutional trading strategies may impact on stock liquidity. To confine with the data availability in Taiwan stock market, we define the passive and aggressive trading strategies by foreign institutional investors in Taiwan stock market as what Boehmer and Kelley (2009) did. The direction of institutional trading relative to the current month's return is exploited. If foreign institutions end with a positive (negative) trade imbalance on negative (positive) return days, they are likely to provide liquidity in the market and result from a passive trading strategy. In contrast, if foreign institutions end with a positive (negative) trade imbalance on positive (negative) return days, they probably demand liquidity via an aggressive trading strategy. The impacts under different trading strategies are compared.

This paper is structured as follows. Section 2 describes the variables used in this paper and provides summary statistics of the data. Section 3 provides empirical models and results of our findings. We conclude our paper in Section 4.

2. Data

Our data consist in three datasets of TEJ (Taiwan Economic Journal) database for TWSE/GTSM stocks. The first one provides the daily stock trading summary, including daily stock returns, trading value and end-of-day bid and ask prices. The second one provides institutional trading activities, including institutional ownership level and change by the three main types of institutional investors (foreign institutional investors, mutual funds and proprietary traders), foreign institutional trading imbalances and the number of foreign institutional investors buying and selling for each stock. The third one provides the fundamentals of listing firms in Taiwan stock markets, including firm capitalization, book-to-market ratio and shares outstanding for each stock. The sample period is from January, 2001 to December, 2012.

2.1. *Liquidity Measures*

Literature focused on understanding the liquidity impacts from the microscope of market microstructure often uses high-frequency liquidity measures, such as the quoted bid-ask spread, quoted depth, and the effective bid-ask spread, etc. (e.g. Chordia et al., 2000, 2008; Boehmer and Kelley, 2009; Rhee and Wang, 2009). However, as mentioned by Amihud (2002), high-frequency measures require a lot of microstructure data that are not available in many stock markets. On the other side, Goyenko et al. (2009) run horseraces of some liquidity measures against the benchmarks and proved the illiquidity measure of Amihud (2002) does well measuring price impact. In this study, we use both the proportional quoted spread (Chordia et al., 2000) and price impacts (Amihud, 2002) as measures of stock (il)liquidity.

The proportional quoted spread (Chordia et al., 2000) is computed as a proportion of the end-of-day spread to the midpoint of the bid-ask price for each stock i and averaged it for each month m, denoted as . The price impact measure is from Amihud (2002), defined as the average ratio of the daily absolute return to the (dollar) trading volume on that day, . It follows that,

$$AMIHUD_{i,m} = 1/T_{i,m} \sum_{t=1}^{T_{i,m}} \left|R_{i,t,m}\right| / VOLD_{i,t,m} \qquad (1)$$

where is the return on stock i on day t of month m, is the respective daily trading value and is the number of days for which data are available for stock i in month m. It should be noted that both

SPREAD and AMIHUD are inverse measures of stock liquidity, so we denote both measures as ILLIQ to proxy for stock illiquidity.

2.2. *Foreign institutional trading activities*

We consider three activities involved by categories of foreign institutional trading, foreign institutional ownership, foreign institutional herding and their passive/ aggressive trading. Foreign institutional ownership as well as its change are widely used as proxies of foreign institutional trading activities (e.g. Kamara, et al., 2008; Boehmer and Kelley, 2009; Rhee and Wang, 2009). Our study uses monthly foreign institutional ownership (FOI) and its monthly change (DFOI) to proxy for foreign institutional trading activities.

On the other side, Sias et al. (2006) proposed that aggregate institutional trading may drive the correlation between changes in institutional ownership and same-quarter returns and there is a temporary liquidity component associated with institutional trading, which implies that institutional herding is associated with stock liquidity. According to Sias (2004), herding is defined as a group of investors following each other into (or out of) the same securities over some period of time. We define institutional herding based on the fraction of institutional investors trading the security i that are buyers, which is calculated as follows (Sias, 2004). The herding measure is denoted as HERD and we further separate the herding measures into institutional herding to buy (HERD>0.5) and institutional herding to sell (HERD<0.5).

$$HERD_{i,m} = \frac{number\_of\_institutional\_buyers_{i,m}}{number\_of\_institutional\_buyers_{i,m} + number\_of\_institutional\_sellers_{i,m}} \quad (2)$$

The other foreign institutional trading strategies associated with stock liquidity refer to the effects of institutional aggressive and passive trading strategies. Boehmer and Kelley (2009) exploit the direction of institutional trading relative to the current day's return to identify institutional trading strategy. Because negative (positive) return days arise due to overall selling (buying) pressure, institutional buying (selling) on negative (positive) return days results from institutional passive trading and is likely to provide liquidity. In contrast, if institutions trade in the same direction as the return, they probably demand liquidity via an aggressive trading strategy.

To confine with the data availability in Taiwan stock market, we define the passive and aggressive trading strategies by foreign institutional investors in Taiwan stock market as what Boehmer and Kelley (2009) did and exploit the direction of institutional trading relative to the current day's return. If foreign institutions end with a positive (negative) trade imbalance on negative (positive) return days, they are likely to provide liquidity in the market and result from a passive trading strategy. In contrast, if foreign institutions end with a positive (negative) trade imbalance on positive (negative) return days, they probably demand liquidity via an aggressive trading strategy. We denote institutional ownership for stock i when the passive trading is executed on positive (negative) return days as SellUp (BuyDown) and that when the aggressive trading is executed on positive (negative) return days as BuyUp (SellDown).

2.3. *Dynamic panel generalized method of moments (GMM) estimation*

In this paper, we focus on how foreign institutional trading activity affects market liquidity in Taiwan stock market. To investigate the relationship between market liquidity and foreign institutional trading activity, a dynamic panel-data with fixed effects model is constructed as follows.

$$ILLIQ_{i,m} = \alpha_i + \beta \cdot FIO_{i,m} + \delta \cdot ILLIQ_{i,m-1} + \sum_{k=1}^{K} \gamma_k \cdot X_{ki,m} + \varepsilon_{i,m} \quad (3)$$

where $ILLIQ_{i,m}$ is the measures of liquidity for stock *i* at time *m*. $FIO_{i,m}$ represents for foreign institutional trading activity. α_i is a firm fixed effect to capture the unobserved characteristic of firm. . ***X*** is a vector of observable firm-specific determinants of market liquidity, including the logarithm of market capitalization (*Ln(Size))*, stock price (Ln(Price)), volatility (Volatility), number of trades, trading size, a dummy of MSCI indexation, and the institutional holdings from two domestic institutional investors, mutual fund and securities traders (*MOI* and *SOI*).

Since the dependent ($ILLIQ_{i,m}$) and independent variables ($ILLIQ_{i,m-1}$) both depend on the unobserved time-invariant firm characteristic (α_i), it is obviously that covariance of independent variable and error term is not zero, leading an endogeneity problem. Basically, we can first-difference model (3) to remove the time-invariant fixed effect as follows:

$$(ILLIQ_{i,m} - ILLIQ_{i,m-1}) = \beta(FIO_{i,m} - FIO_{i,m-1}) + \delta(ILLIQ_{i,m-1} - ILLIQ_{i,m-2}) + \sum_{k=1}^{K} \gamma_k (X_{ki,m} - X_{ki,m-1}) + (\varepsilon_{i,m} - \varepsilon_{i,m-1})$$

However, the differenced lagged dependent variable remains correlated with the differenced error term. Without the fixed effect, the instrumental variables estimator with suitable instruments can be used to deal with this endogeneity problem. In practice, identifying and justifying a strictly exogenous instrument is very difficult. Anderson and Hsiao (1981) use the lagged differences of dependent variables ($ILLIQ_{i,m-2} - ILLIQ_{i,m-3}$), or $ILLIQ_{i,m-2}$ and $ILLIQ_{i,m-3}$ as instruments for ($ILLIQ_{i,m-1} - ILLIQ_{i,m-2}$). Arellano (1989) pointed out that $ILLIQ_{i,m-2}$ performs better for finite-sample properties. However, as Arellano and Bond (1991) and Ahn and Schmidt(1995) observed, there is still a lot of information can be used for estimation. Arellano and Bond (1991) use the all possible past dependent variables uncorrelated with differenced error term. Basically, the values of $ILLIQ_{i,m-2}$ lagged two periods or more can be used as valid instruments which are uncorrelated with the differenced error term. For example, for the period $m = 3$, we have

$$(ILLIQ_{i,3} - ILLIQ_{i,2}) = \beta(FIO_{i,3} - FIO_{i,2}) + \delta(ILLIQ_{i,2} - ILLIQ_{i,1}) + \sum_{k=1}^{K} \gamma_k (X_{ki,3} - X_{ki,2}) + (\varepsilon_{i,3} - \varepsilon_{i,2})$$

In this case, $ILLIQ_{i,1}$ is a valid instrument, it is correlated with $(ILLIQ_{i,2} - ILLIQ_{i,1})$ but uncorrelated with $(\varepsilon_{i,3} - \varepsilon_{i,2})$. Similarly, for the period $m = 4$, we have

$$(ILLIQ_{i,4} - ILLIQ_{i,3}) = \beta(FIO_{i,4} - FIO_{i,3}) + \delta(ILLIQ_{i,3} - ILLIQ_{i,2}) + \sum_{k=1}^{K} \gamma_k (X_{ki,4} - X_{ki,3}) + (\varepsilon_{i,4} - \varepsilon_{i,3})$$

But in this case $ILLIQ_{i,1}$ and $ILLIQ_{i,2}$ are valid instruments. Thus, for the period *M*, the valid instruments are $ILLIQ_{i,1}$, $ILLIQ_{i,2}$, $\cdots$, and $ILLIQ_{i,M-2}$. The previous argument implies the following $(M-2)(M-1)/2$ moment conditions:

$$\mathrm{E}\{ILLIQ_{i,m-s}(\varepsilon_{i,m} - \varepsilon_{i,m-1})\} = 0, \quad s = 2, 3, \ldots, M-1; \; m = 3, 4, \ldots, M \qquad (4)$$

For each stock *i*, we can define the instruments matrix $\mathbf{Z}_i$ as follows:

$$\mathbf{Z}_i = \begin{pmatrix} [ILLIQ_{i,1}] & & & 0 \\ & [ILLIQ_{i,1}, ILLIQ_{i,2}] & & \\ & & \ddots & \\ 0 & & & [ILLIQ_{i,1}, ILLIQ_{i,2}, \ldots, ILLIQ_{i,T-2}] \end{pmatrix}$$

here $\mathbf{Z}_i$ is a $(M-2)$ by $(M-2)(M-1)/2$ matrix. Now, we rewrite (a5) expressed in vector form:

$$\mathbf{Y}_i = \mathbf{X}_i \boldsymbol{\beta} + \mathbf{e}_i \qquad (5)$$

where $\mathbf{Y}_i$ is a $(M-2)\times 1$ vector defined as $(\Delta ILLIQ_{i,3}, \; \Delta ILLIQ_{i,4}, \; \cdots, \; \Delta ILLIQ_{i,M})'$ and Δ is the first-difference operator. $\mathbf{X}_i$ is a data matrix of all explanatory variables defined as $(\Delta\mathbf{FIO}_i \;\; \mathbf{Y}_i^{-1} \;\; \Delta\mathbf{X}_{ki})$ with $\Delta\mathbf{FIO}_i$ and $\mathbf{Y}_i^{-1}$ are both $(M-2)\times 1$ vectors defined as $(\Delta FIO_{i,2}, \; \Delta FIO_{i,4}, \; \cdots, \; \Delta FIO_{i,M-1})'$ and $(\Delta ILLIQ_{i,2}, \; \Delta ILLIQ_{i,3}, \; \cdots, \; \Delta ILLIQ_{i,M-1})'$, respectively. $\Delta\mathbf{X}_{ki}$ is a data matrix of control variables. $\boldsymbol{\beta}$ is a parameters vector of interest. $\mathbf{e}_i$ is a $(M-2)\times 1$ vector defined as $(\Delta\varepsilon_{i,3}, \; \Delta\varepsilon_{i,4}, \; \cdots, \; \Delta\varepsilon_{i,M})'$.

Similarly, we can rewrite the previous moment conditions expressed in vector form as follows:

$$E(\mathbf{Z}_i^{'}\mathbf{e}_i) = E\left\{\sum_{t=1}^{T}\mathbf{Z}_i^{'}(\mathbf{Y}_i - \mathbf{X}_i\boldsymbol{\beta})\right\} = 0, \ \ i = 1, 2, \ldots, \ \ N. \quad (6)$$

and its sample analog is $1/N\sum_{i=1}^{N}\mathbf{Z}_i^{'}\mathbf{e}_i$. Arellano and Bond (1991) estimate (5) using GMM estimator based on the moment conditions (6). We can apply the two-stage least-squares (2SLS) estimator with instruments $\mathbf{Z}_i$ to estimate $\boldsymbol{\alpha}$ as follows:

$$\hat{\boldsymbol{\beta}}_{2SLS} = \left[\left(\sum_{i=1}^{N}\mathbf{X}_i^{'}\mathbf{Z}_i\right)\left(\sum_{i=1}^{N}\mathbf{Z}_i^{'}\mathbf{Z}_i\right)^{-1}\left(\sum_{i=1}^{N}\mathbf{Z}_i^{'}\mathbf{X}_i\right)\right]^{-1}\left[\left(\sum_{i=1}^{N}\mathbf{X}_i^{'}\mathbf{Z}_i\right)\left(\sum_{i=1}^{N}\mathbf{Z}_i^{'}\mathbf{Z}_i\right)^{-1}\left(\sum_{i=1}^{N}\mathbf{Z}_i^{'}\mathbf{Y}_i\right)\right] \quad (7)$$

and obtain the sample residuals $\hat{\mathbf{e}}_i$. Then, compute the weight matrix $\widehat{\mathbf{W}}$ for GMM estimator based on those residuals as follows:

$$\widehat{\mathbf{W}} = \left[\frac{1}{N^2}\left(\sum_{i=1}^{N}\mathbf{Z}_i^{'}\hat{\mathbf{e}}_i\hat{\mathbf{e}}_i^{'}\mathbf{Z}_i\right)\right] \quad (8)$$

The GMM estimator based on the moment conditions (6) minimizes the quadratic function:

$$Q(\boldsymbol{\beta}) = \left[\sum_{i=1}^{N}\mathbf{Z}_i^{'}(\mathbf{Y}_i - \mathbf{X}_i\boldsymbol{\beta})\right]\widehat{\mathbf{W}}^{-1}\left[\sum_{t=1}^{T}\mathbf{Z}_i^{'}(\mathbf{Y}_i - \mathbf{X}_i\boldsymbol{\beta})\right] \quad (9)$$

The GMM estimator that minimizes this quadratic function (9) is obtained as

$$\hat{\boldsymbol{\beta}}_{GMM} = \left[\left(\sum_{i=1}^{N}\mathbf{X}_i^{'}\mathbf{Z}_i\right)\widehat{\mathbf{W}}^{-1}\left(\sum_{i=1}^{N}\mathbf{Z}_i^{'}\mathbf{X}_i\right)\right]^{-1}\left[\left(\sum_{i=1}^{N}\mathbf{X}_i^{'}\mathbf{Z}_i\right)\widehat{\mathbf{W}}^{-1}\left(\sum_{i=1}^{N}\mathbf{Z}_i^{'}\mathbf{Y}_i\right)\right] \quad (10)$$

2.4. *Summary Statistics*

Following Chordia et al. (2000), Amihud (2002) and Kamara et al. (2008), we filter the data according to the criteria below. First, the liquidity measure, AMIHUD, is calculated only for positive trading values (VOLD) and non-missing, non-zero stock returns (R). Second, we exclude the stocks traded at a price less than the par value of common stock in Taiwan (NT$10). Third, we trim off the outliers of liquidity measure, AMIHUD, in the lowest and highest 1% percentiles and multiply the measure by 10^6, performed in Amihud (2002) and Lesmond (2005). Fourth, the proportional quoted spread is calculated only for non-missing, non-zero midpoint of end-of-day bid-ask prices. Finally, we include the stock in our sample only if the stock has at least 10 valid observations each month after applying the previous filters.

There are 109,008 firm-month observations and on average, there are 757 sample firms for each month over our sample period. Table 1 provides a sketch of stock illiquidity and institutional investing in Taiwan from January, 2001 to December, 2012. The price impact measure of illiquidity, AMIHUD is much more volatile than the spread measure, SPREAD. The average foreign institutional ownership is almost 5 times more than that held by mutual funds and 9 times more than that held by proprietary traders. The average change of institutional ownership is 0 for three types of investors, indicating that the proportion of institutional buying may cancel off that of institutional selling.

To investigate whether foreign institutional trading facilitates stock liquidity, we use 2012 data to rank institutional ownership (both holding level and its relative change) and the controlling variables, firm capitalization and book-to-market ratio from the lowest quintile to the highest one as shown in Table 2. For each quintile, we present the average illiquidity measures, AMIHUD and SPREAD. As both SPREAD and AMIHUD are inverse measures of stock liquidity, the smaller the measures, the more liquid the stocks are. The results of t-test on the null hypothesis that for each independent variable, the stock illiquidity in the highest quintile (Q5) does not differ from that in the lowest (Q1) quintile are presented. Some insights are found as follows. First, except for the facet of foreign institutional holding level (FOI), we find that stock liquidity monotonically increases with the holding levels of domestic institutional investors (mutual funds, MOI and proprietary traders, SOI) and firm size, but decreases with the book-to-market ratio. For these facets, stock liquidity in the two extreme quintiles statistically differs, implying that stock liquidity may be associated with institutional trading, firm's size and firm's growth. Furthermore, as we observe the changing facets of institutional holdings (DFOI, DMOI, and DSOI), the most liquid stocks fall on the two extreme quintiles where stocks are most actively sold (Q1) and bought (Q5). For the changing facets of foreign institutional investors and proprietary traders, stock liquidity in the most-buying quintile is statistically higher than that in the most-selling quintile, implying stock liquidity is more likely to be associated with institutional buying.

3. Empirical Results

3.1. *Does Foreign Institutional Ownership Impact on Stock Liquidity?*

As investigating whether foreign institutional ownership impacts on stock liquidity in Taiwan, one may argue that stock liquidity may simultaneously attract institutional trading; i.e. the relationship between foreign institutional trading and stock liquidity may be endogenous. One cannot estimate one-way relationship without dealing with the endogenous problem. On the other hand, as the lagged term of stock liquidity is considered in our estimated model, one cannot bypass the correlation between the regressors and the error term since the lagged term of stock liquidity depends on the residual terms, which is a function of the firm specific effect. Due to this correlation, the dynamic panel data estimation suffers from Nickell's (1981) bias problem. Several econometric techniques have developed to correct the bias, including instrumental variables, generalized method of moments (GMM) estimators, long differencing, and bias correction formulae. Flannery and Hankins (2013) demonstrate that the Blundell and Bond's system GMM estimator (1998) is reliable regardless of the level of endogeneity or dependent variable persistence. Taking both endogeneity and bias problems into consideration, we construct our model as follows and the associated coefficients are estimated by using the Blundell and Bond's system GMM,

$$ILLIQ_{i,m} = \alpha_i + \tau_m + \beta \cdot FIO_{i,m} + \delta \cdot ILLIQ_{i,m-1} + \sum_{k=1}^{K} \gamma_k \cdot X_{ki,m} + \varepsilon_{i,m} \tag{11}$$

where ILLIQ represents for the measures of stock illiquidity, SPREAD and AMIHUD. FIO represents for foreign institutional ownership and we use foreign institutional holding level and the monthly change of foreign institutional ownership (FOI and DFOI) to identify the effects from foreign institutional trading. X represents for the controlling variables, including the market capitalization (Ln(Size)), the book-to-market ratio (BM) and the institutional holdings from two domestic institutional investors, mutual fund and proprietary traders (MOI, DMOI, SOI and DSOI).

Model (3.1) in Panel A of Table 3 uses institutional holding level (FOI, MOI and SOI) to investigate the effects of institutional trading on stock liquidity as measured by Amihud (2002) and the proportional quoted spread (SPREAD). The results indicate that both AMIHUD and SPREAD increase as foreign institutional investors' holding levels increase, indicating a decrease in stock liquidity as foreign institutional holdings increase. Since the average foreign institutional ownership is almost 5 times more than that held by mutual funds, the higher the proportion of stocks preserved in foreign institutional portfolios, the less free floats of the stocks traded in the stock market, leading illiquidity of the stock. As observed in the preliminary statistics, stocks of large firm size are more liquid, but stocks with high book-to-market ratios are less liquid. Stock liquidity also varies with time and firm characteristics.

As institutional ownership level reveals institutional interests to preserve stocks in their portfolios in the long run, the change of institutional ownership reveals the net purchases or sales of stocks some moment in time. Model (3.2) uses the change of institutional ownership to investigate the effects of foreign institutional short-term trading. We find that foreign institutional short-term trading does narrow the quoted spreads of stocks, which facilitates stock liquidity in Taiwan; while it brings no effects on the price impact measured by AMIHUD. Domestic institutional trading of mutual funds and proprietary traders does not provide stock liquidity, either.

Since the average change of foreign institutional ownership (DFOI) mixes up foreign institutional buying and selling effects, we further divide our sample into two subsamples, foreign institutional net buying (DFOI>0) and net selling (DFOI<0) and run the Blundell and Bond's system GMM as models (3.3) and (3.4). We find that foreign institutional buying does facilitate stock liquidity in Taiwan. However, the coefficient of DFOI, -0.2740 in Model (3-4) of Panel B indicates that foreign institutional selling increases the quoted spread, which decreases stock liquidity. On the other hand, mutual funds' buying activities also facilitate stock liquidity here. But, it is beyond the market's expectations that proprietary traders' trading has no effects on stock liquidity in our study. This may be due to their relatively low trading volumes as compared with those of foreign institutional investors and mutual funds. The effects from two controlling variables are consistent, where the larger (smaller) the firm size (book-to-market ratio), the more liquid the stock.

3.2. *Does Foreign Institutional Herding Behavior Provide Stock Liquidity?*

Literature on the relationship between institutional herding and stock liquidity lays particular stress on whether stock liquidity attracts institutional herding (e.g. Sias, 2004; Cremer and Nautz; 2013). However, few have ever investigated the impacts of institutional herding on stock liquidity. Chen et al. (2008) proved that foreign institutional investors participating in Taiwan stock market do herd towards some particular stocks. Except for institutional holding, we further investigate whether institutional intents to trace the same stock facilitate stock liquidity by adding herding measure (HERD) for stock i to equation (11), taking institutional ownership levels as the controlling variables.

$$ILLIQ_{i,m} = \alpha_i + \tau_m + \beta \cdot FIO_{i,m} + \eta \cdot HERD_{i,m} + \delta \cdot ILLIQ_{i,m-1} + \sum_{k=1}^{K} \gamma_k \cdot X_{ki,m} + \varepsilon_{i,m} \qquad (12)$$

To identify whether institutional herding to buy or to sell is related to greater stock liquidity, we divide our sample into two subsamples each month. The first subsample includes stocks with the herding measure (HERD) larger than 0.5, which represents a subsample with institutional herding to buy. The other subsample includes stocks with the herding measure (HERD) less than 0.5, which represents a subsample with institutional herding to sell. We then perform the Blundell and Bond's system GMM to estimate the associated coefficients in equation (12).

Table 4 reports the impacts of institutional herding on stock liquidity as taking endogeneity problem into consideration. The result in the subsample of HERD>0.5 indicates that foreign institutional herding to buy reduces both the price impacts and the quoted spreads, which does facilitate stock liquidity. However, the negative coefficients of HERD in the subsample of HERD<0.5, -57.9784 and -0.0604, indicate a decrease in stock liquidity as foreign institutional investors herd to sell.

3.3. *Does Foreign Institutional Passive/ Aggressive Trading Matter with Stock Liquidity?*

Boehmer and Kelley (2009) suggested that negative (positive) return days arise due to overall selling (buying) pressure. Thus, institutional buying (selling) on negative (positive) return days may result from institutional passive trading, which is likely to provide liquidity. On the contrary, if institutions trade in the same direction as the return, they probably demand liquidity via an aggressive trading strategy. We calculate foreign institutional imbalances for stock i when the passive trading is executed on positive (negative) return months as SellUp (BuyDown) and those when the aggressive trading is executed on positive (negative) return months as BuyUp (SellDown) and perform the Blundell and Bond's system GMM to estimate the associated coefficients in equation (13), taking institutional ownership levels as controlling variables.

$$\begin{aligned} ILLIQ_{i,m} &= \alpha_i + \tau_m + \beta \cdot FIO_{i,m} + \zeta_1 \cdot SellUp_{i,m} + \zeta_2 \cdot BuyDown_{i,m} \\ &\quad + \zeta_3 \cdot BuyUp_{i,m} + \zeta_4 \cdot SellDown_{i,m} + \delta \cdot ILLIQ_{i,m-1} + \sum_{k=1}^{K} \gamma_k \cdot X_{ki,m} + \varepsilon_{i,m} \qquad (13) \end{aligned}$$

Table 5 reports the impacts of foreign institutional passive/ aggressive trading strategies on stock liquidity. We find that foreign institutional trading is related to smaller price impact as measured by Amihud (2002) regardless of whether trading strategies are passive or aggressive, indicating that no matter stock prices go up or down, foreign institutional investors provide stock liquidity on the one hand, but they also need liquidity. We also find that on the negative return days, foreign institutional trading widens quoted spreads. It is possible that on negative returns, foreign institutional investors quote at a relatively low price to buy and a relatively high price to sell, leading a larger spread on the negative return days.

4. Conclusion

Financial liberalization to lift foreign investment ceilings on the common stocks in 2003 facilitates foreign institutional investors' participating in Taiwan stock market. Foreign institutional holding as a proportion of total market capitalization in Taiwan stock market increases from 6.99% in 2002 to 26.03% in 2012. It is expected that increased foreign institutional participation would reduce information asymmetry and increase stock liquidity. This paper investigates whether foreign institutional trading in Taiwan stock market facilitates stock liquidity.

We apply the proportional quoted spread (Chordia et al., 2000) and price impact of Amihud (2002) as stock illiquidity measures and find that foreign institutional ownership level decreases stock liquidity. It is intuitive since the higher the proportion of stocks preserved in institutional portfolios, the less the free floats of the stocks available to be traded in the stock market, leading to stock illiquidity. However, foreign institutional ownership change decreases the quoted spreads of stock, indicating an improvement on stock liquidity. As we divide our sample into two subgroups, we find that foreign institutional buying does facilitate stock liquidity, but their selling increases the quoted spread, which decreases stock liquidity.

Furthermore, we identify two types of foreign institutional trading strategies, herding and passive/ aggressive trading and examine whether these strategies facilitate stock liquidity. Foreign institutional herding is defined as the proportion of the number of foreign investors buying to the total number trading the same stock. We find that their herding to buy reduces both the price impacts and the quoted spreads, which does facilitate stock liquidity. However, a decrease in stock liquidity is found as foreign institutional investors herd to sell.

As suggested by Chan and Lakonishok (1993) and Boehmer and Kelly (2009), institutions can gain by trading passively if they have superior ability to recognize that sellers in the market are uninformed. In such a case, institutional investors are identified as passive traders. On the other side, if institutions have private information about the firms' fundamentals or about impending order flow, they need liquidity to trade in the appropriate direction and are identified as aggressive traders. In this study, we examine whether foreign institutional passive/ aggressive trading is associated with stock liquidity. The results indicate that foreign institutional trading is related to greater stock liquidity regardless of the trading strategy.

This table reports the summary statistics of stock illiquidity and institutional investors' trading activity over the period from January, 2001 to December, 2012. For each firm, we require a minimum of ten monthly observations. Here, both *SPREAD* and *AMIHUD* are inverse measures of stock liquidity. *SPREAD* is the effective spread and *AMIHUD* is the monthly illiquidity measure proposed by Amihud (2002). The foreign institutional ownership (*FOI*) as well as its change (*DFOI*) are widely used as proxies of institutional investor' trading activities. *D* indicates the change during the current month. *MOI*, *ΔMOI*, *SOI* and *ΔSOI* are the institutional holdings from two domestic institutional investors, mutual fund and securities dealers, respectively.

Table 2 Summary Statistics of Stock Illiquidity Based on the Ranking of Institutional Investors' Trading Activities

This table reports stock illiquidity based on the ranking of institutional investors' trading activities from the lowest quintile (Q1) to the highest quintile (Q5) in 2012. *SPREAD* and *AMIHUD* are inverse measures of stock liquidity. The foreign institutional ownership (*FOI*) as well as its change (*DFOI*) are widely used as proxies of institutional investor' trading activities. *D* indicates the change during the current month. *MOI*, *DMOI*, *SOI* and *DSOI* are the institutional holdings from two domestic institutional investors, mutual fund and securities dealers, respectively. *Size* and *BM* are respectively the market capitalization and book-to-market. The column of Q5-Q1 reports the results of t-test on the null hypothesis that institutional ownership in Q1 does not differ from that in Q5. Statistical significance at 10%, 5% and 1% is denoted by *, ** and ***, respectively.

This table reports the results of foreign institutional herding behavior (*HERD*) on the stock liquidity from panel-data regression with firm and year effects from January, 2001 to December, 2012. Estimations are performed using Blundell and Bond (1998) system GMM estimator. *AMIHUD* and *SPREAD* represent for the measures of monthly stock illiquidity. *FOI* is the monthly foreign institutional ownership to proxy for foreign institutional trading activities. Lag indicates a value lagged by one month. Ln*Size* and *BM* are respectively the natural logarithm of market capitalization and book-to-market ratio. *MOI* and *SOI* are the institutional holdings from two domestic institutional investors, mutual fund and securities dealers, respectively. Here, we divide the sample into two subsamples each month. The first subsample includes stocks with the herding measure (*HERD*) larger than 0.5, which represents a subsample with institutional herding to buy. The other sample includes stocks with the herding measure less than 0.5, which represents a subsample with institutional herding to sell. The numbers in parenthesis are the t statistics. Statistical significance at 10%, 5% and 1% is denoted by *, ** and ***, respectively. AR(1) and AR(2) are the p-values for first and second order autocorrelated disturbances in the first differences equations.

This study examines the impact of board characteristics on bank performance and risk-taking behavior during the financial crisis and non-financial crisis periods, using a sample of 59 U.S. commercial banks and savings banks during 2000 to 2013. The empirical findings indicate that board structure does affect bank performance and their risk-taking behavior at different performing banks. For high-performing banks, CEO duality would decrease bank's market performance either in crisis or non-crisis period, and it would also decrease market volatility. For low-performing banks, board structure plays more significant effect on bank performance and bank risks than it does on high-performing banks either crisis or non-crisis period. We find that independent board, CEO duality and board size have significantly positive effects on low-performing bank performance, but only CEO duality stays its influence in bank performance during financial financial tsunami of 2008. Moreover, board size, CEO duality and independent board have significantly negative effects on low-performing bank risks and only board size stay its significant influence in bank risks during financial tsunami.

Keywords：Bank Performance, Risk-taking, Board structure, Financial Crisis

1. Introduction

Since the Asian Financial crisis in year of 1997, the issue of corporate governance has been extensively addressed not only in the related research of financial studies but also in the practice of corporate business.

Corporate governance has been defined by several organizations, for instance, Organization for Economic Co-operation and Development, Basel Committee, World Bank, and so on. According to the Organization for Economic Co-operation and Development (OECD), corporate governance is defined as the protection between shareholders' rights and stakeholders' rights, fairness to all shareholders, board of directors' responsibilities, financial disclosure, and financial transparency. According to the Basel Committee, the role of corporate governance in banking industry is used to emphasize on the roles of management and board of directors (especially independent directors), effective management to reduce conflicts, internal and external audit, governance transparency, and importance of regulations. Moreover, World Bank proposes the structure of corporate governance in 1999, including internal governance and external governance. It asserts that board of directors should ensure information and management transparency, managers and board of directors should balances stakeholders rights and fairness. However, internal governance might involves moral hazard problems, external governance (ex: regulations) also plays an important role to improve the effectiveness of governance and thereby maximizes the value of a firm.

The definition and scope of corporate governance varied with the industries. In general, the board of director plays a key role in the corporate governance. The Sarbanes-Oxley Act (SOX) at year of 2002 mandated strict reforms to improve function of corporate governance for US-listed firms, it emphasizes the independence of auditing committee and board of director to enhance the financial transparency in order to achieve better shareholder's protection. This motivates to examine the impact of board structure on firm performance in this study.

The subprime crisis in 2008 heavily deteriorated bank performance due to high risk loan and high leverage operation, and the financial globalization speeded up the shocks to the other countries. Past literature has discussed the risk-taking behavior from different perspectives, for example, bank regulatory capital (Distinguin et al., 2013), ownership structure (Knyazeva et al., 2013), market discipline (Cubillas et al., 2012). Thus, the risk-taking behavior in banks that is seldom addressed in current literature deserves further investigation, especially in the role of board structure to bank's risk-taking.

This study focuses on the influence of board structure in bank performance and risk-taking behavior, and compares the different influences between crisis period of 2008 and non-crisis period, using a sample of U.S. commercial banks and savings banks during 2000 to 2013. The empirical findings indicate that board structure does affect bank performance and their risk-taking behavior at different performing banks. For high-performing banks, CEO duality would decrease bank's market performance either in crisis or non-crisis period, and it would also decrease market volatility. For low-performing banks, board structure plays more significant effect on bank performance and bank risks than it does on high-performing banks either crisis or non-crisis period. We find that independent board, CEO duality and board size have significantly positive effects on low-performing bank performance, but only CEO duality stays its influence in bank performance during financial financial tsunami of 2008. Moreover, board size, CEO duality and independent board have significantly negative effects on low-performing bank risks and only board size stay its significant influence in bank risks during financial tsunami.

2. Literature review and hypothesis establishments

Changes of corporate governance at banks during past decades substantially altered the governance of banking organization. Adams and Mehran (2003) has documented the difference of corporate governance, especially in board structure, between US banking holding companies and manufactured firms. How does these changes in corporate governance affect bank performance and risk-taking behavior needs to be further addressed.

2.1 The impact of board structure on bank performance

Adams and Mehran (2003) pointed out that average board size of US BHC (bank holding company) during 1986 to 1999 is 18 directors on the board which is significantly higher than that in manufactured firms of 12 directors. Will larger board size improve bank performance ? Most literature indicated that there existed positive relationship between board size and firm performance (Dalton et al. ,1999; Mak and Li ,2001;Kiel and Nicholson,2003;Dalton and Dalton,2005). Andres and Vallelado (2008), using firm sample of six OECD countries, think larger board size would enhance firm performance due to various background and professional knowledge from larger board; the optimal board size is 19 directors in the board. They also found the inverse U shape relationship between bank performance and board size. Aebi, Sabato and Schmid (2012) also supported the positive relationship between board size and US bank performance during financial crisis.

Based on above, we establish the following hypotheses.

H_{1a} : The board size has positive effect on bank performance.

H_{1b}: The board size has positive effect on bank performance in financial crisis.

2.2 The impact of CEO duality on bank performance

Past literature have proposed that dual role of CEO also serving the president of the board plays certain influence on the firm performance. Fama and Jensen (1983) and Jensen (1993) think that CEO duality would weaken the independent monitoring of the board. However, according to Boyd (1995), CEO duality helps efficient decision making to improve firm performance in financial crisis, thus, the positive relationship between CEO duality and firm performance exists during financial distress period. Thus, we establish the following hypotheses.

H_{2a}: CEO duality has negative effect on bank performance.

H_{2b}: CEO duality has positive effect on bank performance during financial crisis.

2.3 The impact of independent board on bank performance

The function of independent board is to mitigate the potential opportunism of CEO so as to decrease the interest conflicts between managers and shareholders (Crespí-Cladera and Pascual-Fuster, 2013). Lee, Rosenstein and Wyatt(1999) and Byrd and Hickman (1992) also supported the positive relation between independent director and firm performance.

Whether above positive relation between independent director and firm performance exists during financial distress period had been barely documented. Francis et al. (2012) investigated the influence of corporate governance in firm performance. They found that firm performance during crisis period which is measured by accumulated stock return during crisis could be improved by higher ratio of independent director in the board. Based on above, we establish the following hypotheses.

H_{3a} : The board independence has positive effect on bank performance.

H_{3b} : The board independence has positive effect on bank performance during financial crisis.

This research is designed to test the relation between board characteristics and bank performance. Considering the higher risk-taking followed by greater profitability, we examine above hypotheses by measuring bank performance in terms of both bank performance and risk-adjusted bank performance.

2.4 The impact of board size on bank risks

Whether agency problems between management and shareholders with respect to risk-taking behavior may also vary with the bank's board characteristics. Past literature has documented whether bank risk-taking varies with bank's ownership structure (leaven and Levine, 2009; Jensen and Meckling, 1976) and with managerial incentives (Coles, Naveen and Naveen, 2006). Yet, few research has assessed how board structure shapes the risk taking behavior of banks. The way to meet capital requirement is either to reduce risk-taking incentives of banks by restricting banks from engaging in nonlending activities, such as securities and insurance underwriting or to raise bank capital. Some research suggested that loss for bank shareholders from stringent capital requirements might intensify shareholder's risk-taking incentives(Koehn and Santomero, 1980; Buser, Chen, and Kane,1981). We would investigate the role of board characteristics in the agency problems between management and shareholders with respect to bank risk-taking behavior in this study.

Pathan (2009) show the significantly positive relation between strong board and risk-taking behavior, that is, risk control capability is stronger for strong board in terms of smaller board, higher ratio of independent directors. Accordingly, we establish the following hypotheses.

H_{4a} : The board size has negative effect on bank's risk-taking behavior.

H_{4a} : The board size has negative effect on bank's risk-taking behavior during financial crisis.

2.5 The impact of CEO duality on bank risk

Amihud and Lev(1981),Pathan(2009),Castañer and Kavadis (2013) suggested the negative relation between CEO power and bank risk management. CEO power is measured by CEO duality and whether internally hired. The wealth of dual CEO is less likely to be diversified, considering the expected value of debt tax shield and bankrupt costs(Parrino et al., 2005), CEO would choose to be a risk-averter to avoid the wealth loss. Castañer and Kavadis (2013) indicated that dual CEO tends to decrease risk exposure in the way of diversification. However, Ferrero et al. (2012) presents insignificant relation between dual CEO and risk-averse in S&P500 firms during 2008 financial financial tsunami. Even though, we argue that dual CEO would help reduce bank's risks during financial crisis. Accordingly, we establish the following hypotheses.

H_{5a} : The dual CEO has a negative impact on bank risks.

H_{5b} : The dual CEO has a negative impact on bank risks during financial crisis.

2.6 The impact of independent board on bank risks

Fredrickson, Hambrick and Baumrin(1988), Connors(1989), Baysinger and Hoskisson(1990) indicated that independent board could effectively monitor CEO's decision making in the development of firms. Also, Ferrero, Izquierdo and Torres (2012) show that higher ratio of independent directors on the board could restrict over risk-taking during financial financial tsunami of 2008. Accordingly, we establish the following hypotheses.

H_{6a} : The independent board has a negative impact on bank's risk-taking.

H_{6b} : The independent board has a negative impact on bank's risk-taking during financial crisis.

3. Research methodology

3.1 sample description

We examine the impact of board structure on both bank performance and risks by using pooled sample of 59 US commercial banks during 2000 to 2013. The financial information and board structure data are obtained from Bankscope, Execucomp and U.S. Securities. Board information are hand-collected from Exchange Commission website.

3.2 Empirical model

The empirical models are established as follow.

$$perform_{it} = \beta_0 + \beta_1 bosize_{it} + \beta_2 indepr_{it} + \beta_3 dual_{it} + \beta_4 lnass_{it} + \beta_5 debt_{it} + \beta_6 liqratio_{it} + \beta_7 capratio_{it} + \beta_8 yeardum_{it} + \beta_9 intbosz_{it} + \beta_{10} intdual_{it} + \beta_{11} intyrind_{it} + \varepsilon_{it}$$

Where i=1,...,N , t=1,...,T (1)

$$risk_{it} = \beta_0 + \beta_1 bosize_{it} + \beta_2 indepr_{it} + \beta_3 dual_{it} + \beta_4 lnass_{it} + \beta_5 debt_{it} + \beta_6 liqratio_{it} + \beta_7 capratio_{it} + \beta_8 yeardum_{it} + \beta_9 intbosz_{it} + \beta_{10} intdual_{it} + \beta_{11} intyrind_{it} + \varepsilon_{it}$$

Where i=1,...,N , t=1,...,T (2)

Variable definition:

Dependent variables:

$perform_{it}$ is measured by ROA, ROE and one-year stock return (RET1YE).

$risk_{it}$ is measured by the standard deviation of performance of three-year at t, t-1 and t+1,VOLROA, VOLROE, and VOLRET.

Independent variables:

Board structure is measured by board size (BOSIZE), dual role of CEO (DUAL) and the ratio of independent directors (INDEPR).

(1) BOSIZE：number of directors on the board

(2) DUAL：1 if CEO also serves as the president of the board, otherwise, it is 0

(3) INDEPR： the ratio of independent directors on the board

(4) Yeardum：1 if the sample year is equal to 2008 or 2009, otherwise, it is 0

(5) Intbosz：interaction term of Yeardum and BOSIZE

(6) Intdual：interaction term of Yeardum and DUAL

(7) Intyrind：interaction term of Yeardum and INDEPR

Control variables

(1) CAPRATIO：bank's capital divided by total risky assets

(2) lnass：logarithm of total Assets。

(3) DEBT：total debt divided by total assets

(4) LIQRATIO：total liquidity assets divided by total assets

4. Empirical results

4.1 Descriptive statistics

Table 4.1 show the descriptive statistics of all variables. Panel A is the measure of bank performance with mean ROA of 0.89%, ROE of 8.15% and RET1YE of 8.94%, and the mean ADJROA of 11.04%, ADJROE of 11.55% and ADJRET of 8.94%. Panel B show the bank risks, both ROE and RET1YE have greater volatilities than that in ROA. We also list the performance and risks before, during and after financial financial tsunami year defined as year of 2008 and 2009. In general, we find the performances before and after financial tsunami year are better than that in financial tsunami year; and the risk of financial tsunami year is much higher than that before and after financial crisis. Comparing performance and risks before and after financial tsunami year, we find the performance is generally higher and risks is lower before crisis than those after crisis.

There is around 60% of the sample with CEO duality, and mean board size is 25 showing banks with greater board size. The average ratio of independent directors is 79%.

Note: ROA is EBIT divided by total assets; ROE is EBIT divided by total equity value; RET1YE is one year stock return; VOLROA is the standard deviation of ROA at year t-1,t, t+1; VOLROE is the standard deviation of ROE at year t-1,t, t+1; VOLRET is the standard deviation of RET1YE at year t-1,t, t+1; DUAL is one if CEO also serving as the president of the board, otherwise, 0; BOSIZE is the total number of directors on the board; INDEPR is the ratio of independent directors to board size; Asset is logarithm of total assets (in thousands dollars); DEBT is total debt divided by total assets; LIQRATIO is total liquid assets divided by total assets; CAPRATIO is total capital divided by total risky assets.

4.2 Empirical results

All regression analyses are results of robust adjusted regressions. In section 4.2.1, Table 4.2 and 4.3 present the results for both bank performance and bank risks respectively. In section 4.2.2, the high and low bank performance empirical results are shown in Table 4.4, 4.5, 4.6 for high-performing banks and in Table 4.7,4.8 and 4.9 for low-performing banks.

4.2.1 Board structure, performance, and risk

From Table 4.2, we find that CEO duality has a significantly positive effect on bank performance in terms of ROA and ROE while they become insignificant after adjusting the risks, implying the risk increasing with higher performance. Board size has a significantly positive effect on adjusted ROA only. The independent board doesn't present any influence in bank performances. Therefore, H_{2a}, H_{2b}, H_{3a}, H_{3b} are not confirmed in this study. Taking a look at the results on financial crisis, we find bank performance does show significantly lower at ROA and ROE during financial tsunami (Yeardum), but, the adjusted performance presents to be insignificant which again might be due to the high volatilities during financial tsunami. As to the effect of board on bank performance during crisis period, we only find board size has significantly negative effect on adjusted stock return, meaning larger board size during crisis period would deteriorate bank adjusted performance. Most hypotheses for crisis period cannot be confirmed. We think the insignificant results might be because the cross out effects between high and low performance. Therefore, we further try to explore the analysis by dividing sample into high and low performance group based on median value of bank performance. Those results are shown in section 4.2.2 later.

Table 4.3 reveals the results of board effect on bank risks. We find significantly positive effect of board size on bank risks in terms of ROA volatility, that is, larger board help mitigate bank risks, confirming H_{4a}. Besides, CEO duality also shows significantly negative influence in stock volatility, confirming H_{5a}. During financial tsunami, there is not any board characteristics shown significant effects on bank risks.

In summary, we cannot find consistently significant results of the board structure on bank performance or banks risks from whole sample. However, we argue that the insignificant results might be because the cross out effects between high and low performance. Thus, we further examine the same issue by using high-performing and low-performing banks sample next in section 4.2.2.

4.2.2 Regression analyses for high-performing and low-performing banks

We further examine the same issue by using median value of bank performance to further separate sample into high-performing and low-performing banks. Table 4.4, 4.5 and 4.6 show the results for sample of high-performing banks, Table 4.7 to 4.9 for sample of low-performing banks. Table 4.4 presents performance results of both basic models and models with interactions between board characteristics and crisis year. Similarly, Table 4.5 gives the results of adjusted performances and Table 4.6 shows the results of bank risks. As shown in Table 4.4 and Table 4.5, we find the CEO duality has significantly negative effects on stock returns at high-performing banks, but, it becomes insignificant after adjusting the risk factor. The interaction term between CEO duality (DUAL) and crisis year (Yeardum) has a significantly negative effect on stock returns, adjusted ROA and adjusted ROE, that is, during financial crisis, high-performing banks with CEO duality would have significantly lower performances than those without CEO duality.

Table 4.7 shows the results of bank risks for high-performing banks. The results indicate that high-performing banks with CEO duality have relatively lower stock volatility than those without CEO duality. During financial tsunami, CEO duality would intensify bank's volatility of ROE; high-performing banks with higher ratio of independent director and larger board have relatively lower bank risks in terms of ROA measure.

In summary of results in high-performing banks, we find the CEO duality does play certain role on bank performance and risks. When bank CEO also serving as the president of the board will reduce bank market performance in favor of H_{2a} and also decrease market volatility in favor of H_{5a}. During crisis period, high-performing banks with CEO duality will reduce bank's accounting performance in terms of ROA and ROE after adjusting risk factor. Besides, higher independent board in terms of independent director ratio and higher board size will also help control bank risks during financial tsunami in favor of in favor of H_{4b} and H_{6b}.

Table 4.7 to 4.9 show the results for sample of low-performing banks. We do find the significant influence of board structure on low-performing bank's performance and risks. Banks with CEO duality have a consistently and significantly positive impact on bank accounting performance in terms of ROA and ROE while this significant effect on performance disappears after considering the risk factor. Although CEO duality does not have significant effects on market performance of stock return, it reduces market volatility of low-performing banks in favor of H_{5a} and also helps improve risk-adjusted bank market performance during crisis period, confirming H_{2b}. Those results indicate that CEO duality helps efficient decision making to improve firm performance in financial crisis, thus, the positive relationship between CEO duality and firm performance exists during financial distress period which result is consistent with findings in Boyd (1995).

Except for CEO duality, board independence is also supported to have a significantly positive effect on low-performing bank's performance and negative effects on bank risks. Table 4.7 shows that bank performance in terms of ROA is improved by the higher ratio of independent directors on the board regardless of ROA or risk-adjusted ROA, confirming H_{3a}. We also find that higher independence of the board helps mitigate the low-performing bank's risks in terms of VOLROA and VOLRET, in favor of H_{6a}. Independent board could mitigate the potential opportunism of CEO though monitoring of independent board, thus, improve bank performance and reduce bank risk-taking behavior. However, above positive relation between independent board and bank performance, hypothesis H_{3b}, is not supported during financial distress period.

Taking a look at the effect of board size on low-performing bank's performance and risks, we find significantly positive relation between board size and market performance in terms of RET1YR and ADJRET (confirming H_{1a}), and significantly negative relation between board size and bank risks in terms of VOLRET and VOLROE, confirming H_{4a}. During financial tsunami, larger board will enhance low-performing bank's risk adjusted accounting performance (ADJROA) in favor of H_{1b}, and also help control market volatility (VOLRET) in favor of H_{4b}.

Overall, we conclude that using the whole sample to test research hypotheses, board structure seems unrelated to bank performance and bank risks in terms of inconsistent results. However, dividing bank performance to high-performing and low-performing banks based on median of performance, we find different results for high- and low-performing banks. For high-performing banks, CEO duality would decrease bank's market performance either in crisis or non-crisis period, and it would also decrease market volatility. For low-performing banks, except for CEO duality, independent board and board size also play significant role in bank performance and bank risks. We find that independent board, CEO duality and board size have positive effects on bank performance, but only CEO duality stays its influence in bank performance during financial tsunami. As to the effect of board structure on bank risks at low-performing banks, we find board size, CEO duality and independent board have negative effects on bank risks and only board size stay its significant influence in bank risks during financial tsunami.

5. Conclusion

This study investigates the role of board structure on US bank performance and risks during crisis and non-crisis period by using 59 commercial banks during 2000 to 2013. We find that board structure does affect bank performance and their risk-taking behavior at different performing banks. For high-performing banks, CEO duality would decrease bank's market performance either in crisis or non-crisis period, and it would also decrease market volatility. For low-performing banks, board structure even plays more significant effect on bank performance and bank risks either financial tsunami or non-crisis period than it does on high-performing banks. We find that independent board, CEO duality and board size have significantly positive effects on bank performance, but only CEO duality stays its influence in bank performance during financial tsunami. Moreover, board size, CEO duality and independent board have significantly negative effects on low-performing bank risks and only board size stay its significant influence in bank risks during financial tsunami.

Overall, our results show that board structure presents to play more important role on low-performing banks than on high-performing banks. During financial crisis, CEO duality would deteriorate bank's risk-adjusted performance. These results suggest that corporate governance during crisis period in banking industry still remains room to be improved, especially in board independence. Sound bank governance system definitely helps banks risk management and safely experience through financial crisis.

This study investigates if a firm's innovation influences its performance via firms' banking relationships. Using a panel data of Chinese listed firms over1999 to 2008, this study examines the issue by exploiting the impact of banking relationships on innovation and then the impact of this innovation on firm growth opportunities. Using a 2SLS simultaneous equation model, we find that a non-linear relationship between banking relationships and innovation, however, innovation significantly and positively influences firm growth opportunities. We also find that maintaining the banking relationships with one or two is the optimal number for firms to obtain an innovative capacity and better performance. When firms borrow from more than five banks, it destroys the innovation investments. Some implications are valuable for banks and enterprises.

Keywords: Innovation, Banking Relationship, Growth Opportunity.

JEL Code: G32, L33, O31, O43.

1. Introduction

Innovation had been viewed as one of the key instrumentals for firm growth to increase profit in an existing market, enter new markets, and sustain competitive advantages over the long term. There are numerous studies investigating the relationship between innovation and firm growth over the past decades. The original point of view of Schumpeter (1934) claims a positive impact of innovation on firm profitability. This view holds for the last few decades.

Recently, Sirelli (2000) suggests that firms are encouraged to innovate since it leads to a higher growth rate. Klette and Griliches (2000) present the model of endogenous firm growth with innovation as an engine of growth. Bottazzi et al. (2001) analyze the world's largest pharmaceutical companies across 11 years and provide the evidences that either new chemical entities or patent products which captured by innovation have significant impact on firm growth. They are the starting point for our research. We adopt the above discussion in the case of Chinese firms. China is the typical example of the incredible booming economy thanks to ramping up on innovation. Start from the mid of 1990s, the Chinese Government has engaged in nurturing technology-based industries which government encouraged firms to innovate product and process. Romer (1994) states that the judicious direction is considered are the crucial factor for the rapid economic growth.

The unique characteristics of innovation as it is intangible and contains greater asymmetric information than physical investment make it to be difficult for investors to measure the effect of innovation on firm growth. However, it is still attracted researchers to examine the correlation between innovation and firm growth. Chan et al. (1990) and Zantout and Tsetsekos (1994) find a positive market response to innovation for high-tech-industry firms, but an inverse market response for firms in low-tech industries. Acs and Isberg (1996) indicate that the impact on innovation on Tobin's Q depends on the size of firms. Nelson and Winter (1982), Aghion and Howitt (1992), Klette and Griliches (2000), Klette and Kortum (2004) suggest a close relationship between innovation and firm growth in sales. Ho et al. (2006) suggests that firm growth opportunity is associated with innovation by firm size, leverage and industry diversify. In contrast, some researchers find an insignificant relationship between these two factors. The contradictory conclusions from the previous studies are the pioneers for us to investigate how innovation adds value to firm growth in the case of Chinese firms.

The other issue we consider is whether presenting a model endogenous innovation via banking relationships may indirectly influence firm growth. Banking relationships represent the access-to-credit ability has been recognized as the key component of innovation in the extant research. Frazzoni et al.(2014) show that the strength of banking relationships significantly affects the probability of innovation in introducing product. Lagaras (2014) demonstrates that banking relationships stimulate firm innovation. Another point that makes banking relationships valuable to innovation is banks reduce the asymmetric information between outsiders and firms. One argument for the appreciation of banking relationships in fostering innovation is the fact that banks may access inside information as insiders through the bilateral contracts whereas outside debt holders must rely mostly on publicly available information (Fama, 1985). Prior literature also provides the evidences support that banking relationships are the power factors to determine firm growth, Gambini and Gazzaro (2011) consider the link between banking relationships and firm growth. They report the influence of close banking relationships on asset growth of a large sample of Italian firms. Otherwise, the findings of Gopalan et al. (2011) suggest small U.S firm experienced an increase in sales growth when they form a new banking relationship. The results of this work document the relationship between firm growth and banking relationships leave us a room to analyze whether banking relationships impacts firm growth through innovation.

The unique characteristic of Chinese bank-firm relations is quite different among other economies. Chinese banks tend to focus on loan quality, so they reduce amount of loans for individual enterprise and widen the firm-client portfolios in order to limit the risks (Chang et al., 2010). Therefore, almost the large firms are in favor of multiple banking relationships since banks recognize those firms are less likely to default. Conversely, small and medium firms are associated with single banking relationships as they are not the optimal choice for banks (Yin and Matthews, 2014). Maintaining single banking relationships, firms face to low monitoring cost and collateral requirements (Farinha and Santos, 2002) but they are also more likely to be locked-in by the lending bank and cope with higher switching cost. However, multiple banking relationships may help firms control the informational locked-in and liquidity risks, but they have to suffer from higher transaction and monitoring costs (Yin and Matthews, 2014). The topic of single versus multiple banking relationships has not been explored in China. We hence concern this issue by testing whether the number of banking relationships has a significant impact on innovation.

The aim of this paper is to illuminate the effect of innovation on firm growth based on the Chinese firm-level data in the period on 1999 to 2008. We use 2SLS regression to explain the impact of innovation on firm growth through the number of banking relationships. In other words, banking relationships are used as an instrumental variable for innovation to employ the correlation of innovation and firm growth. Moreover, we add industry dummies and owner diverse dummies to control for the biases resulting from industry characteristics and different firm owners.

The remainder of the study is organized as follows. The next section summarizes theories on the relationship among the three dimensions. The third section describes the data and methodology used in this study, followed by a report of the estimation and the expected results in the next section. The results and suggestions for future research in this area are discussed in the last section.

2. Literature review

The idea to link innovation and banking relationships is discussed in theoretical literature. Banks directly affect the quantity of R&D and investment spending. They affect the nature of selected projects, the quality of internal inputs, and their effectiveness in generating innovation. First, when firms launch innovative products, banking relationships may assist them in selecting appropriate distribution channels. Second, firms can improve the quality of internal inputs by disclosing information to the relationship bank without worrying about unauthorized disclosure to competitors. Finally, the bank can offer firms multi-period contracts, which are more effective (saving transaction costs) and safe (extracting information) than one-shot contracts. Thus, the arrangement allows firms to commit resources to innovative activities. Giannetti (2009) suggests a higher share and a longer relationship with a main lending bank have a positive impact on the innovation capacity of high-tech firms. Herrera and Minetti (2007) test the correlation of the information of firms' main bank - measured by the duration of credit relationship- and innovation and state that it promotes innovation

Innovation is a powerful factor that affects firm performance. Companies that innovate successfully have superior performance to that of their less able competitors. To survive, a firm must not only produce a given set of goods or employ a given set of inputs and process technologies, but also develop the ability to innovate and profit from that innovation (Nelson, 1991). R&D investment is a crucial factor for firm success. Yang and Huang (2005) examine the effect of R&D on firm growth and find that firms with intensive R&D are associated with high growth rates. Niefert (2005) also find evidence on the positive effects of innovation on firm growth.

Numerous studies extend the association of innovation and firm growth opportunity. Roper (1997) emphasizes on SMEs and indicates that innovative products significantly contribute to the sales growth of SMEs, which grow faster than non-innovative SMEs. Engel et al. (2004) analyze German SMEs and conclude that the sales turnover of innovative SMEs grows faster than that of non-innovative firms. All these findings suggest that fast-growing firms are innovative firms.

3. Data and methodology

3.1 Data

Data are collected from four sources, namely, (a) the China Stock Market and Accounting Research (CSMAR) database, (b) the Ju-Chao website on Listed Firms Information Release Panel, (c) the Shanghai Stock Exchange, and (d) the Shenzhen Stock Exchange. We obtained 10,929 observations from approximately 1400 firms listed on the Shanghai and Shenzhen exchanges of financial data and 6,407 observations of banking relationship data from 1999 to 2008.

3.2 Methodology

Because the two equations are estimated using the same data, their error terms may be correlated. To address this problem, we use a 2SLS regression model, an extension of the linear regression model, to solve correlated errors between equations.

This study investigates the nature of the relation between innovation and firm growth as measured by Tobin's Q using a 2SLS regression for Chinese listed firms. The study also examines the difference of innovation and growth between Stated-owned firms (SOEs) and private-owned firms (POEs). We use the percentage of shares owned by the state as a proxy for state owner diverse. Firms with more than 50% public ownership are defined as state-owned, whereas firms with less than 50% public ownership are considered private firms.

Our simultaneous equations are expressed as Equations (1) and (2).

$$GROWTH\_OPP = \beta_0 + \beta_1 INNOVATION_{t-1} + \beta_2 AGE + \beta_3 SIZE + \beta_4 DEBT\_TA + \beta_5 CAPEX\_TA + \beta_6 FCF\_TA + \beta_{7-12} INN\_D + \beta_{13}\ POEs + \varepsilon_t \quad (1)$$

$$INNOVATION = \gamma_0 + \gamma_1 BR \quad + \gamma_2\ SIZE + \gamma_3 AGE + \gamma_4 FCF_{TA} + \gamma_5 POEs\ + \gamma_{6-11} INN_D + \propto_t \quad (2)$$

3.2.1 Description of variables in Eq. (1)

We use Tobin's Q as a proxy for growth opportunities GROWTH_OPP. Tobin's Q is given by the market value of assets (the market value of equity plus the book value of debt) divided by the book value of assets. For a given year, growth companies are firms with Tobin's Q greater than the median for that year.

One determinant of GROWTH_OPP is INNOVATION, as measured above. We use the ratio of expenditure on intangible assets to total assets, such as the R&D expenditure ratio and property rights, to present this variable. Because data on the R&D expenditure ratio are incomplete before 2005, the results may be biased. Roper (1997) and Engel et al. (2004) find a strong relationship between firm innovation and growth opportunity. Yasuda (2005) shows a significant correlation between R&D expenditure per employee and firm growth. We expect the significant and positive effect of INNOVATION on GROWTH_OPP.

Firm age and size are the two most common independent variables that affect firm growth. The SIZE logarithm of total assets and AGE, which pertains to the age or maturity of the company, are labeled as firm size and firm age. Almus and Nerlinger (1999) find that firm age affects growth negatively, implying that old firms grow more slowly than young firms. Hall (1987) analyzes US manufacturing firms and indicates that large firms are associated with low growth. Becchetti and Trovato (2002) also find an inverse relationship between growth and size. Following the most recent findings, we expect that the size and age of firms negatively affect the growth of firms.

The capital expenditure ratio (CAPEX_TA) is the ratio of capital investment expenditure to total assets. The evience from Houston and James (1996) document that market value (Tobin's Q) definitely relies on firm growth opportunities, which are impacted by capital expenditure. We control the firm liquidity by cash ratio (CASH_RT). It is calculated by the ratio of total cash and cash equivalents to total liabilities. This determinant suggests that companies grow faster if they hold a sustained level of current assets to pay off their short-term liabilities. An increase in the cash ratio reinforces the liquidity position of the firm. Gill and Mathur (2011) suggest that maintaining a high liquidity level helps firms face less severe financing constraints. We expect that liquidity positively affects firm growth.. The debt ratio (DEBT_TA) is the ratio of short-term debt to total assets. According to Majumdar and Chhibber (1999), it is found to have sifnificantly negative impact on firm performance for the sample of Italian firms. Conversely, Abor (2005) reveals the evidence to support that short term debt to total assets is significantly positively correlated with firm profitability (measured by ROE).

We also add different industry dummies (INN_D) to our model to control for industry-specific differences in growth rates. Firms in different industries exhibit different growth rates. Harhoff (1998) suggests that the effects of different growth factors are slightly different in four selected industries, namely, the manufacturing, construction, trade, and service industries. Almus and Nerlinger (1999) split their sample into firms that operate in high-, medium-, and low-technology industries. Dunne and Hughes (1994) include 19 industry dummies in their investigation. We investigate the possibility that the effect of the independent variables varies with the industry. Furthermore, we run the model include six industries, namely, public utilities, real estate (property) development, general, industrial (manufacturing), commercial and other industries

We include POEs as a dummy variable to measure the growth difference of two types of owners diverse. POEs is 1 for private-owned firms or 0 otherwise. Because each firm has different characteristics, we expect different rates of growth.

3.2.2 Description variables in Eq. (2)

Our dependent variables are presented by INNOVATION. Consistent with Equation (1), we use the ratio of expenditure on intangible assets to total assets, including the expenditure on R&D expenditure and property rights, to represent innovation.

We add the number of the banking contacts of firms to this model as a control variable. We use BR to measure the closeness of the bank–borrower relationship. BR is the number of banks the firm borrows from, that is, borrowing concentration. Benfratello et al. (2008) indicate that banking relationships significantly affect process innovation but weakly affect product innovation. Bhattacharya and Chiesa (1995) point out that an inverse relationship exists between firm innovation and the number of banking relationships because of information dissemination problems.

The variables that describe the internal structure of the company include variable SIZE, which shows the size of the business; the natural logarithm of total assets; and AGE, which shows the age or maturity of the company. Fernández (1996) claim that large companies have advantages to innovate, such as economy of scale, low risk, a large market, and great opportunities for appropriation. Thus, we find a report on the positive relationship between size and innovation. On the age variable, an old firm indicates that the experience and knowledge it accumulated throughout its history are advantageous to the creativity and communication necessary to innovate (Galende and De la Fuente, 2003). Therefore, the expected sign for the age variable is positive, consistent with literature.

The free cash flow ratio (FCF_TA), which pertains to the availability of the internal cash of the firm, is one key determinant of innovation. It is measured by taking free cash flow divided by total assets. The variable is considered such a determinant and the main form of financing innovation because of its lower cost and risk than external finance. Pinkowitz et al. (2012) state that if firms have insufficient internal funds, some innovations will not be accomplished. Therefore, we hypothesize that firms with high free cash flow invest in considerable innovation and are thus more innovative than others.

We also include ownership, which may significantly affect firm innovation. POEs is the owners diverse dummy variable, used to test the influence of corporate ownership. POEs is 1 if the firms are private-owned or 0 otherwise. According to a Russian research, inefficient and unprofitable firms are not forced into bankruptcy because of state intervention. Policies reduce the incentive of SOEs to develop new methods and products and thereby reduce innovation. By contrast, POEs face the threat of bankruptcy and the constraints of financing. They are constantly under pressure to meet their target profits. POEs have strong incentive to adopt new practices and introduce innovative products that would further increase their innovation capacity because of the pressure.

The last determinant of innovation is industry-specific characteristics, which, in the form of knowledge externalities, may determine innovation activity (Cohen et al., 1987). We cluster the sample firms into six groups according to firm type as in Equation 1, namely, public utilities, real estate (property) development, general, industrial (manufacturing), commercial and other industries. We employ firm diversification as the dummy variable. For example, 1 denotes the public utility industry, and 0 denotes others; 1 denotes the general industry, and 0 denotes others.

4. Empirical Results

Panel A of Table 1 shows the results of the summary statistics on the endogenous and exogenous variables for full sample data. For the endogenous variable GROWTH_OPP, the highest value of Tobin's Q is 40774.68, whereas the lowest is 0.6. All sample firms grow, but significant differences are observed in growth ability among them. The mean of GROWTH_OPP is 6.59 (with a median of 1.82) which is high compared to U.S firms that have an average of 2.89 (Cui and Mak, 2002). The second endogenous variable is INNOVATION, which has a mean of 0.04, which is low compared to American firms that have average of 0.1 to 0.16 (Ho et al., 2006; Cui and Mak, 2002). The min is 0 reveals that some firms even do not spend expenditure on any innovation projects

The minimum of BR is 0, implying that firms do not borrow from banks. By contrast, some firms even deal with as many as 15 banks. SIZE represents the size/scale of the firm and has an average value of 21.12, which significantis higher in comparison of US firms that have the mean of 17.89 (Cui and Mak, 2002), implying that the difference in firm size may exist. The average age of firms is 26, the youngest firms are 3, and the oldest is 107 years old. The DEBT_TA mean is 0.67 while the average value of CAPEX_TA is -0.19. Free cash flow to total assets ratio (FCF_TA) have the value approximately equal to cash ratio (CASH_RT) with the mean and median are 0.14 and 0.12.

Panel B of Table 1 is the comparison on statistics of variables for firms with multiple and those with single banking relationships. Firm that maintain single banking relationships have extremely larger GROWTH_OPP than those with multiple banking relationship (21.4 compared to 2.77) even the expenditure on innovation of two type firms are almost equivalent (0.04). Firms that deal with single bank have the average value of size and age are 21.1 and 24.88 whereas those values of multiple-bank lending firms are 21.22 and 26.49 indicate that small and young firms tend to deal with one bank while large and old firms are in favor of lending from multiple banks. The results are consistent with the study of Yin and Matthews (2014).

Panel C of Table 1 reports the different statistics which is classified by owner diverse.. The mean (median) of Tobin's Q for POEs is 14.24 (1.71) and range from 0.6 to 40774.68 implies the far different of growth opportunity among private firms. SOEs even have lower Tobin's Q on average (2.38) but it substantially changes from 0.65 to 52.91, which is significantly different to the range of POEs. The mean of BR (3 vs. 2) and cash ratio (0.14) of two type firms are close similar . Not surprisingly, POEs show higher growth opportunity (14.24 vs 2.38), higher innovation expenditure

(0.046 vs 0.038) , extremely higher debt ratio (0.91 vs 0.14) and larger size (21.43 vs 21.06). However, it shows a lower median capital expenditure ratio (0.02 vs 0.03) and free cash flow ratio (0.12 vs. 0.48) compared to SOEs. It implies that POEs are lager, spend more on innovation projects, have higher liquidity capability and higher growth opportunity. However, these firms have lower capital expenditure and free cash flow.

Panel D summarizes the selective statistics on different industries. Commercial shows the highest innovation expenditure of 5% associated with the highest growth opportunity of 9.16 and the highest banking relationship of 2.9, follows by general and other industries. Public utilities remain the lowest innovation expenditure of 3.7% associated with 1.56 growth opportunity and 0.69 number of banking relationships. The results in panel D and chart 2 demonstrate the correlation of innovation expenditure and growth opportunity with in an industry.

Table 2 shows the sample distribution and the Tobin's Q and innovation across different years, industries, ownership types. First, the growth opportunity of Chinese enterprises decreased from 2000 to 2005 and then increased from 2006 to 2008. Innovation rose twice from 0.032 to 0.065 during the decade (panel A). Panel B implies the different firm opportunities and innovations across the five industries. Commercial has the highest firm opportunity innovation, whereas public utilities have the lowest value. Panel C measures the change in innovation and banking relationship based on the number of banking relationships. Firms obtain the highest innovation expenditure at three banking relationships for both full sample and two ownership types. We also note that banking relationships are rising with the number of banking relationships when banking relationships are less than three. Otherwise, when banking relationships are greater than three, innovation is decreasing with an increasing of banking relationships. These are the evidenced to expect the significant effect of banking relationship on innovation.

Table 3 shows the results of the simultaneous equation model, implying that growth opportunity and innovation are endogenous variables. Column (1) shows the results of the full sample. It reports an insignificant impact of number of banking relationships on innovation expenditure. However, when we divide the full sample in to three sub-samples by the number of banking relationships, the results are different. For the first sub-sample ($0<BR<3$), banking relationships significantly affect innovation expenditure with positive coefficient of 0.003. It suggests dealing with one or two banks is optimal for firm to innovate since firms may access to abundant capital but the cost paid not too high. Firm size and free cash flow are decreasing with innovation with the coefficients are -0.01 and -0.082, respectively which means small firms are more likely spend much more on innovation and firms with high free cash flow are not interested in investing in innovation projects. Firm owner diverse is correlated positively with innovation with the coefficient of 0.009 indicates that POEs have higher innovation expenditure compared to SOEs. The second regression on firm growth opportunity in column (6) reports the significant positive relationship between innovation and growth opportunity. Innovation is increasing with growth opportunity with the coefficient of 350.8 which reflects that innovation is the powerful determinant of firm growth opportunity. However, owner diverse is negative correlated with growth opportunity suggests that even POEs invest much more in innovation than SOEs but they have lower growth opportunity compared to SOEs. The other variables also have significant impacts on growth opportunity as we expected.

For the second sub-sample ($3 \leq BR < 5$), we do not find the significant effect of banking relationship on innovation, implies that dealing with three or four banks is not helped to explain the expenditure on innovation. The results of the last sample ($5 \leq BR \leq 15$) are reported in column (4) and (8). Column (4) provides the significant and negative coefficient of banking relationships on innovation expenditure (-0.002), points out that borrowing from numerous of banks (from five to fifteen banks) leads to low innovation. It is converse to the positive relationship between those variables in the first sub-sample which demonstrates that banking relationships effect is non-linear rather than linear. This finding sounds reasonable: main banking relationships with one or two banks helps reduce asymmetric information problem and save costs so firms have great advantages and resources to innovate. In contrast, innovation investment is destroyed for those firms which maintain more than five banking relationships. Dealing with too many banks put firms in the pressure of information leakage and extremely high transactional costs, thus innovation expenditure declines compared to other firms.

Although banking relationships shows different impact on innovation in each sub-sample, the correlation between innovation and growth opportunity is consistent. Innovation adds value to Tobin's Q with the coefficient is 33.447. The significant coefficients of AGE, DEBT_TA and CASH_RT are -0.018, 1.303 and 3.995 respectively show that small firms, high debt ratio and cash ratio have higher growth opportunity. The effect of SIZE and POEs are insignificant while the effect of CAPEX_TA is significantly negative. This finding differs from most of the extant literature.

The coefficients on the industry dummies (INN_D1 – INN_D6) in model (1)-(4) show that there is no effect of industry type on innovation expenditure. For growth opportunity regression, just only IND_D1 is correlated with Tobin's Q suggests that firm growth opportunity is increasing in public utilities industry.

5. Conclusion

Using 2SLS SEM approach of the Chinese firm-level data, our results have implications for the understanding of the effect of innovation on firm growth opportunity through the number of banking relationships. First, we find that innovation significantly and positively influences a firm's Tobin's Q. Firms invest more in innovation, the higher growth opportunity they exhibit. Secondly, a non-linear relationship between banking relationships and innovation was found. Banking relationships add value to firms via innovation investment when firms deal with one or two main banks; whereas it destroys innovation and the reflective Tobin's Q when firms maintain more than five banking relationships. Additionally, we hypothesize that POEs spend more innovation investments compared to SOEs, however, these investments may not be efficient enough that lower Tobin's Q on POEs was found . Besides, we find significant industry effects on growth opportunities, whereas it is insignificant on innovation expenditure, implying that innovation investments do not differ significantly across various industries. Enterprises, especially some special industries, should make more efforts to create the comparative advantage via innovation inputs.

Table 1 Summary Statistics

This table shows the results of a two-stage least squares SEM. The first model is based on firm innovation (INNOVATION), and the second model is based on firm growth (GROWTH).
GROWTH is the firm growth opportunity; measured by Tobin's Q. Tobin's Q is given by the market value of assets (the market value of equity plus the book value of debt) divided by the book value of assets. INNOVATION refers to R&D expenditure, determined by the ratio of R&D expense to the total assets of the firm. BR is the number of banks the firm has to access loans. SIZE shows the size of the business, the natural logarithm of total assets, and the variable AGE shows the age or maturity of the company. . CAPEX_TA is the capital expenditure ratio, which captured by the ratio of capital expenditure and total assets. FCF_TA is the free cash flow ratio, which is free cash flow divided by total assets. DEBT_TA is the debt ratio, measured as short-term debt divided by total assets. CASH_RATIO is the ratio of cash and cash equivalent and total liabilities.

This paper examines if CEO compensation moderates the relationship between ownerships types and firm innovation performance. Using a simultaneous equation model for U.S listed firms over 1992-2013, we find that compensation significantly and positively moderates the relationships between different types of ownerships and innovation. Due to different types of ownerships have different incentives on innovation activities, the compensation scheme may apply variously. Some valuable implications are developed for enterprises for setting an incentive mechanism.

Keyword: Compensation, Ownership Structure, Innovation.

1. Introduction

Executive compensation or executive pay is composed of the financial compensation and other non-financial awards received by an executive from their firm for their service to the organization and rewards for performance. Schumpeter (1934) argued that anyone seeking profits must innovate. Scott (2003) stated that executive compensation plan is the agency contract between the company and his manager is trying to unite the interests of owners and managers by basing compensation manager at one or more sizes of business managers to operate companies. Generally, managers or executives are portrayed in the literature as being risk-averse rather than a risk - taker. Mondy (2008) defines compensation as a total of all rewards provided employees to return to their services.

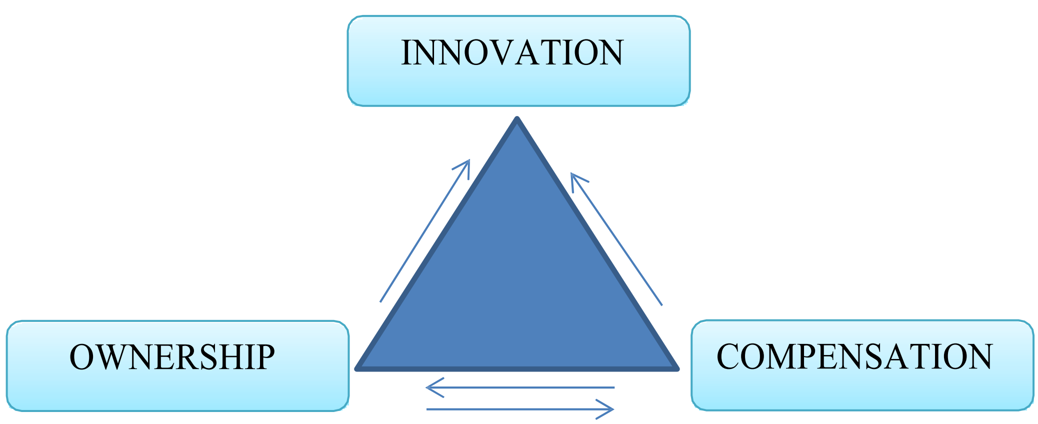
There are a number of papers that discuss the relationship between CEO compensation and firm performance. Faria, et al. (2014) examines the relationship between corporate performance and the Chief Executive Officer compensation in high technology firms in the S&P 1500. Their findings indicate that there is a strong and positive relationship between CEO compensation and firm performance. Canyon (2013) investigates US executive compensation and governance, he finds on average executive pay is positively correlated to firm performance and firm size. Conyon & He (2011) they find that executive compensation is positively correlated to firm performance. Study from Lilling (2006) to find the relationship between CEO Compensation and market value of a firm, he reports a positive relationship between CEO compensation and market value of a firm. This study concludes that incentive based contracts are effective, due to the positive pay-to-performance link, when controlling for simultaneity.

Chen et.al (2008) examines the relationship between ownership and innovation show that the distinct types of owners have different objectives and motivations and this will affect how they exercise their control right over the firm invest in and because executive wealth was sensitive to firm performance (Frydman and Saks 2010). This research in line with Love et al., 2009, Choi et al., 2011, and Jiang et al., 2013. From family firm perspective Lodh et al., (2014) found that the impact of family ownership on innovation productivity is positive (after controlling for possible endogeneity).

Several studies have been conducted to examine the relationship between ownership, and compensation. The research carried out on some type of ownership such as a family firm, private and state ownership enterprises (SOEs) in different places. Study from Cheung et.al. (2005), Sapp (2008) and Adu et.al (2010), found a positive relationship between ownership and compensation. Most of all research above examines separately and rarely that examines the triangular relationship between ownership, compensation, and innovation a simultaneous. However, the research not examines the ownership in dual class share. Thus, this is lack in the literature of financial management. Furthermore the research that used panel data using US Firm. Thus, this research will contribute to fill the lack of literature in this area.

This study makes three contributions to the extant literature. First, until recently, the empirical study mostly discussed separately to examine the relationship between ownership, compensation and innovation. Second, we analyze three relationship, they are: the impact of the type of ownership in dual class share to the innovation, the impact of the compensation to innovation, and the relation between ownership in dual class share and compensation simultaneity. Lastly, this study investigated the interrelationship used a simultaneous equation model (SEM). After examines the puzzle among ownership dual class share, compensation and innovation. My research question will be as follows: how do the relation between the executive ownership, compensation and the innovation in US.Firm?

The conceptual model of this research as figure below:



2. Literature Review

Linking between Ownership and Compensation

Mondy (2008) define compensation as a total of all rewards provided employees in return to their services. The overall purposes of providing compensation are to attract, retain, and motivate employees. Furthermore Byars & Rue (2008) stated that compensation as all the extrinsic reward that employees receive in exchange for their work. Composes of the base wage or salary, any incentive or bonus, and any benefit. In other word Milkovich & Newman (2011) stated that compensation is refers to all form of financial returns and tangible services and benefits employees receive as part of an employmentrelationship.

Bergman & Scarpello (2001) stated that they are two goals of compensation. Firstly is to elicit desired behaviors from employees and secondly is to achieve the first goals within a set of constraints (the organization's ability to pay, legislation, labor unions, internal labor market and external labor market). At least they are three goals of compensation. Firstly, motivate people to join the organization. Every organization uses people in the process of producing its unique goods or services. Organizations must create this labor force by motivating appropriate individuals to join the organization. Secondly, motivate people to stay with the organizations. Motivating people to join the organization does little good if the organization cannot retain them. Thus, motivating individuals to stay with organization is also influenced by a complex set of variables. Thirdly, motivate people in the organization to perform at high level, most organizations would like to motivate employees to perform beyond minimally acceptable levels. Organization do many things other than use wage payment to elicit high performance. Thus, the goals of compensation in line with equity theory that mentioned about motivation theory: people assess their performance and attitudes by comparing both their contribution to work and benefits they drive from it to contributions and benefits of comparison others whom they select – and who in reality may or may not be like them.

Jensen and Meckling (1976) argue that the ownership structure is believed to have the ability to influence the company that eventually can affect the performance of a company. In order to understand whether and when family firms are more or less valuable than nonfamily firms Villalonga and Amit (2004) stated one must distinguish among three fundamental elements in the definition of family firms: ownership, control, and management. They argue that family ownership creates value only when the founder serves as the CEO of the family firm or as its

Chairman with a hired CEO. Control mechanisms including dual share classes, pyramids, and voting agreements reduce the founder's premium. When descendants serve as CEOs, firm value is destroyed. Based on agency theory Combs et.al (2010), describe a different scenario wherein family representatives engage in strategic control that reduces family-member CEOs' compensation. Family-member CEOs accept lower compensation only when additional family members are represented in management or on the board. In comparison with CEOs at nonfamily firms, they find that family-member CEO compensation is 13% lower when multiple family members are involved, but 56% higher when the CEO is the lone family member.

From Continental Europe study, Croci et.al (2012) investigates the impact of family control and institutional investors on CEO pay packages in. They find that family control curbs the level of CEO total and cash compensation, and the fraction of equity-based compensation. Moreover, they do not observe a significant effect of family control on the excess level of total and cash compensation. This evidence indicates that controlling families do not use CEO compensation to expropriate wealth from minority shareholders. They show that institutional ownership is associated with higher levels of CEO cash and total compensation in Continental Europe, especially in family firms. Also, foreign institutional investors have a positive and significant impact on CEO compensation level. Finally, results indicate that institutional investors affect CEO pay structure: they increase the use of equity-based compensation in both family and non-family firms.

Thus, we suppose the hypothesis besides explanation according the relationship between Ownership and Compensation in hypothesis 1 below:

H1. Ownership Concentration will be positively related to the Executive Compensation.

Linking between Compensation and Innovation

The sensitivity of executive pay to share price performance has been the main focus of Western executive pay studies, reflecting shareholders' efforts to reduce agency problems by better aligning the rewards of executives with their own. However, these studies have ignored motivational effects and possible two-way pay–performance causation. Buck et.al (2008) reports Chinese executive pay–performance sensitivity, with international comparisons, to examine whether China's unique institutional environment has produced outcomes consistent with those for Western market economies. This same unique environment makes possible the first estimates of two-way causation based on panel data analysis. The results show that executive pay and firm performance mutually affect each other through both reward and motivation.

Chhaochharia and Grinstein (2009) In Response to corporate scandals in 2001 and 2002, major U.S. stock exchanges issued new board requirements to enhance board oversight. Find a significant decrease in CEO compensation for firms that were more affected by these requirements, compared with firms that were less affected, taking into account unobservable firm effects, time-varying industry effects, size, and performance. The decrease in compensation is particularly pronounced in the subset of affected firms with no outside blockholder on the board and in affected firms with low concentration of in investigating the relationship between CEO compensation and firm diversification over.

Rose and Shepard (1997) Investigating the relationship between CEO compensation and firm diversification over 1985-1990, they find that the CEO of a firm with two lines of business averages 13% more in salary and bonus than the CEO of a similar-sized but undiversified firm, ceteris paribus. Kato and Kubo (2006), present the first estimates on pay-performance relations for Japanese CEO compensation. finds consistently that Japanese CEO's cash compensation is sensitive to firm performance (especially accounting measures), and that the "semi-elasticity" of CEO's cash compensation with respect to ROA is 1.3 to 1.4, which is in general agreement with prior estimates. They also find that stock market performance tends to play a less important role in the determination of Japanese CEO compensations and they find that the bonus system makes CEO compensation more responsive to firm performance in Japan. The finding is in contrast to the literature on compensation for regular employees in Japan which often argues that bonus is a disguised base wage.

Furthermore Firth.et.al (2006) examines the compensation of CEOs in China's listed firms. They discuss what is known about the setting of CEO compensation and then examine factors that may help explain variations in the use of performance related pay. In China, listed firms have a dominant or controlling shareholder and they argue that the distinct types of controlling shareholder have different impacts on the use of incentive pay. They find that firms that have a State agency as the major shareholder do not appear to use performance related pay. In contrast, firms that have private blockholders or SOEs as their major shareholders relate the CEO's pay to increases in stockholders' wealth or increases in profitability. However the pay–performance sensitivities for CEOs are low and this raises questions about the effectiveness of firms' incentive systems. Therefore, compensation is being important aspect to encourage high more firm performance in many countries.

Thus, we suppose the hypothesis besides explanation according the relationship between Compensation and innovation in hypothesis 2 below.

H2. Compensation will be positively related to Innovation or firm performance.

Linking between Ownership and Innovation

Cyert & March (2001) argue that the assumption of rationality in theory of the firm can be reduced to two propositions. Firstly, firms seek to maximize profit, secondly, firms operate with perfect knowledge. So, the owners will ask to managers to improve more innovation for pursuing profits. Joseph Schumpeter (1934) has comprehensive definition according to innovation. Definitions of innovation are: The introduction of a good (product), which is new to consumers, or one of higher quality than was available in the past, methods of production, which are new to a particular branch of industry, the opening of new markets, the use of new sources of supply, new form of competition, that leads to restructuring of an industry.

Furthermore Michael porter (1990) defined innovation: to include both improvements in technology and better methods or ways of doing things. It can be manifested in product changes, process changes, new approaches to marketing, new forms of distribution, and new concepts of scope (innovation) results as much from organizational learning as from formal R&D. Both Schumpeter and Porter use the word "new" in their definition. Freedman (1988) stated when a company decides to innovate, it make an investment. It commits fund resources. If the investment comes from existing business within the parent organization, it will show up on the respective balances sheets of enterprises. If the corporate office decides to invest in a new innovation group its commitment will often resemble that of a venture capital firm, this time the commitment will show up on balances sheet of the corporation.

Kellermanns et.al (2012) argues that family firm influence can have both positive and negative consequences for family firm performance. Jefferson (2002) using a panel of these enterprise data for 1994–1999 from China, find a rapidly diversifying ownership structure in which the role of the state is steadily retreating. At the same time, they find considerable variation in measures of performance across ownership types and see emerging within Chinese industry, evidence of high-intensity R&D performers that exhibit substantial innovation capabilities. Furthermore Ding et.al (2008) confirms that family-owned firms in China achieve significantly better performances than state-owned enterprises. These results support the general consensus that China is increasingly reliant on private companies as an engine for economic growth and an employment hub. Xu and Wang (1999) investigate whether ownership structure significantly affects the performance of publicly listed companies in China within the framework of corporate governance. A typical listed stock company in China has a mixed ownership structure with three predominant groups of shareholders the state, legal persons (institutions), and individuals. Empirical analysis shows that the mix and concentration of stock ownership do indeed significantly affect a company's performance. Therefore, ownership concentration is being important aspect to encourage innovation in many countries.

Thus, we suppose the hypothesis besides explanation according the relationship between ownership and innovation in hypothesis 3 below.

H3. Ownership will be positively related to Innovation.

3. Data and Methodology

Data Construction

We use three data sets: Execucomp provides us with data on CEO compensation. Regressions presented in this article were performed with Execucomp data extracted from WRDS in 2013. We use Compustat to retrieve information on the size of US-based firms. The data were obtained from Compustat North America and is a panel data from the years 1992 through 2013. with 48,755 total observations. We Use Patent Numbers of US Firm that issued outside US from IPtech Taiwan.

Methodology

Dependent Variables. *CEO Compensation*. Following Mehran (1995) we use three measures of compensation; (1) percentage of total compensation in grants of new stock option, with the options valued by the black-Scholes Formula, (2) percentage of total compensation that is equity based, and (3) percentage of total compensation in salary plus bonus. Following Michiels et.al (2012) we take the logarithm of the CEO compensation to reduce the impact ofoutliers.

Independent Variables. *Firm Performance*. The proxies for firm performance are Tobin's Q measure by the ratio of the market value of the firm. Return on Asset (ROA) measured by the ratio of net income to the book value of the firm's total asset.

Ownership structure. Is measured by the variables of owners, which indicate the number of shareholder. Following Mitchiels et.al (2012) we take the natural logartithm of the number of owners to account for the nonlinear effect of an increasing number of owners.

Control variables. We include several control variables in our model to account for other factor that affect CEO Compensation. ***Patents number*** from IPtech, we measured innovation in terms of the number U.S. patent issued in IPtech submitted by our sample firms. ***R&D ratio***, measure by the R&D Expenditure to total assets. G***rowth opportunities***, the proxy for growth opportunity is research and development as percentage of sales. **Leverage** ratio, The proxy for leverage is the ratio of long term debt to total assets. ***Firm size***, Size is measured by the log of the book value of assets. **CEO Age**, Firm age measures by the log of firm's age. **CEO Tenure**, CEO Tenure measures by the numbers of year that an executive serve as CEO.

Table 1
Deskription of variables

Variables	Descriptive
Dependent Variables	
Total Compensation	Log[1+(Salary+Bonus+Other annual Compensation+Restricted stock Gain)]
Cash Compensatio	Log [1+(Salary+Bonus)]
Equity Based Compensation	Log[1(value of restricted stock granted+The Balck Sholes value of Stock option Granted)]
Independent Variables	
Tobin Q	Market to book ratio= (market value of equity + The book value of total assets – The book value of equity)/the book value of total assets.
ROA	Net profit divided by total assets
Control Variables	
Patents Number	Numbers of patents issued by the sample
R&D Ratio	R&D expenditure to total assets
Growth Opportunities	Percentage of sales
Leverage	Long term debt/Total assets
Firm Size	Log (total assets)
CEO Age	CEO Age
CEO Tenure	The numbers of year that an executive serve as CEO

To test hypothesis 1 we follow Cheung et al (2005). The empirical models for this test is:

$$\ln(\text{CEOcomp}) = \alpha + \beta 1 \text{ Tobin's Q} + \beta 2 \text{ ROA} + \beta 3 \text{ Owners} + \delta \text{ Controls} + \varepsilon \qquad (1)$$

The independent variable of this research is the owners, is measured as the fraction of total company shares outstanding held by the types of ownership. And the dependent variable is Executive compensation that measure by the natural logarithm of the cash emoluments (salary, bonus, housing allowance and other benefits) received by the CEO and the Chairman. And also analysis the proportion of cash emoluments in the total compensations (where total compensation includes cash emoluments and dividend income derived from shareholdings), and the firm's dividend yield (dividend per share divided by share price). This research includes regressions two sets of control variables. They are: Set comprises firm characteristics. ROA (net profit divided by total assets), Market-to-book ratio (market value of equity divided by book value of equity), Debt-to-assets ratio (long-term debt divided by total assets), Annual sales growth, and The natural logarithm of the firm's deflated total assets. Set of control variables includes proxies for corporate governance. CEO duality (dummy variable equal to one when the CEO is also Chairman of the board of directors), The natural logarithm of the number of directors on the board, The fraction of independent non-executive directors on the board, and The presence of an audit committee (dummy variable equal to one if such a committee exists).

To test hypothesis 2, we follow Michiels et.al (2012) empirical model. They model is:

$$\ln(\text{CEOcomp}) = \alpha + \beta_1 \text{ Tobin's Q} + \beta_2 \text{ ROA} + \delta \text{ Controls} + \varepsilon \qquad (2)$$

The dependent variable is CEO compensation as total CEO compensation. This measure contains one figure that comprises both base salary and cash bonuses. Variables: CEO comp measures by Total CEO cash compensation, ROA Return on assets measure by calculated by income after expenses excluding taxes divided by total assets, Owners measure by The number of shareholders, Firm size measure by The total number of employees in the firm, Firm age measure by The number of years since the firm was founded

To test hypothesis 3 we follow Lodh et al (2014) model. For measure operating performance use some measurement as: Innovation productivity measure by Number of patents/R&D expenses, R&D intensity measure by R&D expenditure/Sales, Management ownership measure by (%) Percentage of all classes of shares held by the Management, Firm size measure by Log of total sales, Firm age measure by Log of firm's age, Knowledge stock measure by Number of patents in last 4 years assuming 15% annual depreciation and an 8% growth backward in times.

4. Preliminary Results

We find that compensation significantly and positively moderates the relationships between different types of ownerships and innovation. But different types of ownerships firms have different incentives for innovation. The compensation incentive may apply variously. Some valuable implications are developed for enterprises for setting an incentive mechanism.

□ □ □ □ □ □ FACTORS RELATED TO THE PROCESS OF ACCOUNTING TREATMENT AFFECTING THE QUALITY OF FINANCIAL STATEMENTS

Phan Đức Dũng
University of Economics - Law, National University of Ho Chi Minh City

email@com.edu

In terms of the economy of our country is in the process of integration with the world economy, the publicized accounting information of enterprises in general and the company's shares in particular is essential to an enterprise can improve the competitiveness and sustainability of their business operations. This study was carried out for the purpose of finding out the factors that affect the quality of the information presented in the financial statements. With data collected from surveys and through processing, statistical data analysis, this study hopes to provide for the management of the company in particular and the use of financial reporting general insight and a more comprehensive level of influence of each factor on the quality of the information presented in the financial statements. From the above research issues, addressing only a single answer the following questions: What factors in accounting processes affect the quality of financial reporting by enterprises in Vietnam?.
Keywords: quality, financial reporting, accounting processing, accounting and State regulations.

1. Introduction

Although, Vietnam has accounting law, accounting standards and accounting regulations, but in fact the work of accounting firms still have the false information, affecting the quality of the information presented on financial statement. Thus, the question is the legal framework Vietnam issued based on the provisions of international accounting practices, and based on the actual situation of economic - social development in Vietnam, but not guaranteed on the reliability of financial reporting. The study indicates the quality of financial reporting is affected by how the process accounting transactions (including the provisions on the system of accounting documents, the account system, the system of bookeepings and the financial reporting system, the tools support for accounting done its job), the tax policy of the state (which is essentially the value added tax, income tax policy now) as well as perceptions of administrators in the management of the company to ensure the implementation of corporate objectives but does not affect the quality of financial reporting.

2. Overview of Research

For research in 2003 "Factors affecting the transparency of information" Robert Bushman, Joseph Piotroski and Abbie Smith based on the results of factor analysis of the variables measuring environmental information scope of business are collected from companies in several countries and the author has found two factors: financial factors and governance factors. They also put two factors in relation to the legal system and political economy to draw conclusions about their interactions. The result is that the governance factors related to the legal system during the financial factors related to the national political economy. Uyen Thi Thao Doan (2009) has carried out research "Lessons and solutions to enhance the role of accounting information from the economic crisis of 2008" with the object of study is the accounting information in the financial statements of the largest financial institutions in the United States Lehman Brothers Holdings Inc.'s investment funds of Bernard Madoff and Stanford Interational Bank. The study says the importance of accounting information for business decisions of companies, investors, especially for the management and control of the government’s macro-economy. Le Truong Vinh (2008) research "Modeling and verification of quantitative scale information transparency of listed companies in Ho Chi Minh City Stock Exchange" with 30 listed businesses, the authors offer models with 5 variables determine the factors affecting the information transparency of listed companies is: firm size is expected, the profitability of the company, the rotation assets, fixed assets, liabilities. Vo Thi Anh Hong (2008) with the theme "The solutions to improve the usefulness of accounting information for decision-making process of investors in the stock market," surveyed 100 investors on the market the securities in which bank employees 59% and 41% in other sectors including financial sector is 14%, accounting 7%, 3% production business, trade in services is 10% is other components. The results show that investors most interested to increase the EPS, income/equity ratio P/E, income/total assets, the ratio of debt/equity and margin from business activities. The above results show that accounting information is a reference resource important to investors implementing investment decisions and the accounting information is not currently clear and transparent, so investors’ desire provided information transparency.

On the other hand, Sutherland, Edwin H. (1924) – a study of the American crime – the study of the principles of criminal offense that is growing due to links with the offender rather those who have not sinned. From his research, he concluded that offenses arising from the environment, a person can not motivated crime without the impact of external factors. To understand the nature and identify criminals, we need to study and promote attitudes offense. Cressey, Donald R. - is an excellent student of Sutherland, but he studied fraud under the direction of embezzlement, unlike his mentor. Cressey focused analysis through fraud conducted a survey of about 200 cases of economic crime in order to find out the causes of the violations of the law on. The model of "fraud triangle" is one of his typical study, presented the factors leading to the fraud that is now widely used in many occupations relevant as audit, security, criminal investigation ... Meanwhile, Pham Thi Ngoc Anh author (2004) in "Understanding the common errors and fraud in audits of financial statements" refers to three most common ways to deal with fraud: prevention, detection and punishment. In addition, the author Tran Thi Giang Tan (2009): "Fraud on the financial statements and the study of fraud" refers to the 10 signs of the staff suggests the possibility of fraud appear high as most live below the average, high debt, the desire to have a high income, have a close relationship with the client, that the remuneration received disproportionate contribution, have a good relationship with owners, who wish to demonstrate that could pass the control of the company, has a habit of gambling, from excessive pressure, no company is recognized for achievement, signs related to organization. Ten signs of organization suggests the possibility of fraud appear highest placed too much trust in key personnel, lack of relevant approval procedures, not full disclosure of investments and receivables personal income, no separation of functions and functional preservation approval, lack of testing independently review the implementation, not detailed monitoring activities, no separation of functions with accounting preserved, not separating some related accounting functions, lack of clear guidance on the responsibilities and powers, lack of supervision of internal auditors.

These situations may indicate the possibility of financial statements free of material misstatement due to fraud include: The difference between actual and accounting books, such as transactions are recorded in full and on time, or write the wrong amount, misclassified, is inconsistent with the policy of the unit; transactions or balances not approved or no documentation, the adjustment at the end of the reporting period had a material effect on the business results in particular or on the financial statements in general, there is evidence of the employees have no authority to access the accounting system and records of the unit, bribery or complained to the auditor about alleged fraud. The contradiction between the evidence or lack of evidence, such as a missing document, the document may have been altered, only undocumented photo or electronic documents instead of providing the original document, with the Large differences can not explain, answer inconsistency between staff and board of management or board of directors when auditors interviewed or perform analytical procedures, abnormal difference between books and unique authentication establishment of an auditor, loss of inventory or other assets in large numbers, e-vouchers can not or have lost, inconsistent with the actual notes or policies of the company, may not provide evidence of the development of information systems or test key change programs and activities related to the implementation of changes and implementing information systems in the current year. Relationship abnormalities or problems between the auditors and the Board of Directors, eg, Board of

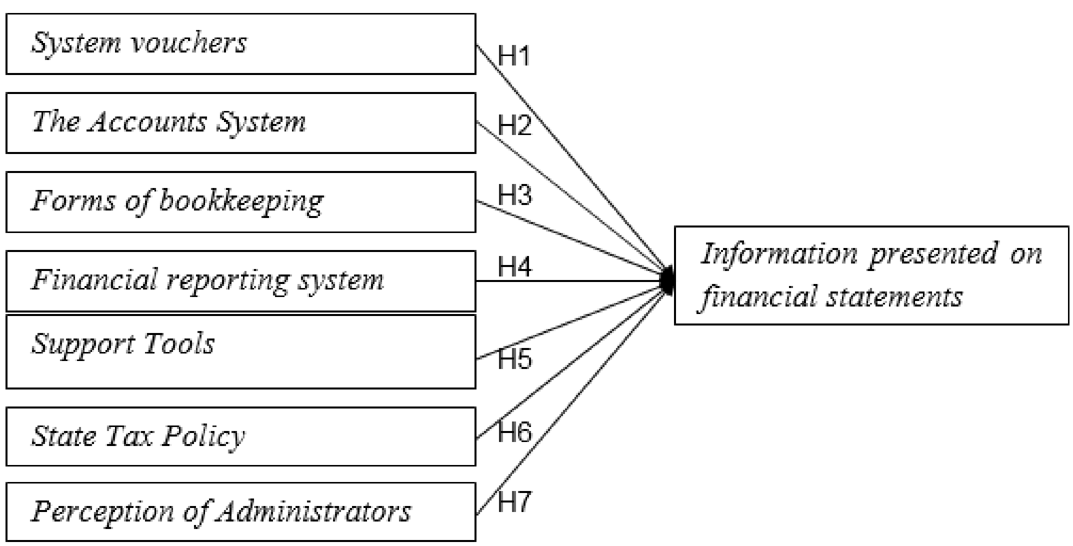
Directors does not allow or deny or restrict auditors access to some documents, employees, customers supplier or some other individuals have the ability to help auditors gather audit evidence. Board of Directors created great pressure on auditors of time solving complex problems or disagreements. The board of directors' complaining of the audit, or a threat from the board of directors for the audit team, especially as related to the assessment, review of auditors or audit evidence about the resolve potential disagreements with the Board of Directors. Board of directors deliberately delaying the provision of information at the request of the auditor, is not willing to allow auditors to access the electronic document is important to check with the technical audit with the assistance help of computers. Refusing contact between auditors with information technology personnel or equipment of key information technologies, including security personnel, operation and development of the system. Do not agree to add or edit auditors of financial statements in order to make full financial statements and transparent, easier to understand. Along with the view to recognize the factors affecting the accounting process but considered in relation to small and medium-sized enterprises, according to Nguyen Thi Huyen Tram author (2007) "Organization of accounting in small and medium enterprises in Vietnam". Topics raised the factors affecting the accounting work in small and medium enterprises as legal regulations, internal control systems, the ability to apply information technology, financial services, accounting and thereby propose a complete solution of accounting in small and medium enterprises in Vietnam. Meanwhile, the author Tran Dinh Khoi Nguyen (2010) mentioned: "Discussing the model of factors affecting the accounting regime applied in small and medium enterprises", including factors such as: The level of accountants; The independence of the profession; The complexity of the standards; Results of the study will be the basis to be able to create and develop on many aspects of accounting. From the perspective of micro and macro, consider the impact of the model to the accounting of small and medium enterprises. For author Anh Tuyet Nguyen (2013) are only interested in Binh Dinh province "The accountant in small and medium enterprises in the province of Binh Dinh" include: Organization of business accounting now. The organization of accounting; The nature and work of outsourced accounting; Provides information of business accounting; The objective of accounting small and medium enterprises; Organization of accounting firms; The organization of accounting; The nature and work of outsourced accounting; Provides information of business accounting; The objective of accounting small and medium enterprises; The views of the administrators with the accounting work. The study results indicated that targets small and medium businesses today it is particularly concerned about issues like tax compliance of tax declarations and minimize the cost to pay. The goal of providing information to the corporate governance are also interested. The provision of information to other entities outside the enterprise hardly be emphasized, in the survey sample size was too small compared to the actual. The business survey is not representative for small and medium enterprises in the province. The previous studies though in a different perspective and recognize each separate issue, but the factors affecting the quality of the information presented in the financial statements are related to the rules of evidence accounting, financial accounting, the accounting records, the financial statements, support tools, policies and awareness of the state of governance.

3. Research Methodology

Research conducted through two steps: preliminary research and formal research. Preliminary research conducted through qualitative research methods are discussed between the experts group on the basis of reference articles and reviews related to the topic, the research team carried out discussions to find out the factors affecting the quality of the information presented in the financial statements; since it will serve as a basis to establish the questionnaire used in formal study. Formal research using quantitative methods, using survey techniques directly through questionnaires. In particular, the random sample of non-probabilistic method for conducting data collection. The data is encrypted and processed by SPSS 22.0 software. To consolidate multiple choice and composition of the scale, the researchers used the method Cronbach's Alpha testing, EFA factor analysis to determine the hidden factor behind the observed variables. Linear regression analysis was used to determine the coefficients of the factors in the equation of linear regression and analysis of the impact of these factors to the information presented in the financial statements of the business.

Research data sources include primary data is the data that the team collected directly at the data source and process to serve the research, will be collected by surveys, online surveys and secondary data to the type of data has been collected through the documents available, openly on the net ...

4. The proposed research model



5. The assumptions are set for research

H1: Accounting documents are the appropriate regulations affecting the same way with the quality of the information presented in the financial statements.

H2: Flexible account systems affect the quality of the information presented in the financial statements in the same way.

H3: Simple bookkeeping forms impact the quality of the information presented in the financial statements in the same way.

H4: Presentation of financial statements in compliance with the fundamental principles of accounting change in the same direction with the quality of the information presented in the financial statements.

H5: Favorable support tool impact in the same direction with the quality of information presented in the financial statements.

H6: Rational tax policy affect the quality of the information presented in the financial statements in the same way.

H7: Perceptions of administrators affect in the same direction to the quality of information presented in the financial statements.

From the study of the theoretical basis of the factors in business processes affect the quality of the information presented in the financial statements of the business including: Accuracy of the information, timeliness, the satisfaction of the users, to meet the needs of information, ... with the ultimate goal is to help managers make appropriate decisions and provide the necessary information for those wishing to use. Derived from the practice of accounting in the enterprise, the authors have studied the design and construction of the model. According to this model, the process accounting operations depends on the eight groups of factors: (1) factors related to the accounting records; (2) factors related to the accounts, (3) factors related to bookkeeping, (4) factors related to the accounting reporting, (5) factors related support tools (6) factors related to tax policy, (7) factors related to the perception of managers and (8) factors related to the information presented in the financial statements. Each group includes several elements observed variables (independent variables), each observed variable is built on 5 point Likert scale, with a choice of "1-entirely without influence" to " 5-Full influence ". Tools collected primary data in this study is designed questionnaire covering all observed variables, then, was sent to the chief accountant, accountant, chief financial officer, auditor ... in the business in the provinces of southern, central and northern Vietnam.

With 280 samples generated, number of samples used to meet the requirements of 225 (80.4% occupancy rate). The questionnaire was distributed to the accountants in many different joint stock companies. After collection, the questionnaires were reviewed and eliminated the table unsatisfactory. Then, the observed variable is encrypted, data entry and data cleaning using SPSS software version 22.0 and conducted statistical analysis of the data was collected.

From the results of testing the reliability of the scale, the overall scale of measurement for the observed variables as well as two groups of factors - the system of accounts (Alpha = 0.679), group 3 elements - window system accounting (Alpha = 0.806), the factor 6 - tax policy (Alpha = 0.660) and group factors 8 - quality requirements (Alpha = 0.630). The observed variables corresponding to the factors mentioned above are acceptable. This proves that the items are correlated with each other questions and we have contributed to measure "quality of the information presented in the financial statements," which the authors are studying.

Implementation of factor analysis in this study to help to realize a set of a few dominant variables from a set of variables to be used in multiple regression analysis.

With 38 observed variables used to measure the independent factor 8 (1) The system of accounting documents; (2) financial accounting system; (3) The system records; (4) accounting reporting system; (5) Support Tools; (6) The tax policy; (7) Aware of the administrator; (8) the information presented in the financial statements chinhPhan volume element is performed by the method of extracting the main components - Principal Components, just extract the valuable element Eigenvalue greater than 1 (because of factors Eigenvalue smaller one will not work better summary original variable, so after normalization of each original variable variance is 1), using Varimax rotation angle of the material factors to minimize the number of large amounts of variable coefficients in the same factor. So, will enhance the ability to explain the factors, observed variables are selected variable coefficients load factor (Loading factor) greater than or equal to 0.45. This coefficient that each item asked "belong" public key factors. Also, check the KMO with 0.5 <KMO <1 and 95% significance level.

Summary of Cronbach Alpha testing and factor analysis (EFA) includes: Scale of "accounting system account" Alpha coefficient = 0.679; The scale of "bookkeeping system" Alpha coefficient = 0.806; The scale of "tax policy" Alpha coefficient = 0.660; The scale of "quality requirements of financial statements" coefficient alpha = 0.630.

Name factor	**The observed variations in factors**
Factor 1: Account Details	TK1, TK2, TK3, TK4
Factor 2: Flexibility account	TK5, TK6
Factor 3: Bookkeeping	SS1, SS2, SS3, SS4, SS5, SS6
Factor 4: Tax Policy	TT1, TT2
Factor 5: Objects used	BC1, BC4, BC5
Factor 6: Rationality information	BC2, BC3

Overall, six new factors are average values of factors point to achieve relatively high.

In particular, the users information (F5), the tax policy of the state (F4) and the validity of the information that companies provide (F6) are accountants particularly interested in assessing regulations processing accounting transactions affecting the quality of information in the financial statements. Besides, the number of F4 mode - policy of the State Tax is assessed as very high, showing how important and special interest of the accountants to handle the accounting profession and presents information on the financial statements. On the other hand, the observed variable coefficient higher load factors were rated as more important and influential than the name represents that factor.

Results of factor analysis to explore, we have a new model consisting of six factors. In particular, there are five independent factors, including details of the account properties (F1), Flexibility of accounts (F2), the form of bookkeeping application (F3), the tax policy of the State (F4) and the users information (F5) and a dependent factor is the validity of information (F6). In this section, researchers consider the quality of information on financial statements decided rationality of accounting information depends on how the business processes from the use of the account details, flexible of the accounts, books and applicable forms, tax policy of the State and the users of accounting information. The steps are as follows:

Multivariate regression analysis in SPSS 22.0, using Enter, this is the default method in SPSS, SPSS handle all variables are put into one. The inclusion and exclusion of other variables are based on the role of the independent variable on the dependent variable, based on implicit behavior between the variables, the reliability of the data collected, the ability to explain ability to collect data processing.

Regression analysis in SPSS, select Collinearity diagnostics to check the phenomenon of multicollinearity (Multicollinearity). Acceptance of variables (tolerances) and magnification factor variance (VIF) was used to detect the phenomenon of multicollinearity. The rule is when the VIF exceeds 10 signs of multicollinearity occurs.

Coefficients[a]

Model	Unstandardized Coefficients		Standardized Coefficients	t	Sig.	Collinearity Statistics	
	B	Std. Error	Beta			Tolerance	VIF
1 (Constant)	1.336	.325		4.117	.000		
F1	.134	.069	.131	1.930	.045	.754	1.326
F2	.038	.066	.041	.585	.049	.708	1.413
F3	.105	.076	.101	1.381	.009	.655	1.527
F4	.271	.059	.304	4.612	.000	.801	1.248
F5	.104	.084	.087	1.236	.008	.704	1.421

a. Dependent Variable: F6

From the table we see Coefficientsa, regression coefficients of the independent variables are statistically significant (Sig. <0.05). The significance of the partial coefficients measure the average change Y values when exporting to change one unit, keep the independent variables remaining constant. Beta coefficient was used to compare the independent variables and measurement units. We can rewrite the model as follows: Rationality = 1.336 + 0.134 Information (As detailed account) + 0.038 (Flexibility account) + 0.105 (Form bookkeeping) + 0.271 (the State tax) + 0.104 (Who uses accounting information).

Multivariate regression stepwise method estimates show that providing appropriate information (quality of information): As the details of the account, the account Flexibility, Forms bookkeeping , tax policy of the State and target users of accounting information can impact directly proportional to the "Provide information reasonably". In particular, the tax policy of the State to have the strongest impact on the "Provide information reasonably".

Observe coeficients table saw, VIF values are very small (<2) for all independent variables. Thus, this model is no multicollinearity phenomenon occurs. Through the above analysis, we can see the Adjusted R2 explained 50% of the dependent variable (in fact, there are other factors affecting the dependent variable - the random factor, but the model has not explained) and the t-test results showed five independent variables we included in the accepted sense because they explain the dependent variable. On the other hand, the phenomenon does not exist multicollinearity. Therefore, this model is appropriate.

Results of the analysis above shows, the model explains only 50% of the dependent variable. In particular, elements of the tax policy of the state is considered the most important, followed by factors related to the accounts, accounting records and information to users. Thereby, we can conclude, this model may be suitable for today's perspective of accountants in business in Vietnam.

6. Conclusion

Results of testing the scale Cronbach Alpha, 38 observed variables using 5 point Likert scale was eliminated after turning 19 by non-standard, 19 observed variables remaining after performing factor analysis was extracted into 6 factors: (1) As detailed account, (2) Flexibility of account, (3) Forms bookkeeping, (4) Tax policy of the State, (5) Who uses accounting information and (6) The reasonableness of accounting information (quality of information on the financial statements). Thus, the combination of factors, may be used as criteria to assess the quality of the information presented in the financial statements diminishing influence as follows: (1) The tax policy of the State; (2) As the details of the account; (3) Form of bookkeeping; (4) Who uses accounting information and (5) Flexibility of the account.

Applying Intuitionistic Fuzzy with MCDM to Measure the Enterprises' ICT Maturity in Vietnam

Pham Xuan Kien
Industrial University of Ho Chi Minh City, HCMC, Vietnam
pxkien@yahoo.com

Generally, measuring the Information and Communication Technology (ICT) maturity is the first step to build a knowledge system in an enterprise. Knowing their ICT maturity helps enterprises make a plan for improving their ICT state to strengthen their competitive capability. In this paper, the concept of intuitionistic fuzzy set is applied to Analytic Hierarchy Process (AHP) and Analytic Network Process (ANP) approaches to propose a model for measuring enterprise's ICT maturity under uncertain environment. A case study in Vietnam is also used to show a better performance of the new method for ICT maturity measurement.
Keywords: ICT maturity, Intuitionistic fuzzy logic, IF-AHP, IF-ANP.

1. Introduction

In the era of information and knowledge, knowledge has become an essential resource that organizations need to manage effectively. Many studies approved that the knowledge management in organizations is one of the most important element to enterprises' innovation capability to help them get their own competitive advantage and develop steadily. Obviously, the knowledge management in enterprise depends mostly on the development level of Information and Communication Technology. The ICT maturity of an enterprise is a solid foundation for successful implementation of knowledge management. This reason encourages most enterprises to increase their ICT status. With the very fast development of technology, most enterprises need to know their current state of ICT use or ICT maturity in order to apply effectively ICT to do their business better. Moreover, knowing current ICT maturity state is the foundation of making plan to newly build or to improve an information system.

This research concentrated on designing a new measurement of ICT maturity in enterprise and dealing with uncertainty of fuzzy environment that influences the accuracy of measured result. And it is also tested practically in several Vietnam's enterprises for effective performance. To measure the ICT maturity, we have to know the importance weights of each factor and their indicators. In this paper, aggregative intuitionistic fuzzy AHP (IF-AHP) and ANP (IF-ANP) approaches are both used to determine the weights. The following parts of this paper consist: Session 2 defines ICT maturity and introduces a measurement for it. In session 3, the basic concept of intuitionistic fuzzy set will be given. Session 4 proposes a model to measure enterprise ICT maturity using group IF-AHP and IF-ANP. An illustrative example is presented in session 5. The paper will be ended by conclusion part.

2. DEFINITION, MODEL AND MEASUREMENT FOR ICT MATURITY

2.1. *Definition and Model*

The term ICT maturity of enterprise refers to a state of an enterprise, in which the enterprise reaches full development in applying ICT in doing its business. Other words, ICT maturity shows how well an enterprise uses ICT in support its business. To determine the current maturity state of ICT use in an enterprise, it is required to carry out measuring the ICT maturity of that enterprise.

Following is a proposed model to measure ICT maturity of an enterprise. There are four main ICT factors inside an enterprise: ICT Infrastructure, ICT Application, ICT Human Resource and ICT Policy, see Figure 2-1.

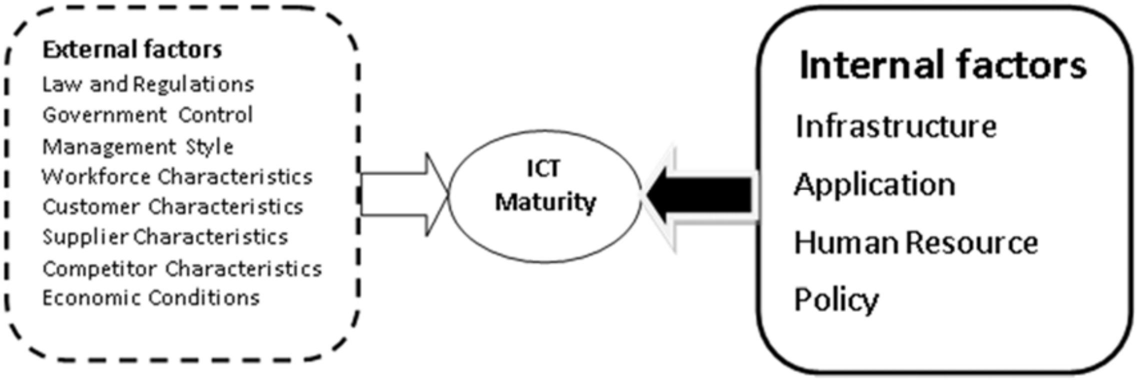

Figure 2 1. Model for main factors of ICT maturity in an enterprise

- ICT infrastructure is considered as hardware consisting of ICT devices and services such as server, desktop, laptop, telephone, mobile, fax, network, internet, LAN, WAN… for enterprises to collect, store, process, achieve, distribute and search information. This factor is considered as the basic foundation on which ICT applications are set up.
- ICT application are software and firmware. ICT applications must be installed upon ICT infrastructure. These applications facilitate all business activities in enterprise. Some kinds of application typically used in enterprises are Transaction Processing System (TPS), Management Information System (MIS), Decision Support System (DSS), Executive Information System (EIS), E-commerce, Knowledge-based System, Social Network Services, etc.
- ICT human resource includes staff literacy, ICT skills, innovation skills, IT experts, IT leaders, ICT training, R&D activities. It is very important factors of ICT maturity in enterprise.
- ICT policy consists of regulations, rules and procedures relating to the ways of using and developing ICT in an enterprise. Policy factor effects on all other factors of ICT maturity.

In this research we only focus on 4 main internal factors, because they have strong influences on ICT development in enterprises. Moreover, we can go further to consider the relations between 4 internal main factors influencing on ICT maturity. It is not always possible to assume the main factors to be independent. The more optimal result can be obtained by considering inner dependences among main internal factors. The network relation model of main internal factors is depicted schematically in Firgure 2-2.

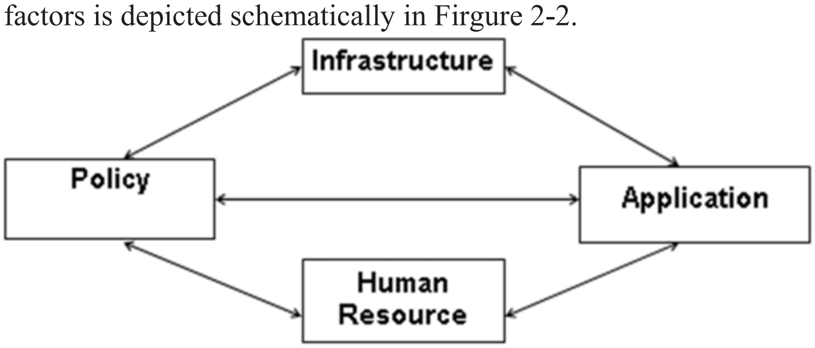

Figure 2 2. Inner dependences among main internal factors

In addition, to measure the ICT maturity, we have to know the importance weights of factors and their respective indicators. To serve this purpose, the proposed model of this research has suggested methods to calculate importance weights of each indicators. The calculation is based on decision makers' judgments and multiple criteria decision making approaches combining with intuitionistic fuzzy logic. The existing models commonly are based on single judgment from one expert and are working in certain situations, not in fuzzy environments where the uncertainty and impreciseness on judgments of the decision makers always exist. The fuzzy environment is caused by the increasing complex of socio-economic environment and the subjective nature of human thinking.

In this research, an aggregative intuitionistic fuzzy analytic hierarchy process (IF-AHP) approach and an aggregative intuitionistic fuzzy analytic network process (IF-ANP) approach were used to determine the importance weights of measurement indicators in uncertain environment. Multiple criteria decision making (MCDM) becomes more and more popular recently and has been widely applied to solve decision problems in many different fields. This research utilized two most commonly-used MCDM approaches AHP and ANP as calculation methods in building a complete model for measuring ICT maturity in enterprises.

2.2. *Measurement for ICT Maturity*

In this research, we utilize the 5-stage road-map suggested by Pham in his work (Pham, 2010). This road map of ICT develop is to determine the level of ICT maturity in an enterprise.

- Stage 1: Inactive – no current use of ICT in company
- Stage 2: Basic – including word processing and other desktop packages
- Stage 3: Substantial – extending into the networking of PCs and applications
- Stage 4: Web-based – extending to e-commerce with many web-based services
- Stage 5: Knowledge-oriented – integration of applications and using ICT tools for innovation and knowledge management.

In order to create a list of indicators for measuring ICT maturity in enterprise, more details should be added to the model of ICT maturity. Each dimension of 4 main factors could be measured by many indicators. The main purpose is that these indicators should be easy to get information as well as exactly show the ICT maturity of an enterprise. Table 2-1 shows the list of 52 indicators that will used to measure the ICT maturity of enterprise. They are divided into 4 main groups respectively corresponding to 4 main factors. The column 'Stage' expresses the development stage of each indicator. Note that, all indicators listed below are used to evaluate the development level of ICT use. That is why there is no indicator with the stage 1. The stage values will be used to make a futher classification on all indicators in respect to a particular main factor.

The ICT maturity index (ICTMI) will be calculated by following formula:

$$ICTMI = \alpha I + \beta A + \gamma H + \theta P \quad (0 \le I, A, H, P, ICTMI \le 1, \alpha + \beta + \gamma + \theta = 1) \qquad (1)$$

I, A, H, P are respectively contributions of 4 main factors Infrastructure, Application, Human Resource and Policy to the ICTMI. The α, β, γ, θ are coefficients of 4 main respective factors. In his paper, Pham let the weights of I, A, H, P as $\alpha=\beta=\gamma=\theta=1/4$. The calculated ICTMI can be mapped to 5 stages of ICT development road-map by the rule: 0-1/5: Inactive; 1/5-2/5: Basic; 2/5-3/5: Substantial; 3/5-4/5: Web-based; 4/5-1: Knowledge–oriented. This paper uses group IF-AHP and IF-ANP approaches to determine more appropriate coefficients for I, A, H and P in order to get a better ICTMI.

Table 2 1. Indicators of the proposed ICT maturity measurement

Number	Factor		Indicator	Stage
1	Infrastructure (I)		Number of fixed telephones	2
2			Number of mobile devices	5
3			Number of computers (desktop, laptop)	2
4			Type of internet access	4
5			Local Area Network (LAN)	3
6			Internet bandwidth	4
7			Security of Internet server/ Hosting	4
8			Security & backup system	4
9			Wide Area Network (WAN/ GAN)	3
10			Wireless LAN/ Wi-Fi Internet	5
11			WAP/ i-mode access	5
12			Telephoning over the internet/ VoIP	4
13	Application (A)		Standard application software	2
14			Getting information about goods/ services via Internet	4
15			Getting information about government organizations	4
16			Website presence	4
17			Internet service is used	4
18			Proportion of online purchases	4
19			Proportion of online sales	4
20			Providing customer services	5
21			Delivering product online	5
22			E-mail/ IM for communicating	2
23			Social network for cooperate	5
24			Remote meeting/ video conference	5
25			Using services through Intranet/ Extranet	3
26			Internet banking	5
27			Management/ transaction information systems	3
28			Integrated Information Systems (SCM/ ERP/ CRM)	3
29			Business intelligent/ Knowledge-Based systems	5
30	Human Resource (H)		ICT training	3
31			Share of employee using a computer	2
32			Share of employee using the internet	4
33			Average royalty payment & receipt per year	5
34			Number of patent/ license application	5
35			Average company spending on R&D per year	5
36			Capacity for innovation	5
37			Number of IT specified employee	3

38			Separate IT department with CIO	4
39			Number of business specified employee	2
40			Self-learning encouragement	5
41			ICT use for supporting expertise reuse	5
42	Policy (P)		ICT investment	3
43			Quality policy	2
44			Privacy policy	4
45			Regulatory policy	2
46			Security policy	4
47			Piracy policy	5
48			IT expert recruitment/ training	5
49			Staff internal or external recruitment/ training	5
50			Upgrade ICT hardware/ software	3
51			Assessment effectiveness	5
52			ICT use for KM is a priority	5

3. BASIC CONCEPT OF INTUITIONISTIC FUZZY SET

3.1. *Triangular Fuzzy Number*

A triangular fuzzy number Ã can be defined by a triplet (l, m, u), where u ≤ m ≤l, l and u stand for the lower and upper value of the support of Ã respectively, and m is the mid-value of Ã. If l = m = u, it is a non-fuzzy number by convention (a crisp number). The graph of triangular fuzzy can be shown in Figure 3-1.

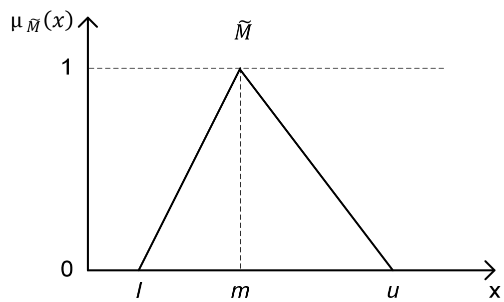

Figure 3 1. A triangular fuzzy number.

The membership function μÃ (x) is defined as:

$$\mu_{\tilde{A}}(x) = \begin{cases} \dfrac{x-l}{m-l} & 1 \le x \le m \\ \dfrac{u-x}{u-m} & m \le x \le u \\ 0 & otherwise \end{cases}$$

3.2. *Intuitionistic Fuzzy Set*

Let a set X be fixed, an intuitionistic fuzzy set (IFS) Ã in X is an object having the form

Ã = {<x, μÃ(x), νÃ(x)> | x ∈ X}, where the μÃ(x): X ⍰ [0,1] and νÃ(x): X ⍰ [0,1] define the degree of membership and degree of non-membership respectively, of the element x ∈ X to the set Ã, which is a subset of X, for every element x ∈ X, 0≤ μÃ(x) + νÃ(x) ≤1. An IFS is shown in Figure 3-2.

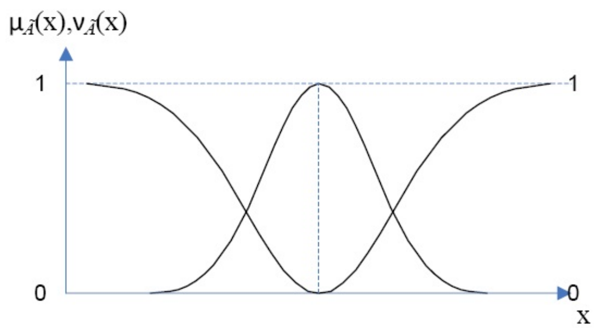

Figure 3 2. Membership and non-membership function of Ã

Definition of intuitionistic fuzzy index:

For each IFS Ã in X, if $\pi_{\tilde{A}}(x)=1-\mu_{\tilde{A}}(x) - \nu_{\tilde{A}}(x)$, $0\leq \pi_{\tilde{A}}(x) \leq 1$, then $\pi_{\tilde{A}}(x)$ is the third parameter of IFS and is usually called the intuitionistic fuzzy index or hesitation degree. IFSs is reduced to fuzzy sets when $\nu_{\tilde{A}}(x) = 1- \mu_{\tilde{A}}(x)$ and $\pi_{\tilde{A}}(x) = 0$.

Definition of triangular intuitionistic fuzzy number:

A triangular intuitionistic fuzzy number (IFN) Ã is represented as:

$$\tilde{A} = <[(a'_1, b'_1, c'_1); \mu_{\tilde{A}}], [(a_1, b_1, c_1); \nu_{\tilde{A}}]>.$$

The membership functions $\mu_{\tilde{A}}$ is used to derive the lower bounds of membership μ_L for IFN Ã, where the upper bound of membership μ_U is derived by taking the compliment of non-membership functions $\nu_{\tilde{A}}$, respectively. A triangular IFN is shown in Figure 3-3.

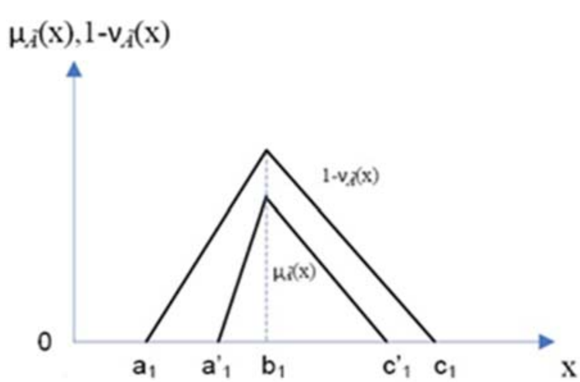

Figure 3 3. A triangular IFS Ã

3.3. *Arithmetic Operation for Triangular Intuitionistic Fuzzy Number*

For two triangular IFNs
$\tilde{A}1 = \langle[(a'1,b'1,c'1);\ \mu\tilde{A}1],\ [(a1,b1,c1);\ \nu\tilde{A}1]\rangle$ and $\tilde{A}2 = \langle[(a'2,b'2,c'2);\ \mu\tilde{A}2],\ [(a2,b2,c2);\ \nu\tilde{A}2]\rangle$
Four common arithmetic operations for IFNs:
Addition
$\tilde{A}1 + \tilde{A}2 = \langle\ [(a'1+a'2,\ b'1+b'2,\ c'1+c'2);\ \min(\mu\tilde{A}1,\ \mu\tilde{A}2)],\ [(a1+a2,\ b1+b2,\ c1+c2);\ \max(\nu\tilde{A}1,\ \nu\tilde{A}2)]\ \rangle$ (3-2)
Subtraction
$\tilde{A}1 - \tilde{A}2 = \langle\ [(a'1+c'2,\ b'1-b'2,\ c'1+a'2);\ \min(\mu\tilde{A}1,\ \mu\tilde{A}2)],\ [(a1-c2,\ b1-b2,\ c1+a2);\ \max(\nu\tilde{A}1,\ \nu\tilde{A}2)]\ \rangle$ (3-3)
Multiplication
$\tilde{A}1 \times \tilde{A}2 = \langle\ [(a'1 x a'2,\ b'1 x b'2,\ c'1 x c'2);\ \min(\mu\tilde{A}1,\ \mu\tilde{A}2)],\ [(a1 x a2,\ b1 x b2,\ c1 x c2);\ \max(\nu\tilde{A}1,\ \nu\tilde{A}2)]\ \rangle$ (3-4)
Division
$\tilde{A}1 / \tilde{A}2 = \langle\ [(a'1/c'2,\ b'1/b'2,\ c'1/a'2);\ \min(\mu\tilde{A}1,\ \mu\tilde{A}2)],\ [(a1/c2,\ b1/b2,\ c1/a2);\ \max(\nu\tilde{A}1,\ \nu\tilde{A}2)]\ \rangle$ (3-5)
The above arithmetic operations are used to develop group IF-AHP and IF-ANP methods.

4. THE PROPOSED MODEL FOR MEASURING ICT MATURITY

A group intuitionistic fuzzy AHP or ANP method is applied in the proposed model to measure an enterprise's ICT maturity. The process of measuring includes following steps:
Step 1: Define measuring factors, indicators and linguistic variables.
Firstly, define measuring factors and indicators. As presented in previous chapter, the measurement of ICT maturity consists of 4 main factors. Each factor has its own indicators: 12 indicators for Infrastructure (I), 17 indicators for Application (A), 12 indicators for Human resource (H) and 11 indicators for Policy (P). In a particular factor, each indicator is assigned to a stage of ICT development. So we will divide indicators from one factor into 4 groups respectively 4 stages (from 2 to 5) later.
Then, define the appropriate linguistic variables for the importance weight of factors, indicators and stages. This research suggests linguistic terms that can be expressed in triangular fuzzy numbers and intuitionistic fuzzy numbers, see Table 4-1.

Table 4 1. Linguistic variables for important weight

Linguistic terms		**Linguistic value in fuzzy set**	**Value in intuitionistic fuzzy set**
JE	Just Equal preferred	(1,1,1)	<[(1,1,1),0.8],[(1,1,1),0.1]>
EP	Equally preferred	(1,1,3/2)	<[(1,1,3/2),0.8],[(1,1,2),0.1]>
WMP	Weakly more preferred	(3/2,2,5/2)	<[(3/2,2,5/2),0.8],[(1,2,3),0.1]>
SMP	Strongly more preferred	(5/2,3,7/2)	<[(5/2,3,7/2),0.8],[(2,3,4),0.1]>
VMP	Very strongly more preferred	(7/2,4,9/2)	<[(7/2,4,9/2),0.8],[(3,4,5),0.1]>
AMP	Absolutely more preferred	(9/2,5,11/2)	<[(9/2,5,11/2),0.8],[(4,5,6),0.1]>

Step 2: Develop pairwise comparision matrix using intuitionistic fuzzy

In F-AHP, a paiwise comparison can be expressed by a triangular fuzzy number as (value-Δ, value, value+Δ), where Δ is fuzzification factor used to account for the vagueness in uncertainty. In case of IF-AHP, a pairwise comparison is expressed by an interval-value membership [μL, μU]. In addition, the decision makers can specify their degree of belief and degree of non-belief for the pairwise comparisons. The belief is represented by a membership function μx so the lower bound membership μL = μX. The non-belief is represented by a non-membership function ϑ_x, so the upper bound membership $\mu_U = 1 - \vartheta_x$. The fuzzification factors $\Delta^{\mu L}$ and $\Delta^{\mu U}$ for μL and μU respectively may not be the same. Therefore, a pairwise comparison in term of triangular IFS can be written as $([(value - \Delta^{\mu L}, value, value + \Delta^{\mu L}), \mu_X], [(value - \Delta^{\mu U}, value, value + \Delta^{\mu U}), \nu_X])$.

To simplify the problem, in the practical experiment (session 5) we assume that the degree of belief μX = 80% = 0.8 and the degree of non-belief ϑ_x = 10% = 0.1. The fuzzification factors for μL and μU are $\Delta^{\mu L}$= 0.5 and $\Delta^{\mu U}$= 1.0 respectively.

Firstly, collect judgments in term of linguistic variable from a group of some experts then create a intuitionistic fuzzy pairwise comparison matrix. Consider a IF judgment matrix $\bar{\bar{J}}$ with n criteria.

$$\bar{\bar{J}} = \begin{bmatrix} \bar{\bar{j}}_{11} & \bar{\bar{j}}_{12} & \cdots & \bar{\bar{j}}_{1n} \\ \bar{\bar{j}}_{21} & \bar{\bar{j}}_{22} & & \bar{\bar{j}}_{2n} \\ \vdots & & \ddots & \vdots \\ \bar{\bar{j}}_{n1} & \bar{\bar{j}}_{n2} & \cdots & \bar{\bar{j}}_{nn} \end{bmatrix}$$

For diagonal entries i=j, =1. Upper right-hand triangle entries are pairwise comparisons defined by decision makers, whereas lower left-hand triangle entries are derived by taking reciprocal, i.e., .

Step 3: Check for consistency of judgments

The AHP utilizes consistency index (CI) and consistency ratio (CR) to determine if the fuzzy judgment matrix is consistent or not. The threshold of the CR is usually 0.1.

Step 4: Determine the IF weights for main factors, stages and indicators.

There are several techniques to compute the weights. In this paper, the geometric mean is used to compute the intuitionistic fuzzy weights. For each row , firstly taking the geometric mean (equation 3-6) , then calculating IF weights (equation 3-7).

$$\bar{\bar{J}}_i = \left(\bar{\bar{J}}_{i1} \times \bar{\bar{J}}_{i2} \times \ldots \times \bar{\bar{J}}_{in}\right)^{1/n}$$ **(Error! No text of specified style in document.**-1)

$$\bar{\bar{w}}_i = \bar{\bar{J}}_i \times \left(\bar{\bar{J}}_1 + \bar{\bar{J}}_2 + \ldots + \bar{\bar{J}}_n\right)^{-1}$$ **(Error! No text of specified style in document.**-2)

Applying the method above, we can calculate the local weights of 4 main factors, the local weights of 4 stages (from 2 to 5) within each main factor, then the local weights of each indicators within a stage of a particular main factor.

Step 5: Normalization and intuitionistic defuzzification for IF weights

The intuitionistic fuzzy weights calculated in previous step will be normalized based on then most likely value. Firstly, use the equation (3-8) & (3-9) as a procedure proposed by Wang, Y. M. and Elhag, T. (2006) to check for normality. If it is not satisfied, they suggested a normalization method in equation (3-10).

$$\sum_{i=1}^{n} w_i^{LI} + \max_j\left(w_j^{UI} - w_j^{LI}\right) \le 1 \quad and \quad \sum_{i=1}^{n} w_i^{UI} - \max_j\left(w_j^{UI} - w_j^{LI}\right) \ge 1$$

(Error! No text of specified style in document.-3) & (**Error! No text of specified style in document.**-4)

$$(\widehat{w}_i)_\alpha^{LI} = max\left\{(w_i)_\alpha^{LI}, 1 - \sum_{j\neq i}^{n}(w_i)_\alpha^{UI}\right\} \; and \; (\widehat{w}_i)_\alpha^{UI} = min\left\{(w_i)_\alpha^{UI}, 1 - \sum_{j\neq i}^{n}(w_i)_\alpha^{LI}\right\}$$

(Error! No text of specified style in document.-5)

The intuitionistic defuzzification converts an IF-AHP weight into a crisp value that includes two following tasks:

Task 1: Mendel, J. M. (2004) suggested a method to reduce an IFS into a fuzzy set by taking an arithmetic mean of interval-value memberships [μL, μU] at each xd, representing predefined discrete points over the universe of discourse.

Task 2: Lee & Li (1988) and Chen, Hwang, Beckmann & Krelle (1992) suggested the use of generalized mean and standard deviation in defuzzification. Consider $\overline{w_i}$ is "reduced fuzzy set" of $\overline{w_i}$. Generalized mean and standard deviation are:

$$\overline{x}(\overline{W_i}) = \frac{\int_a^b x\,\mu_{\overline{W_i}}(x)\,dx}{\int_a^b \mu_{\overline{W_i}}(x)\,dx}$$

(Error! No text of specified style in document.-6)

$$\sigma(\overline{W_i}) = \left[\frac{\int_a^b x^2\mu_{\overline{W_i}}(x)dx}{\int_a^b \mu_{\overline{W_i}}(x)dx} - [\overline{x}(\overline{W_i})]^2\right]^{1/2}$$

(Error! No text of specified style in document.-7)

In two equations above, a and b are the lower and upper bounds when the membership is not equal to zero.

Step 6: Calculate the ICTMI.

Use formula from (3-1) to (3-5) along with the result of survey (to get the values of indicators) to calculate the ICTMI.

5. PRACTICAL EXPERIMENT (CASE STUDY)

Based on the proposed measurement of 52 indicators in Table 2-1, a questionnaire is designed, then a survey was conducted in numerous enterprises in Vietnam. The questionnaires were delivered to 124 enterprises all located in Ho Chi Minh city, Vietnam by sending e-mail to or direct interviewing the person responsible. The number of valid response is 80 enterprises.

After having questionnaires given back, the data of all indicators have to be quantized in the range of (0, 1), mainly by proportion, percentage, frequency.
A group of 3 experts have convened to pass their judgments on relative importance of main factors and stages. Next step is to determine relative importance weights of 4 main factors and relative importance weights of indicators with respect to each main factor. For simplicity, in the scope of this study we don't go further to calculate the relative importance weights of each indicators in respect to one main factor. All indicators in the same one main factor are assumed to have equal importance weight. Then, ICTMI of enterprises will be calculated.

5.1. Using IF-AHP Approach:

All pair-wise comparisons then are arranged in a common matrix popularly called pairwise comparison matrix (PCM), see Table 5-1. For each pair of main factors, we have 3 judgments corresponding to 3 experts.
Firstly, we will check the data consistency for judgments from each expert. The consistency ratio (CR) of expert-1 is 0.015 which is less than the consistency threshold 0.1. So expert-1's opinion is consistent. Similarly, we can test the consistency for judgments from 2 other experts. The second expert has the consistency ratio 0.038. The third expert has the consistency ratio 0.030. They are both less than the consistency threshold 0.1. So expert-2's and expert-3's judgments are also consistent.

Table 5 1. Pair-wise comparison matrix of main factors given by expert group

	I	**A**	**H**	**P**
I	JE	WMP	1/SMP	EP
	JE	WMP	1/WMP	EP
	JE	EP	1/WMP	1/WMP
A		JE	1/VMP	1/SMP
		JE	1/SMP	1/SMP
		JE	1/VMP	1/SMP
H			JE	WMP
			JE	SMP
			JE	WMP
P				JE
				JE
				JE

In this experiment, assume that degree of belief □x=0.8, degree of non-belief □x =0.1, the fuzzification factors for □L and □U are □□L=0.5 and □□U=1.0 respectively. The geometric mean method is used to obtain the combined pairwise comparison matrix for whole group of experts, see Table 5-2.

Table 5 2. Combined pair-wise comparison matrix given by expert group

	I	**A**	**H**	**P**
I	<[(1.000,1.000,1.000),0.8], [(1.000,1.000,1.000),0.1]>	<[(2.359,2.884,3.402),0.8], [(1.817,2.884,3.915),0.1]>	<[(2.500,3.000,3.500),0.8], [(2.000,3.000,4.000),0.1]>	<[(1.000,1.000,1.500),0.8], [(1.000,1.000,2.000),0.1]>
A	<[(0.294,0.347,0.424),0.8], [(0.255,0.347,0.550),0.1]>	<[(1.000,1.000,1.000),0.8], [(1.000,1.000,1.000),0.1]>	<[(1.500,2.000,2.500),0.8], [(1.000,2.000,3.000),0.1]>	<[(2.109,2.621,3.129),0.8], [(1.587,2.621,3.634),0.1]>
H	<[(0.286,0.333,0.400),0.8], [(0.250,0.333,0.500),0.1]>	<[(0.400,0.500,0.667),0.8], [(0.333,0.500,1.000),0.1]>	<[(1.000,1.000,1.000),0.8], [(1.000,1.000,1.000),0.1]>	<[(1.990,2.520,3.041),0.8], [(1.442,2.520,3.557),0.1]>
P	<[(0.667,1.000,1.000),0.8], [(0.500,1.000,1.000),0.1]>	<[(0.320,0.382,0.474),0.8], [(0.275,0.382,0.630),0.1]>	<[(0.329,0.397,0.503),0.8], [(0.281,0.397,0.693),0.1]>	<[(1.000,1.000,1.000),0.8], [(1.000,1.000,1.000),0.1]>

If we consider the whole group of experts as a "new expert". The consistency ratio of "new expert" or entire group of expert is 0.015 less than the consistency threshold 0.1. Thus, the whole group comparison is consistent.

The weight vectors of main factors are determined by using equation (3-6):

$\overline{\overline{J}}_1$ = <[(0.767, 0.861, 1.079), 0.8], [(0.677, 0.861, 1.348), 0.1]>

$\overline{\overline{J}}_2$ = <[(0.425, 0.490, 0.559),0.8], [(0.379, 0.490, 0.661), 0.1]>

$\overline{\overline{J}}_3$ = <[(1.774, 2.089, 2.385), 0.8], [(1.428, 2.089, 2.667), 0.1]>

$\overline{\overline{J}}_4$ = <[(0.940, 1.134, 1.278), 0.8], [(0.786, 1.134, 1.463), 0.1]>

Next, the intuitionistic weights $\overline{\overline{w}}_i$ can be computed by using formula (3-7):

$\overline{\overline{w}}_1$ = <[(0.145, 0.188, 0.276), 0.8], [(0.110, 0.188, 0.412), 0.1]>

$\overline{\overline{w}}_2$ = <[(0.080, 0.107, 0.143), 0.8], [(0.062, 0.107, 0.202), 0.1]>

$\overline{\overline{w}}_3$ = <[(0.335, 0.457, **0.611**), 0.8], [(0.233, 0.457, **0.816**), 0.1]>

$\overline{\overline{w}}_4$ = <[(0.177, 0.248, 0.327), 0.8], [(0.128, 0.248, 0.447), 0.1]>

Sum of the most likely values of intuitionistic fuzzy weights above is $\sum \overline{\overline{w}}_i$ = 0.188 + 0.107 + 0.457 + 0.248 = 1 complies with the basic axiom of AHP.

Next step is to check for normality of newly obtained weights above. At μ_L=0.8 and α=0, the lower interval weights are

$(w_1)_{\alpha=0}$=[0.145, 0.276] $(w_2)_{\alpha=0}$=[0.080, 0.143] $(w_3)_{\alpha=0}$=[0.335, 0.611] $(w_4)_{\alpha=0}$=[0.177, 0.327]

Using the equation (3-8) and (3-9), it can be shown that:

$\sum_{i=1}^{n} w_i^{LI} + \max_j\left(w_j^{UI} - w_j^{LI}\right) = 0.737 + 0.276 = 1.013 \leq 1$ (unsatisfied) and

$\sum_{i=1}^{n} w_i^{UI} - \max_j\left(w_j^{UI} - w_j^{LI}\right) = 1.358 - 0.276 = 1.081 \geq 1$ (satisfied)

At μ_U = 0.9 and α=0, the upper interval weights are:

$(w_1)_{\alpha=0}$=[0.110, 0.412] $(w_2)_{\alpha=0}$=[0.062, 0.202]

$(w_3)_{\alpha=0}$=[0.233, 0.816] $(w_4)_{\alpha=0}$=[0.128, 0.447]

Using the equation (3-8) and (3-9), it can be shown that:

$\sum_{i=1}^{n} w_i^{LI} + \max_j\left(w_j^{UI} - w_j^{LI}\right) = 0.533 + 0.583 = 1.116 \leq 1$ (unsatisfied) and

$\sum_{i=1}^{n} w_i^{UI} - \max_j\left(w_j^{UI} - w_j^{LI}\right) = 1.878 - 0.583 = 1.294 \geq 1$ (satisfied)

Since the normality is not satisfied, the lower and upper interval weights have to be adjusted by using equation (3-10). The final results are:

$\overline{\overline{w}}_1$ = <[(0.145, 0.188, 0.276), 0.8], [(0.110, 0.188, 0.412), 0.1]>

$\overline{\overline{w}}_2$ = <[(0.080, 0.107, 0.143), 0.8], [(0.062, 0.107, 0.202), 0.1]>

$\overline{\overline{w}}_3$ = <[(0.335, 0.457, **0.598**), 0.8], [(0.233, 0.457, **0.700**), 0.1]>,

$\overline{\overline{w}}_4$ = <[(0.177, 0.248, 0.327), 0.8], [(0.128, 0.248, 0.447), 0.1]>

With this new set of adjusted weights, equations (3-8) and (3-9) are satisfied now, which means the adjusted weights meet requirement of normality. Using equation (3-11) and (3-12) to do intuitionistic defuzzification for adjusted weights above, we have generalized mean, standard deviation. Then the generalized means are continually normalized so that sum of them equals to 1, thus we have the normalized final weights. The result is in Table 5-3.

Table 5-3. Final importance weights of main factors

Main factors	Generalized mean	Standard deviation	Normalized final weight
I – Infrastructure	0.224	0.058	**0.210**
A – Application	0.114	0.020	**0.107**
H – Human resource	0.458	0.081	**0.431**
P – Policy	0.267	0.056	**0.251**

Finally, the importance weights of 4 main factors corresponding to I, A, H, P is

Table 5-4. Relative importance weights of main factors

Factor	Infrastructure	Application	Human Resource	Policy
Weight	**0.210**	**0.107**	**0.431**	**0.251**

Now we have all the relative importance weights of 4 main factors like above Table 5-4. Note that, in the scope of this study we don't go further to calculate the relative importance weights of each indicators in respect to one main factor. Next, based on the result of survey along with obtained importance weights above, we applied the formula from (3-1) to (3-5) to calculate the ICTMI for enterprises in this experiment. Lastly, the ICT maturity status of enterprise was achieved by match ICTMI with the 5-stage road-map for ICT maturity development. In this experiment, we used an instance of 5-stage road-map as following:

Table 5-5. An instance of 5-stage road map

ICTMI	0.0 - 0.2	0.2 - 0.4	0.4 - 0.6	0.6 - 0.8	0.8 - 1.0
Status	Inactive	Basic	Substantial	Web-based	Knowledge-oriented

5.2. Using IF-ANP Approach:

In ANP approach, it emphasizes the network relation especially the feedback relation between factors. As we mentioned in section 2.1, the more optimum result can likely be obtain by considering inner dependences among main internal factors. We are going to apply IF-ANP approach to determine the importance weights of main factors under consideration of inner dependences among them.

In previous section 5.1, we assumed that 4 main factors are independent. Then we used IF-AHP method to calculate their priority weight as the result in Table 5-4. That result can be called local weight vector of 4 main factors

$$\mathbf{W = (0.210, 0.107, 0.431, 0.251)}$$

To calculate the interdependent weights of 4 main factors, we firsly consider the inner dependence matrices of factors with respect to every other factor. Based on the inner dependence presented in Figure 2-1, pairwise comparison matrices are formed for factors.

Here is the inner dependence matrix of main factors with respect to Policy factor, given by expert group.

P	I	A	H
I	JE	WMP	1/WMP
	JE	WMP	1/WMP
	JE	SMP	1/WMP
A		JE	1/VMP
		JE	1/VMP
		JE	1/VMP
H			JE
			JE
			JE

In this experiment, the degree of belief $\mu_x=0.8$, degree of non-belief $\upsilon_x=0.1$, the fuzzification factors for μ_L and μ_U are $\Delta^{\mu L}=0.5$ and $\Delta^{\mu U}=1.0$ respectively. Applying the same way of calculation we did in section 5.1 with IF-AHP, we have the vector of relative importance weight of factors with respect to Policy factor is $\mathbf{W_P} = \mathbf{(0.321, 0.141, 0.537)}$.

Next, we consider the inner matrices of main factors with respect to Application factor, the vector of relative importance weight of factors with respect to Application factor is $\mathbf{W_A} = \mathbf{(0.279, 0.449, 0.272)}$. Similarly, the vector of relative importance weight of factors with respect to Infrastructure factor is $\mathbf{W_I} = \mathbf{(0.334, 0.666)}$ and the vector of relative importance weight of factors with respect to Human Resource factor is $\mathbf{W_H} = \mathbf{(0.293, 0.707)}$.

Based on 4 vectors W_I, W_A, W_H and W_P we have the dependence matrix of main factors as following

$$\begin{bmatrix} 1.000 & 0.279 & 0.000 & 0.321 \\ 0.334 & 1.000 & 0.293 & 0.141 \\ 0.000 & 0.449 & 1.000 & 0.537 \\ 0.666 & 0.272 & 0.707 & 1.000 \end{bmatrix}$$

The interdependent weights of main factors are calculated by multiplying the dependence matrix above with the local weight vector of factors as following

$$\begin{bmatrix} 1.000 & 0.279 & 0.000 & 0.321 \\ 0.334 & 1.000 & 0.293 & 0.141 \\ 0.000 & 0.449 & 1.000 & 0.537 \\ 0.666 & 0.272 & 0.707 & 1.000 \end{bmatrix} \times \begin{bmatrix} 0.210 \\ 0.107 \\ 0.431 \\ 0.251 \end{bmatrix} = \begin{bmatrix} 0.320 \\ 0.339 \\ 0.614 \\ 0.725 \end{bmatrix}$$

After normalization, the final interdependent weights of 4 main factors are

$$\mathbf{W = (0.160, 0.170, 0.307, 0.363)}$$

So, we have the relative importance weights of 4 main factors as following.

Factor	Infrastructure	Application	Human Resource	Policy
Weight	0.160	0.170	0.307	0.363

Note that, in the scope of this study we will not go further to calculate the relative importance weights of each indicators with respect to one main factor. With the same calculation method used with IF-AHP approach, we can to calculate the ICTMI for enterprises in this experiment.

6. CONCLUSION

This paper contributes to an aspect of building a knowledge system by doing the very beginning step, that is measuring the ICT maturity level in an enterprise. The model of ICT maturity used includes 4 main factors ICT policy, ICT infrastructure, ICT application and ICT human resource. Group intuitionistic fuzzy AHP and ANP approaches are used to determine efficiently important weight of each factor or indicator to ICT maturity. With the obtained result, the enterprise can evaluate their current ICT maturity, so that they make a plan to improve their ICT state. The proposed model using intuitionistic fuzzy set helps to deal with imprecise and uncertain human comparison judgments.

This study adopt quantile causality approach to explore the possibility of a causal relationship between corporate social responsibility (CSR) and firm value under different quantile of corporate social responsibility (CSR) and firm value, using the CSR Index created by Chen and Hung (2013). The results show that CSR holds a two-way influence toward firm value, meaning that the effect CSR has on a firm is correlated with the firm's value. A firm with relatively low value can benefit immensely from emphasizing social responsibility, whereas when a firm makes an effort to enhance its value, it will not necessarily enhance engagement in CSR at the same time, owing to a crowding out effect. Keywords: Corporate social responsibility, Quantile regression, Firm value

I. INTRODUCTION

As investors show greater concern for sustainable corporate development, it has also become a coveted goal for firms. Corporate social responsibility (hereunder referred to as CSR) has been gaining ever more attention from firms, investors and society at large. When a firm engages in social responsibility, is there any noticeable impact on the firm's value? What kind of other effects, if any, does CSR bring? As of yet, the literature has not been able to provide any definitive answers. Furthermore, few studies have explored whether firms are willing to put forth effort in performing CSR when the firm seeks to increase its value. Preston & O'Bannon (1997) have ventured the following hypotheses regarding the relationship between CSR and corporate performance: First, the social impact hypothesis, which is based on stakeholder theory, assumes a positive correlation between stakeholder expectations of a firm and the firm's financial performance (Freeman, 1984). Second, trade-off hypothesis assumes that CSR exerts negative effects on corporate financial performance, thus the cost of social responsibility may diminish the firm's profits and as well as the wealth of shareholders. Third, positive synergy hypothesis presumes that when businesses take on ethical duties toward social welfare, their corporate performance will get better, and therefore such businesses obtain more resources that can be put toward social responsibility. This is a positive cycle for firms and society (Allouche & Laroche, 2005). Fourth, negative synergy hypothesis assumes that taking social responsibility on might have a negative effect on a firm's performance, thus curtailing its further investment in social welfare.

Chen, Hung and Lee (2014, 2015) seem to have proved otherwise: according to their research results, a firm with relatively low value can benefit immensely from taking CSR on as an intangible asset to the firm, whereas when a high-valued firm takes on social responsibility, the effect of CSR on firm value enhancement is decreased. This suggests that for a firm with higher value, CSR does not help much in enhancing firm value. On the other hand, when the CSR efforts are relatively low, a moderate increase in firm value does little to boost CSR due to a crowding out effect; yet when involvement in CSR increases, increasing firm value paves the way for the firm to engage in even greater social responsibility.

Therefore this paper proposes that a differing causal relationship exists between firm value and CSR among various conditional quantiles. It follows that the conditional distribution provided by quantile regression will prove to be a more workable tool for testing non-abnormal distribution, as Leider (2012) suggested, rather than using mean distribution by least regression (Leider, 2012).

II. METHODOLOGY

II.1 Non-parametric Granger Causality Test

The non-parametric causality method developed by Granger considers two time series and determines whether one causes the other. Yet such causality might be composed of different quantiles and thus demonstrates differing causal relationships(Lee and Yang, 2012). According to Hong et al. (2009) the Granger causality test produces a more robust result. Balcilar et al. (2014) defined the Granger causality quantile as follows:

1. x_t does not cause y_t in the θ-quantile with respect to $\{y_{t-1}, \dots, y_{t-i}, x_{t-1}, \dots, x_{t-j}\}$
if $Q_\theta(y_t|y_{t-1}, \dots, y_{t-i}, x_{t-1}, \dots, x_{t-j}) = Q_\theta(y_t|y_{t-1}, \dots, y_{t-i})$ (1)

2. x_t is a Granger cause y_t in the θ-quantile with respect to $\{y_{t-1}, \dots, y_{t-i}, x_{t-1}, \dots, x_{t-i}\}$ if $Q_\theta\left(y_t | y_{t-1}, \dots, y_{t-i}, x_{t-1}, \dots, x_{t-j}\right) \neq Q_\theta\left(y_t | y_{t-1}, \dots, y_{t-j}\right)$ (2)

where $Q_\theta(y_t|\Lambda)$ is the θth conditional quantile of y_t given Λ which depends on t and $0 < \theta < 1$.

Let's consider $\{x_t, y_t\} = \{Tobin'q, CSRI\}$, with *Tobin'q* as the proxy variable of firm value, while CSRI serves as the index for CSR.

$X_{t-1} \equiv (x_{t-1}, \dots, x_{t-i})$, $Y_{t-1} \equiv \left(y_{t-1}, \dots, y_{t-j}\right)$, $Z_{t-1} \equiv \left(y_{t-1}, \dots, y_{t-i}, x_{t-1}, \dots, x_{t-j}\right)$, $V_t = (X_t, Z_t)$. $\mathrm{F}_{y_t|Z_{t-1}} = \mathrm{F}_{y_t|Z_{t-1}}(y_t|Z_{t-1})$ and $\mathrm{F}_{y_t|Y_{t-1}} = \mathrm{F}_{y_t|Y_{t-1}}(y_t|Y_{t-1})$ stand for the conditional probability of Y_t under Z_{t-1}, and Y_{t-1} respectively. Therefore they can be used to announce the null hypotheses of definitions (1) and (2):

$$H_0 = \mathrm{P}\left\{\mathrm{F}_{y_t|Z_{t-1}}\{Q_\theta(y_t|Y_{t-1})|Z_{t-1}\} = \mathrm{F}_{y_t|Z_{t-1}}\{Q_\theta(Z_{t-1})|Z_{t-1}\}\right\} = 1, \tag{3}$$

$$H_1 = \mathrm{P}\left\{\mathrm{F}_{y_t|Z_{t-1}}\{Q_\theta(y_t|Y_{t-1})|Z_{t-1}\} = \mathrm{F}_{y_t|Z_{t-1}}\{Q_\theta(Z_{t-1})|Z_{t-1}\}\right\} < 1. \tag{4}$$

If the evidence is against the null hypothesis (H_0), there is a causality, and vice versa. Jeong et al.(2012) reduced the problem of irrelevancy in all the tests for quantile causality by using $D = \{\varepsilon_t \cdot E(\varepsilon_t|Z_{t-1})f_z(Z_{t-1})\}$) as a distance masure, where ε_t is the regression error term and $f_z(Z_{t-1})$ is the marginal density function of Z_{t-1}. The regression error ε_t arises because the null hypothesis in (3) can only be true if $\mathrm{E}[\mathbf{I}\{y_t \leq Q_\theta(Y_{t-1})|Z_{t-1}\}] = \theta$ or equivalently $\mathbf{I}\{y_t \leq Q_\theta(Y_{t-1})\} = \theta + \varepsilon_t$, where $\mathbf{I}\{\cdot\}$ is the indicator function. Jeong et al. (2012) identified the distance function as

$$D = \mathrm{E}\left[\left\{\mathrm{F}_{y_t|Z_{t-1}}\{Q_\theta(Y_{t-1})|Z_{t-1}\} - \theta\right\}^2 f_z(Z_{t-1})\right] \tag{5}$$

where $D \geq 0$ and the equality holds if and only if the null hypothesis H_0 in equation (3) is true, while $D > 0$ holds under the alternative H_1 in equation (4). Additionally, Jeong et al. (2012) specified that the feasible kernel-based test statistic based on D takes the following form:

$$\hat{D}_T = \frac{1}{T(T-1)h^{2p}} \sum_{t=1}^{T} \sum_{S \neq t}^{T} K\left(\frac{Z_{t-1} - Z_S}{h}\right) \hat{\varepsilon}_t \hat{\varepsilon}_S \tag{6}$$

where T denotes the number of all data, $K(\cdot)$ is the kernel function with bandwidth h, and $\hat{\varepsilon}_t$ is estimated from the unknown regression error of $\hat{\varepsilon}_t = \mathbf{I}\{y_t \leq \hat{Q}_\theta(Y_{t-1}) - \theta\}$ where $\hat{Q}_\theta(Y_{t-1})$ is an estimate of the θ-th conditional quantile of y_t given Y_{t-1}. $\hat{Q}_\theta(Y_{t-1})$ can be estimated by the nonparametric kernel method as $\hat{Q}_\theta(Y_{t-1}) = \hat{F}^{-1}_{y_t|Y_{t-1}}(\theta|Y_{t-1})$. $\hat{F}_{y_t|Y_{t-1}}(y_t|Y_{t-1})$ is the Nadarya-Watson kernel estimator given by

$$\hat{F}_{y_t|Y_{t-1}}(y_t|Y_{t-1}) = \frac{\sum_{s \neq t} L\left(\frac{Y_{t-1} - Y_s}{h}\right) I(Y_s \leq Y_{t-1})}{\sum_{s \neq t} L\left(\frac{Y_{t-1} - Y_s}{h}\right)} \tag{7}$$

with the kernel function $L(\cdot)$ and bandwidth h.

III. DATA ANALYSIS

The data were obtained from listed companies during the 2010 to 2011 period. The data regarding CSR was gleaned from the CSR index compiled by Chen and Hung (2013). Data frequency is annual. The financial reporting data was derived from the TEJ, and actual corporate value was denoted as Tobin's q. A total of 772 companies and 1487 annual reports were employed. Cross-sectional information from both of the 2 year time-series were pooled over the 772 companies to estimate the predictability of the coefficients). Descriptive statistics are shown in Table 1.

Table 1: Summary of statistics for listed, Taiwan-based companies, 2010-2011. N=1487

	Mean	Max.	Min.	Std.	Sk.	K.	J-B
Tobin's q	1.223	5.820	0.460	0.546	2.960	16.463	13400.470***
CSRI	12.215	24.000	0.000	3.733	0.145	3.610	28.222***

Note: Std. denotes standard deviation, SK. denotes the skewness, K. denotes the kurtosis and J-B denotes the Jarque-Bera test for normality. ** and *** indicate significance at the 5% and 1% level, respectively. H_0: SK.=0, K.=3 (normality).

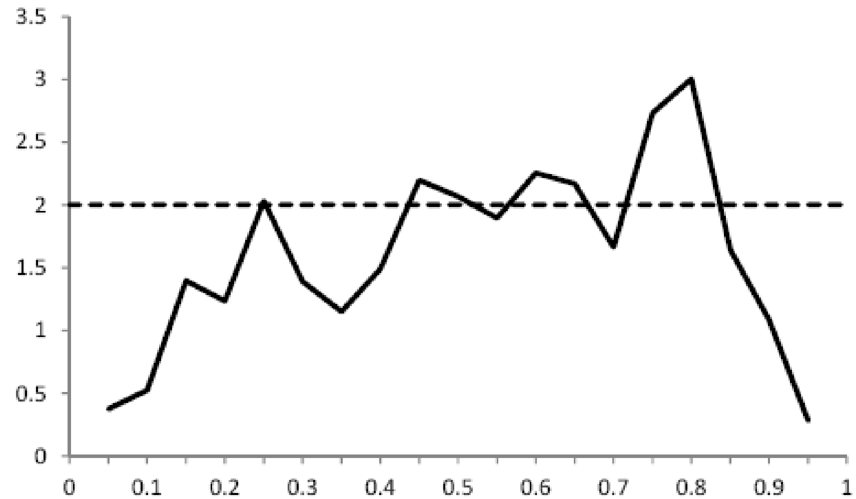

Figure 1: Test statistics with respect to different quantiles for firm value to CSR causality.

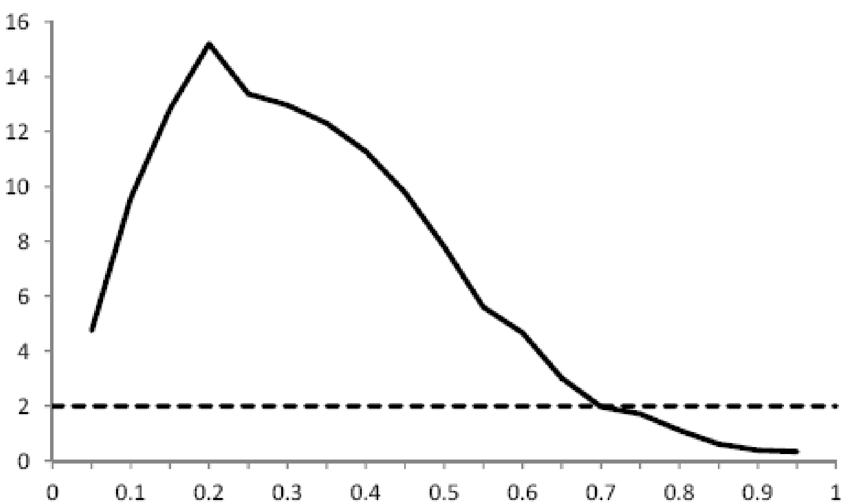

Figure 2: Test statistics with respect to different quantiles for CSR to firm value causality.

IV. RESULTS

Figures 1 and 2 show that (1) when a firm has relatively low value, CSR initiatives may boost prestige and intangible assets, thereby enhancing firm value. On the other hand, CSR initiatives play only a minor role in boosting the value of a firm if the company already has higher firm value. (2). When engagement in CSR is low, the enhancement of firm value does not necessarily lead to an increase in CSR, perhaps owing to a crowding out effect, whereas if engagement in CSR is high, an increase in firm value helps to motivate the company to make continued CSR efforts.

This paper utilized the quantile Granger causality method proposed by Jeong et al., (2012) to explore the two-way causality between the CSR of listed companies in Taiwan and firm value. The solid lines in Figures 1 and 2 denote standardized statistics under different dependent variable quantiles, whilst the dotted lines=1.96 implies a significance level of 5%. Therefore from Figure 1 and 2, we can clearly see causality between CSR and firm value in each conditional quantile. Figure 1 shows the causal relationship between firm value and CSR under various conditional quantiles of CSR. When the equation $\tau = 0.25$ $0.45 < \tau$[1]< 0.85 is true, the causality of firm value and CSR becomes apparent, which suggests higher involvement in CSR is correlated with higher firm value, and higher firm value then gives rise to better involvement in CSR. A crowding out effect is also demonstrated. This phenomenon suggests that a newly founded company only thinks about making money, and cares less about social responsibility. Only when a firm puts considerable effort into enhancing firm value does it also perform ethical duties for social welfare. Figure 2 shows the causality between firm value and CSR under each conditional quantile of firm value. When $\tau<0.70$, CSR exerts a noticeable effect on firm value, which suggests that a firm with lower firm value can turn to CSR initiatives in an effort to enhance firm value. This validates the idea that an enterprise can be protected with a corporate social responsibility shield; therefore, a low value firm may take the CSR initiatives to boost value.

V. CONCLUSION

Corporate social responsibility affects firms in very different ways since only low value firms get a significant boost in firm value from performing CSR. The two-way influences of

[1] τ represents the quantiles (considered quantiles 0.10 – 0.90 with 0.05 increments).

CSR and firm value may vary in accordance with firm value and the way a company performs social welfare duties. A lower-valued firm might see a remarkable benefit from taking on corporate social responsibility. Some firms will put forth little CSR effort owing to a crowding out effect, despite their need to enhance firm value. This validates the idea that a social enterprise needs intervention from the public sector or other resources from society.

dvhung@hcmut.edu.vn, duong.vohung@yahoo.com

Bui Nguyen Hung
School of Industrial Management, HoChiMinh City University of Technology, 268 Ly Thuong Kiet St., Dist. 10, HoChiMinh City, Vietnam

In this research, we proposed a model for capacitated facility location problem, our model deals with outsourcing strategy consideration and direct shipments problems in which products are considered shipments from suppliers or manufacturing plants to retailers directly. Thus, we employed a dummy distribution centers (dummy DCs) to link from manufacturing plants to retailers. We assumed dummy DCs capacities as vehicles capacity (truck load). The advantage of this model is that we can control the number of vehicles requirement at each period. Morever, our proposed model can modified for outsourcing startegy by changing manufacturing plant sources to supplier sources. We believe that this model helps the investors reducing the total investment cost (total fixed costs for openning manufacturing plants and distribution canters). This makes the difference among our model and existing ones. For validation testing, we compared our solutions to the solutions obtained by proposed model of Duong and Hung, 2014 in the same input parameters.
Keywords: Logistic, direct shipment, outsourcing, supply chain, mixed integer linear programming, network design.

1. Introduction

Nowadays, we know that, supply chain (SC) network combines and integrates all business functions in companies such as suppliers, inbound logistics, core manufacturer, outbound logistics, marketing and sales, and end customers (e.g., Chan et al., 2003, Stadtler, 2005, and Klibi et al., 2010). This follows that, SC network is emphasized on modern business activities. In addition, with global market competition, investors and managers paid their attention on their SC network (Simchi-Levi et al., 2000, Matinrad et al., 2013). Therefore, SC operations play a very important role in business activities. Making the SC network effective that is paid attention by managers and researchers, hence, SC problems become a popular topic (Chan and Qi, 2003). Integrating many components and operational functions, the SC problems are very complex, so studying about this field is still valuable.

To support a long-term effectiveness in strategies and operations for the SC network systems, SC network design problems should be serious consideration for realistic cases, specializing in capacitated facilities location problems. One of the initial publications with capacitated facilities location problem for SC network design was developed by Geoffrion and Graves (1974). In their study, a MILP for designing multi-product distribution network by satisfied single-period demand. The objective of this research is to minimize the total cost which consists of transportation cost and fixed cost of the opening distribution centers. A Benders decomposition algorithm was also developed for getting solutions. Continuing this research idea, Pirkul and Jayaraman (1998), Mazzola and Neebe (1999) also studied multi-item and single-period demand for distribution network design, however, they used the lagrangian relaxation algorithm, in which they broke their original problem into n small sub-problems that related to each warehouse and plant by dropping some constraint sets. Recently, Shankar et al., (2013) developed multi objective optimization to support location and allocation decisions in SC network, this model applied for single product in the system.

In the review works of Klibi et al., (2010), Arabani and Farahani (2012), Matinrad et al., (2013), and Farahani et al., (2014) showed that the researchers try to develop complex models for general application in relistic systems. Dynamic approach, multi-objective programmings, uncertainty demands, multi-period, multi echolon/stage,… are futher trends for studying SC, off course, these models require the complex algorithms for finding solutions. However, in the modern SC network operations and management, managers, investors and researchers deal with many realistic cases, they need the specific models with real factors consideration related to their problems. There are many existing research's models meeting realistic requirement. They focused their research on practical problems in SC network. For example, Melachrinoudis and Min (2007) proposed redesign a warehouse distribution network model, as this research, they considered truck-delivery-time parameter as a main factor to make their decision, so some current warehouses maybe closed and some new ones maybe located. Many specific cases in supply chain problems are studied such as: Rezaei and Davoodi (2008) considered the percentage of defective items from suppliers as a new factor in their model, or Bilgen and Ozkarahan (2007) developed a MILP model for bulk grain blending and shipping. Dondo et al. (2011) minimized the total transportation cost by considered vehicle routing problem with cross-docking in their research. Recently, Nagurney and Nagurney (2012) used a tractable network model for SC design to supply medical nuclear products. Sarkis et al., (2011) mentioned about green, environment, social response, sustainable supply chain in their review work. This topic is very specific situations for realistic.

In other research direction, Eksioglu et al. (2006) studied inventory level and inventory cost in operations at the end of each period in their SC network design model. Hinojosa et al. (2000, 2008) also developed MILP models for SC network design by considering multi-product, multi-period and inventory level. Recently, Duong and Bui (2014) considered facilities' capacity levels factor in a mixed integer linear programming for SC network design. We think that this real factor is very important for investors when a SC network is established. For special case with critical needs for survival (disasters, emergencies, epidemics, and attacks…) Nagurney et al., (2011) had considered outsourcing strategy in their SC network design model, we believe that outsourcing strategy is a key successful global SC network, therefore, this factor should be consideration in SC design problems. Moreover, shipment strategies are very important factor for consideration. For instance, the effective transshipment network is studied in research of Lien et al., (2011). Before that, Lejeune and Margot (2008) developed an integer linear programming model for solving inventory-production-distribution problems with the natural of products (bulk, chemical,…), that research employed full truck load distribution policy between suply chain nodes with direct shipments. Other research of Pishvaee and Rabbani (2011) considerd both direct and indirect shipment in supply chain network design. In that research, direct shipment from plants to customers, and indirect shipment from plants to Dcs and DCs to customers are considered, that complex model was solved by heuristic approach.

According to the above review, supply chain management and design become a common topic for mangers and researchers, this topic is still attractive and valuable to study for both general and specific cases. Moreover, in practical situations, we see that the investors and managers paid their attention on total fixed cost for openning all facilities in the new systems. They want to reduce the investment risk when the new SC network is established. Thus, transshipment and outsourcing strategies should be considered seriously. Therefore, our research tries to detect this problem.

In this research, we develop a mixed integer linear programming (MILP) model for supply chain network design problems which considered direct shipment and/or outsourcing strategy. Thus, we employed a dummy distribution centers (dummy DCs) to link from manufacturing plants to retailers. We assumed dummy DCs capacities as vehicles capacity (truck load). The advantage of this model is that we can control the number of vehicles requirement at each period. Morever, our proposed model can modified for outsourcing startegy by changing manufacturing plant sources to supplier sources. We believe that this model helps the investors reducing the total investment cost (total fixed costs for openning manufacturing plants and distribution canters). This makes the difference among our model and existing ones (e.g., Duong and Bui (2014), Pishvaee and Rabbani (2011), Lien et al. (2011), Lejeune and Margot (2011), and Amiri (2006), …). For finding solutions, we then employed a Lagrangian relaxation algorithm. This algorithm is based on relaxing one constraint sets which lead to the decomposition of the MILP model into two sub-problems that can be easily solved to provide an efficient solution to the original problem.

This paper is organized as follows. In the next section, a mathematical formulation of the model is presented. In section 3, the lagrangian relaxation discussion is presented. The extension and discussion of proposed model are discussed in section 4. Some numerical experiments and comparing are discussed in section 5. And the concluding remarks are then presented in last section.

In the remaining parts of the paper, the following notations are used:

(1) indices:

i	index of potential sites for manufacturing plants $i = 1, 2, .., I$
j	index of potential sites for distribution centers $j = 1, 2, .., J$
g	index of dummy distribution centers $g = 1, 2, .., G$
r	index of retailers $r = 1, 2, .., R$
t	time index $t = 1, 2, .., T$

(2) parameters:

T	length of the planning horizon
f_i	fixed cost for opening manufacturing plant i in the system
$f_i^{(1)}$	fixed cost for opening DC j in the system
c_{ij}	transportation cost for shipping a unit of product from plant i to DC j in one period
$c_{jr}^{(1)}$	transportation cost for shipping a unit of product from DC j to retailer r in one period
$c_{ir}^{(2)}$	transportation cost for shipping a unit of product directly from plant i to retailer r in one period
$c_{ig}^{(2)}$	transportation cost for shipping a unit of product from plant i to dummy DC g in one period
$c_{gr}^{(2)}$	transportation cost for shipping a unit of product from dummy DC g to retailer r in one period
p_i	unit production cost at plant i
h_i	holding cost for one unit of product at plant i in one period
$h_j^{(1)}$	holding cost for one unit of product at DC j in one period
$h_r^{(2)}$	holding cost for one unit of product at retailer r in one period
d_{rt}	demand of product at retailer r in period t
wp_i	production capacity at plant i
wd_j	storage capacity at DC j
wh_l	vehicle capacity levels l at dummy DC g

(3) decision variables:

X_{ijt} amount of product shipping from plant i to DC j in period t

Y_{jrt} amount of product shipping from DC j to retailer r in period t

$X^{(1)}_{iglt}$ amount of product shipping vehicle l from plant i to dummy DC g in period t

$Y^{(1)}_{glrt}$ amount of product shipping by vehicle l from dummy DC g to retailer r in period t

Z_{it} a binary variable which indicates whether plant i is operated in period t or not

$Z^{(1)}_{jt}$ a binary variable which indicates whether DC j is operated in period t or not

$Z^{(2)}_{glt}$ a binary variable which indicates whether dummy DC g is operated at level l in period t or not

V_{it} volume of product produced at plant i in period t

Q_{it} volume of product stored at plant i in period t

$Q^{(1)}_{jt}$ volume of product stored at DC j in period t

$Q^{(2)}_{rt}$ volume of product stored at retailer r in period t

2. Mathematical Model

In this research, the mathematical model for capacitated facilities location problem is developed based on the following assumptions:

1) If a plant or DC is opened at a certain site, it will not be closed;
2) All cost factors in the model are known in advanced, i.e. the opening cost of plants and DCs, the production cost, transportation cost, and inventory cost are given;
3) All beginning inventory levels (at plants, DCs, and retailers) are zeros;
4) Each required volume from retailer to dummy DC equals vehicle capacity level at dummy DC respectively.
5) Storage capacity of retailer is large enough to fulfill demand.

The detailed development of the mathematical model is presented in the following paragraphs.

The initial mathematical model that helps to deal with the capacitated facilities location problem considered in this research can be summarized as follows:

Objective function

$$Min\ Z=\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{t=1}^{T}c_{ij}X_{ijt}+\sum_{i=1}^{I}\sum_{g=1}^{G}\sum_{t=1}^{T}c^{(2)}_{ig}X^{(1)}_{iglt}+\sum_{j=1}^{J}\sum_{r=1}^{R}\sum_{t=1}^{T}c^{(1)}_{jr}Y_{jrt}+\sum_{g=1}^{G}\sum_{r=1}^{R}\sum_{t=1}^{T}c^{(2)}_{gr}Y^{(1)}_{glrt}+\sum_{i=1}^{I}\sum_{t=1}^{T}f_i\left(Z_{it}-Z_{i(t-1)}\right)$$
$$+\sum_{j=1}^{J}\sum_{t=1}^{T}f^{(1)}_{j}\left(Z^{(1)}_{jt}-Z^{(1)}_{j(t-1)}\right)+\sum_{i=1}^{I}\sum_{t=1}^{T}p_iV_{it}+\sum_{i=1}^{I}\sum_{t=1}^{T}h_iQ_{it}+\sum_{j=1}^{J}\sum_{t=1}^{T}h^{(1)}_{j}Q^{(1)}_{jt}+\sum_{r=1}^{R}\sum_{t=1}^{T}h^{(2)}_{r}Q^{(2)}_{rt}$$,(1)

Subject to

$$Q^{(2)}_{r(t-1)}+\sum_{j=1}^{J}Y_{jrt}+\sum_{g=1}^{G}Y^{(1)}_{glrt}\geq d_{rt}\quad \forall r\in R,\forall t\in T, \tag{2}$$

$$V_{it}\leq wp_iZ_{it}\qquad \forall i\in I,\forall t\in T, \tag{3}$$

$$\sum_{j=1}^{J} X_{ijt} + \sum_{g=1}^{G} X_{iglt}^{(1)} \le V_{it} + Q_{i(t-1)} \quad \forall i \in I, \forall t \in T, \tag{4}$$

$$\sum_{i=1}^{I} X_{ijt} + Q_{j(t-1)}^{(1)} \le wd_j Z_{jt}^{(1)} \quad \forall j \in J, \forall t \in T, \tag{5}$$

$$\sum_{r=1}^{R} Y_{jrt} \le \sum_{i=1}^{I} X_{ijt} + Q_{j(t-1)}^{(1)} \quad \forall j \in J, \forall t \in T, \tag{6}$$

$$X_{iglt}^{(1)} = wh_l Z_{glt}^{(2)} \quad \forall l \in L, \forall g \in G, \forall t \in T, \tag{7}$$

$$Y_{glrt}^{(1)} = wh_l Z_{glt}^{(2)} \quad \forall l \in L, \forall g \in G, \forall t \in T, \tag{8}$$

$$Q_{rt}^{(2)} = \sum_{j=1}^{J} Y_{jrt} + \sum_{g=1}^{G} Y_{glrt}^{(1)} + Q_{r(t-1)}^{(2)} - d_{rt} \quad \forall r \in R, \forall t \in T, \tag{9}$$

$$Q_{it} = V_{it} + Q_{i(t-1)} - \sum_{j=1}^{J} X_{ijt} - \sum_{g=1}^{G} X_{iglt}^{(1)} \quad \forall i \in I, \forall t \in T, \tag{10}$$

$$Q_{jt}^{(1)} = \sum_{i=1}^{I} X_{ijt} + Q_{j(t-1)}^{(1)} - \sum_{r=1}^{R} Y_{jrt} \quad \forall j \in J, \forall t \in T, \tag{11}$$

$$Z_{it} \ge Z_{i(t-1)} \quad \forall i \in I, \forall t \in T, \tag{12}$$

$$Z_{jt}^{(1)} \ge Z_{j(t-1)}^{(1)} \quad \forall j \in J, \forall t \in T, \tag{13}$$

$$Z_{it}, Z_{jt}^{(1)}, Z_{glt}^{(2)} = 0,1 \quad \forall i \in I, \forall j \in J, \forall g \in G, \forall l \in L, \forall t \in T, \tag{14}$$

$$X_{ijt}, X_{igt}^{(1)}, V_{it}, Q_{it} \ge 0 \quad \forall i \in I, \forall j \in J, \forall g \in G, \forall t \in T, \tag{15}$$

$$Y_{jrt}, Y_{grt}^{(1)}, Q_{jt}^{(1)}, Q_{rt}^{(2)} \ge 0 \quad \forall j \in J, \forall r \in R, \forall g \in G, \forall t \in T, \tag{16}$$

In the above model, objective function is to minimize the total cost which includes transportation costs from plants to DCs, transportation costs from DCs to retailers, transportation costs from plants to dummy DCs, transportation costs from dummy DCs to retailers, fixed costs for opening plants, fixed costs for opening DCs, production costs, and holding costs at plants, DCs, and retailers.

Related to the constraints, constraint set (2) ensures that demands at retailers are always satisfied. Constraint set (3) represents the capacity constraint at manufacturing plant, they ensure that the products only produce at opened manufacturing plant. Constraint set (4) ensures that the amount of product shipped from a plant in each period will not exceed the on-hand inventory. Constraint set (5) ensures that the total amount of goods stored at a distribution center will not exceed the maximum storage capacity of that distribution center. Constraint set (6) ensures that the total amount of goods shipped from a distribution center does not exceed the on-hand inventory at that distribution center. The vehicle capacity constraint sets (7), and (8) represent the required lot size for each vehicle from plant to dummy DC and from dummy DC to retailer respectively. Constraint sets (9), (10), and (11) are flow balance constraints, these constraints balance the inventory levels at retailers, plants and DCs respectively for each period. Constraint sets (12), and (13) ensure that when a plant or DC is opened, it will not be closed. And the rest constraint sets are variable constraints.

Actually, in the initial formulation presented above, it includes some redundant constraints that must be discarded from the original model to be simplified before applying the Lagrangian relaxation technique. These redundant constraints will be identified as follows (see more detail in Duong and Bui 2014, 2015):

Considering constraint set (9), (10), and (11) which express the balance equations for inventory level at retailers, plants and DCs respectively:

$$Q_{rt}^{(2)} = \sum_{j=1}^{J} Y_{jrt} + \sum_{g=1}^{G} Y_{glrt}^{(1)} + Q_{r(t-1)}^{(2)} - d_{rt} \quad \forall r \in R, \forall t \in T,$$

$$Q_{it} = V_{it} + Q_{i(t-1)} - \sum_{j=1}^{J} X_{ijt} - \sum_{g=1}^{G} X_{iglt}^{(1)} \quad \forall i \in I, \forall t \in T, \text{ and}$$

$$Q_{jt}^{(1)} = \sum_{i=1}^{I} X_{ijt} + Q_{j(t-1)}^{(1)} - \sum_{r=1}^{R} Y_{jrt} \quad \forall j \in J, \forall t \in T,$$

The above equations can be rewritten respectively as follows:

$$Q_{r(t-1)}^{(2)} + \sum_{j=1}^{J} Y_{jrt} + \sum_{g=1}^{G} Y_{glrt}^{(1)} \geq d_{rt} \quad \forall r \in R, \forall t \in T,$$

$$\sum_{j=1}^{J} X_{ijt} + \sum_{g=1}^{G} X_{iglt}^{(1)} \leq V_{it} + Q_{i(t-1)} \quad \forall i \in I, \forall t \in T, \text{ and}$$

$$\sum_{r=1}^{R} Y_{jrt} \leq \sum_{i=1}^{I} X_{ijt} + Q_{j(t-1)}^{(1)} \quad \forall j \in J, \forall t \in T,$$

The above expressions are exactly constraint sets (2), (4), and (6) respectively. Therefore, constraint sets (2), (4), and (6) become redundant constraints, which should be dropped from the initial mathematical model. The structure of the revised mathematical model is more simple, it is easily used the Lagrangian relaxation technique to help find solution for large size problems. This issue will be discussed in details in the next section.

3. A Lagrangian relaxation of the proposed model

It should be noted that the proposed model is a mixed integer linear programming, and it usually takes time for finding solution, especially with large scale problems. Therefore, Lagrangian relaxation technique will be used in this research for solving purpose. For more detailed discussion on the Lagrangian relaxation technique, the reader can refer to Fisher (1981), Duong and Bui (2014, 2015).

Before applying Lagrangian relaxation technique, the revised model in section 2 will be modified as presented below, see Duong and Bui (2014, 2015) for the proof.

At first, considering constraint set (11), i.e.,

$$Q_{jt}^{(1)} = \sum_{i=1}^{I} X_{ijt} + Q_{j(t-1)}^{(1)} - \sum_{r=1}^{R} Y_{jrt} \quad \forall j \in J, \forall t \in T,$$

In generally, can be rewritten as follows:

$$Q_{jt}^{(1)} = \sum_{i=1}^{I} \sum_{\tau=1}^{t} X_{ij\tau} - \sum_{r=1}^{R} \sum_{\tau=1}^{t} Y_{jr\tau} \quad \forall j \in J, \forall t \in T, \tag{17}$$

and,

$$\sum_{t=1}^{T} Q_{jt}^{(1)} = \sum_{t=1}^{T} (T-t+1) \left(\sum_{i=1}^{I} X_{ijt} - \sum_{r=1}^{R} Y_{jrt} \right) \quad \forall j \in J \tag{18}$$

Using (18), the cost component related to total inventory holding cost at DCs in the total cost function can be expressed as:

$$\begin{aligned}\sum_{j=1}^{J}\sum_{t=1}^{T} h_j^{(1)} Q_{jt}^{(1)} &= \sum_{j=1}^{J} h_j^{(1)} \sum_{t=1}^{T} \left(T-t+1\right)\left(\sum_{i=1}^{I} X_{ijt} - \sum_{r=1}^{R} Y_{jrt}\right) \\ &= \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{t=1}^{T}\left(T-t+1\right) h_j^{(1)} X_{ijt} - \sum_{j=1}^{J}\sum_{r=1}^{R}\sum_{t=1}^{T}\left(T-t+1\right) h_j^{(1)} Y_{jrt}\end{aligned} \tag{19}$$

It is also noted that constraint set (5) can be rewritten via expression (17) as follows:

$$\begin{aligned}\sum_{i=1}^{I} X_{ijt} + Q_{j(t-1)}^{(1)} - wd_j Z_{jt}^{(1)} &= \sum_{i=1}^{I} X_{ijt} - wd_j Z_{jt}^{(1)} + \left(\sum_{i=1}^{I}\sum_{\tau=1}^{t-1} X_{ij\tau} - \sum_{r=1}^{R}\sum_{\tau=1}^{t\text{-}1} Y_{jr\tau}\right) \\ &= \sum_{i=1}^{I}\sum_{\tau=1}^{t} X_{ij\tau} - wd_j Z_{jt}^{(1)} - \sum_{r=1}^{R}\sum_{\tau=1}^{t\text{-}1} Y_{jr\tau}\end{aligned} \tag{20}$$

According to the above analysis, we see that equation constraint set (11) is changed to expression (17). We apply this equational characteristic for expression (19) and (20) that are replaced into the objective function (1) of original model. Therefore, equation constraint set (11) is discarded before applying Lagrangian relaxation technique.

So, by introducing Lagrange multiplier $\lambda_{jt}'s$ for the constraints in (5), the objective of the Lagrangian relaxation problem (problem (L)) associated with the original mathematical model can now be derived as

$$\begin{aligned}Min\ Z_L &= \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{t=1}^{T} c_{ij} X_{ijt} + \sum_{i=1}^{I}\sum_{g=1}^{G}\sum_{t=1}^{T} c_{ig}^{(2)} X_{igt}^{(1)} + \sum_{j=1}^{J}\sum_{r=1}^{R}\sum_{t=1}^{T} c_{jr}^{(1)} Y_{jrt} + \sum_{g=1}^{G}\sum_{r=1}^{R}\sum_{t=1}^{T} c_{gr}^{(2)} Y_{grt}^{(1)} \\ &+ \sum_{i=1}^{I}\sum_{t=1}^{T} f_i\left(Z_{it} - Z_{i(t-1)}\right) + \sum_{j=1}^{J}\sum_{t=1}^{T} f_j^{(1)}\left(Z_{jt}^{(1)} - Z_{j(t-1)}^{(1)}\right) + \sum_{i=1}^{I}\sum_{t=1}^{T} p_i V_{it} + \sum_{i=1}^{I}\sum_{t=1}^{T} h_i Q_{it} + \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{t=1}^{T}\left(T-t+1\right) h_j^{(1)} X_{ijt} \\ &- \sum_{j=1}^{J}\sum_{r=1}^{R}\sum_{t=1}^{T}\left(T-t+1\right) h_j^{(1)} Y_{jrt} + \sum_{r=1}^{R}\sum_{t=1}^{T} h_r^{(2)} Q_{rt}^{(2)} + \sum_{j=1}^{J}\sum_{t=1}^{T} \lambda_{jt}\left(\sum_{i=1}^{I}\sum_{\tau=1}^{t} X_{ij\tau} - wd_j Z_{jt}^{(1)} - \sum_{r=1}^{R}\sum_{\tau=1}^{t\text{-}1} Y_{jr\tau}\right)\end{aligned}$$

in which,

$$\sum_{j=1}^{J}\sum_{t=1}^{T}\lambda_{jt}\left(\sum_{i=1}^{I}\sum_{\tau=1}^{t} X_{ij\tau}\right) = \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{t=1}^{T}\lambda_{jt}\left(\sum_{\tau=1}^{t} X_{ij\tau}\right) = \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{t=1}^{T}\left(\sum_{\tau=t}^{T}\lambda_{j\tau}\right) X_{ijt}$$

$$\sum_{j=1}^{J}\sum_{t=1}^{T}\lambda_{jt}\left(\sum_{r=1}^{R}\sum_{\tau=1}^{t\text{-}1} Y_{jr\tau}\right) = \sum_{j=1}^{J}\sum_{r=1}^{R}\sum_{t=1}^{T}\left(\sum_{\tau=t+1}^{T}\lambda_{j\tau}\right) Y_{jrt}$$

Problem (L) can be easily decomposed into two sub-problems (L1) and (L2) as follows:

Sub-problem (L1):

$$\begin{aligned}Min\ Z_{L1} &= \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{t=1}^{T}\left[c_{ij} + \sum_{\tau=t}^{T}\lambda_{j\tau} + \left(T-t+1\right) h_j^{(1)}\right] X_{ijt} + \sum_{i=1}^{I}\sum_{g=1}^{G}\sum_{t=1}^{T} c_{ig}^{(2)} X_{iglt}^{(1)} \\ &+ \sum_{i=1}^{I}\sum_{t=1}^{T} f_i\left(Z_{it} - Z_{i(t-1)}\right) + \sum_{i=1}^{I}\sum_{t=1}^{T} p_i V_{it} + \sum_{i=1}^{I}\sum_{t=1}^{T} h_i Q_{it}\end{aligned} \tag{21}$$

Subject to (3), (7), (10), (12), and (15).

Sub-problem (L2):

$$\begin{aligned}Min\ Z_{L2} &= \sum_{j=1}^{J}\sum_{r=1}^{R}\sum_{t=1}^{T}\left[c_{jr}^{(1)} - \sum_{\tau=t+1}^{T}\lambda_{j\tau} - \left(T-t+1\right) h_j^{(1)}\right] Y_{jrt} + \sum_{g=1}^{G}\sum_{r=1}^{R}\sum_{t=1}^{T} c_{gr}^{(2)} Y_{glrt}^{(1)} \\ &+ \sum_{j=1}^{J}\sum_{t=1}^{T} f_j^{(1)}\left(Z_{jt}^{(1)} - Z_{j(t-1)}^{(1)}\right) - \sum_{j=1}^{J}\sum_{t=1}^{T}\lambda_{jt} wd_j Z_{jt}^{(1)} + \sum_{r=1}^{R}\sum_{t=1}^{T} h_r^{(2)} Q_{rt}^{(2)}\end{aligned} \tag{22}$$

Subject to (8), (9), (13), and (16).

For fixed values of $\lambda_{jt}'s$, it is noted that the value of the objective function of the original model can be determined via the solutions of the two sub-problems (L1) and (L2) as $Z = Z1 + Z2$, in which

$$Z1=\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{t=1}^{T}\left[c_{ij}+(T-t+1)h_j^{(1)}\right]X_{ijt}+\sum_{i=1}^{I}\sum_{g=1}^{G}\sum_{t=1}^{T}c_{ig}^{(2)}X_{iglt}^{(1)}+\sum_{i=1}^{I}\sum_{t=1}^{T}f_i\left(Z_{it}-Z_{i(t-1)}\right)+\sum_{i=1}^{I}\sum_{t=1}^{T}p_iV_{it}+\sum_{i=1}^{I}\sum_{t=1}^{T}h_iQ_{it},$$

$$Z2=\sum_{j=1}^{J}\sum_{r=1}^{R}\sum_{t=1}^{T}\left[c_{jr}^{(1)}-(T-t+1)h_j^{(1)}\right]Y_{jrt}+\sum_{g=1}^{G}\sum_{r=1}^{R}\sum_{t=1}^{T}c_{gr}^{(2)}Y_{glrt}^{(1)}+\sum_{j=1}^{J}\sum_{t=1}^{T}f_j^{(1)}\left(Z_{jt}^{(1)}-Z_{j(t-1)}^{(1)}\right)+\sum_{r=1}^{R}\sum_{t=1}^{T}h_r^{(2)}Q_{rt}^{(2)}$$

Therefore, the value of the objective function of the original model is an acceptable one if and only if the two sub-problems can give feasible solutions. However, with the current formulations of the two sub-problems, it might happen that the above requirement cannot be ensured. This issue will be tackled in the next paragraphs.

Considering sub-problem (L1), it can be seen that there exists no constraint that forces binary variables Z_{it} to receive positive values. This will lead to the fact that all $Z_{it}'s$ will be set to zeros when (L1) is solved. All other decision variables will also receive the value of zero, and hence, the objective value is always zero. To deal with the above problem, sub-problem (L1) requires one additional constraint sets that will be pointed out below.

Additional constraint set 1:

$$\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{\tau=1}^{t}X_{ij\tau}+\sum_{i=1}^{I}\sum_{g=1}^{G}\sum_{\tau=1}^{t}X_{igl\tau}^{(1)}\geq\sum_{r=1}^{R}\sum_{\tau=1}^{t}d_{r\tau}\quad\forall t\in T, \tag{23}$$

This constraint will also be added to sub-problem (L1) to help ensure that the cumulative shipping quantity of product at time period t from all manufacturing plants to DCs and dummy DCs will exceed the total cumulative demand of retailers.

Similarity, considering sub-problem (L2), there is no constraint that forces binary variables $Z_{jt}^{(1)}$ to receive positive values, and all $Z_{jt}^{(1)}$ will be set to zeros when (L2) is solved. Moreover, avoiding to product shipping to retailers from non-operating DCs, sub-problem (L2) requires one additional constraint sets as folows:

Additional constraint set 2:

$$\sum_{r=1}^{R}Y_{jrt}\leq wd_jZ_{jt}^{(1)}\qquad\forall j\in J,\forall t\in T, \tag{24}$$

This constraint is added to sub-problem (L2) to help ensure that the amount of product shipped to all retailers from an operating DC j will not exceed the capacity of DC j.

The Lagrangian relaxation algorithm for the model the reader can refer to Duong and Bui (2014, 2015).

4. The extension and discussion of proposed model

The our proposed models can be easily found out the solutions (see Duong and Bui, 2014, 2015), our model considered direct shipments from manufacturing plants to retailers via dummy DCs. The our solutions show that products shipped directly from manufacturing plants to retailers will help investors to save total cost for openning distribution centers in long-term operations, and investment risk will be reduced, speciallized in the decreasing demand in the future.

Moreover, the established systems can be controlled the number of vehicles at each period by added some constraint set as follows:

$$\sum_{g=1}^{G} Z_{glt}^{(2)} \geq N_l \quad \forall g \in G, \forall t \in T, \forall l \in L, \tag{25}$$

Constraint set (25) presents minimum total number of vehicles l at period t

$$\sum_{g=1}^{G} \sum_{l=1}^{L} Z_{glt}^{(2)} \geq N \quad \forall g \in G, \forall t \in T, \forall l \in L, \tag{26}$$

Constraint set (26) presents minimum total number of vehicles in the system at period t

In addition, our model can be modified to outsourcing strategy when we replace the manufacturing plant sources to outside suppliers by using a supplier set *S*. In this modified model, a new set of variables will be introduced as follows:

$X_{sglt}^{(1)}$ amount of product shipping vehicle l from outside supplier s to dummy DC g in period t

With using the set of variables $X_{sglt}^{(1)}$, products shipped to retailers from outside suppliers. In this case, our model is relevant to outsourcing strategy which is very popular strategies in modern/global supply chain systems. We can control total outsource products to meet the system's demand at each period. Therefore, some manufacturing plants are not necessary to open, the investors can reduce total fixed cost for openning plants, and investment risk will be reduced.

5. Numerical results

In this section, we conduct numerical experiments to compare with the work of Duong and Bui, (2014). Six test problems and comparing results are summarized in Table 1. All six problems, we used 3 types of vehicle with capacity (truck load) 100 units, 150 units, and 200 units respectively. The price of outsourcing products is average of production costs. And the other data are the same for both models.

Table 1: Comparing solutions between our proposed model and model of Duong and Bui (2014)

Problems	I	J	R	T	No. of opened plants	No. of opened DCs	Total No. of vehicles			Optimal cost	Remarks
							N1	N2	N3		
1	4	4	4	4	02 (M1,and 2)	02 (DC2, and 4)				3159800	Model 1
					01 (M2)	01 (DC2)	20	4	1	2297180	Model 2
2	5	5	5	5	03 (M1, 2, and 3)	03 (DC2, 4, and 5)				4026330	Model 1
					02 (M2, and 5)	02 (DC2, and 5)	25	8	0	3137170	Model 2
3	6	6	6	6	03 (M2, 3, and 6)	03 (DC2, 5, and 6)				3820810	Model 1
					02 (M2, and 6)	02 (DC2, and 6)	21	2	0	3118240	Model 2
4	8	8	8	8	04 (M2, 5, 6, and 8)	04 (DC2, 5, 6, and 8)				5616190	Model 1
					02 (M2, and 6)	02 (DC2, and 6)	6	0	18	5317610	Model 2
5	8	8	8	10	05 (M1, 2, 3, 6, and 8)	05 (DC2, 3, 5, 6, and 8)				11406850	Model 1
					04 (M2, 3, 5, and 6)	04 (DC2, 5, 6, and 8)	10	5	26	10716700	Model 2
6	10	8	8	10	06 (M1, 2, 3, 5, 6, 8)	06 (DC2, 3, 5, 6, 7 and 8)				12938640	Model 1
					04 (M2, 3, 5, and 6)	04 (DC2, 5, 6, and 8)	5	3	38	11811800	Model 2

Model 1: model of Duong and Bui (2014)
Model 2: the our proposed model
N1: number of vehicles type 1 (capacity 100 unit); N2: number of vehicles type 2 (150 units);
N3: number of vehicles type 3 (200 units);
M: manufacturing plant; DC: distribution centers
Optimal cost: obtained from LINGO software
I: number of potential sites for opening manufacturing plants;
J: number of potential sites for opening distribution centers;
R: number of retailers;
T: length of the planning horizon.
All test problems are solved by LINGO10.0 software. And the obtained results are optimal solutions from Lingo programs. According to the results in table 1, we see that the total cost (optimal value) of model 2 is better than model 1 because of less than number of opened facilities in the new system. We think that this achievement is very important for managers and investors when the product demand decreases in the future. Moreover, our model can control the number of vehicles in the new systems at each period based on vehicle resource. In addition, we can also manage the total outsource products from outside suppliers. Therefore, our model helps to open effective number of facilites in the SC networks. Based on the results presented in Table 1, and the above analysis, we belive that our model is very usefull and can be applied for realistic situations.

6. Conclusions

In this research paper, we develop a mix integer linear programming model for capacitated facility location problem in supply chain network design. Our model deals with direction shipment and outsourcing strategies that are very common strategies in practice. Our research is succeeded in combining outsourcing strategy with opening facilities in the new established systems. This helps the investors to save the total investment cost, and then reduce the investment risk. Moreover, controlling the total number of vehicles and total outsourcing products are also detected in our model.

Loan quality, ownership and efficiency of Indian Banks: A Bootstrap Truncated Regression Approach

Suneeta Sathye
University of Canberra, Australia
suneeta.sathye@canberra.edu.au

Many prior studies on Indian banking efficiency have typically regressed non-parametric estimates of production efficiency on environmental variables in a two-stage process. However, Simar and Wilson (2007, 2011) have demonstrated that the studies that use such conventional approaches are invalid due to complicated and unknown serial correlation among estimated efficiencies. Using the data envelopment analysis bootstrap procedure suggested by these authors, for the first time, we analyse the technical efficiency of Indian banks and regress the bootstrap scores on a set of environmental variables using a truncated regression. Banks that are on efficiency frontier as per conventional analysis are actually away from the frontier when bootstrap scores are used. Contrary to many prior studies, state ownership was found to have significant negative impact on efficiency.
Keywords: Indian banks, efficiency, truncated regression, bootstrap.

1. Introduction

The objectives of this study are (a) to assess the production efficiency of Indian banks using the bootstrap approach to data envelopment analysis and (b) to examine the impact of loan quality and ownership on bias-corrected bootstrap efficiency scores. It explores these issues by addressing five related questions:

(i) What is the production efficiency of Indian banks using the unbiased bootstrap approach?

(ii) What is the effect of state ownership on bank inefficiency?

(iii) What is the effect of bank soundness on bank efficiency?

(iv) What is the effect of size on bank efficiency?

(v) What is the effect of loan quality on bank efficiency?

The paper also considers whether there was a change in bootstrap efficiency scores of Indian banks during the three periods: pre-GFC, during the GFC and post GFC.

The immediate motivation for the paper is the passage in December 2012 of the Banking Liberalisation Bill in the Indian Parliament that raises the foreign investment limits in Indian banks to 26 per cent from the present 10 per cent and liberalizes the licensing regime for banks (FT 2012). The liberalization is intended to improve the efficiency of the banking system, which is tipped to become the third largest in the world, next only to China and the United States, by 2025 (FT 2012). Further, the extant studies on Indian banking efficiency have used the non- parametric data envelopment analysis and the two-stage regression approach without bootstrapping the efficiency scores. The Reserve Bank of India (2008), for example, found that 17 out of 81 banks were on the efficiency frontier using the data envelopment approach. However, the efficiency scores were not bootstrapped. Simar and Wilson (2007) have demonstrated that these studies are invalid due to complicated and unknown serial correlation among estimated efficiencies.

Further, Dyson and Shale (2010), state that the true efficient frontier lies within the confidence limits that are produced by bootstrap procedures. This removes the main drawback that statistical inference can’t be conducted with DEA efficiency scores (Halkos and Tzeremes, 2010).

Using the data envelopment analysis bootstrap procedure suggested by these authors, for the first time, we analyze the technical efficiency of Indian banks and regress the bootstrap scores on a set of environmental variables using a truncated regression. Second, while the banking sector in many countries of the developed world faced enormous problems of financial stress and sustainability, the Indian banking sector came out of the global financial crisis (GFC) relatively unscathed. Barr et al. (2000) found that banks with higher efficiency are more likely to survive than those with relatively low scores. Consequently, an examination of the efficiency of Indian banks post-GFC becomes important. Podpiera and Cihak (2005) stated that regular screening of banking efficiency is important, as it can serve as an early warning system. Third, The Economist (2012) stated that the Indian banking system runs the "risk of Spanish disease" and that "India has a bigger bad-debt problem than the rather stable level of banks' official 'non-performing" loans suggests." The magnitude of the impact of such non-performing loans (loan quality) on banking efficiency is also an issue that we examine in this paper. Fourth, few studies on Indian banking efficiency have examined the impact of ownership and credit risk (loan quality) together on production efficiency in second-stage regression. Where they have, it is either multiple regression or tobit regression that has been used on non-bootstrapped efficiency scores instead of truncated regression as suggested by Simar and Wilson (2007). Finally, the results would be of interest to researchers in emerging economies like China, Brazil, Russia and other developing countries where banks continue to be publicly owned. Fry (1995) states that a key stylised fact about developing countries is financial intermediation is mostly carried by commercial banks rather than by financial markets. Ataullah and Le (2006) emphasize that it is vital for governments in developing countries to create an environment that enhances commercial banking efficiency for overall economic growth.

Furthermore, as stated by Simar and Wilson (2007), the procedure ensures the efficient estimation of the second stage estimators, a property which is not guaranteed with alternative methods. The use of truncated regression enables us to obtain more reliable evidence (Barros and Garcia-del-Barrio, 2011).

The study proceeds as follows. Section 2 provides a background of the Indian banking system in brief, section 3 reviews prior studies, section 4 provides data and analysis and section 5 provides results. Conclusions of the study are presented in section 6

2. Overview of the Indian banking system

India has a massive banking system that caters to the financial needs of over 1 billion people. At the top of the banking system is the Reserve Bank of India, which is the central bank of the country. Commercial banks are the major type of financial intermediary and consist of 26 public sector, 22 private sector and 41 foreign banks (see Table 1). Besides the commercial banks, cooperative banks, which are also state-partnered institutions, mainly cater to the needs of the rural sector. As per RBI (RTPB 2012, Table IV.1), total assets of the Indian banking sector are Rs 82,994 billion with total deposits of Rs 64,537 billion and total advances of Rs 50,746 billion (INR55/USD). The return on assets of 1.08 (2012) is comparable with that of other countries of the world. The figure for the net non-performing assets as a percentage of net advances at 1.4 does, however, indicate an area of concern, given the report in The Economist cited above that a huge amount of restructured loans are not included in the ratio.

3. Prior studies

Studying banking efficiency is important. Fiordelisi et al. (2010) found that reduction in efficiency increases banks' future risks and indicated bad management. For measuring bank efficiency, the frontier analysis approach is increasingly being used. The approach consists of separating institutions that are performing poorly as compared to those that are performing well using a particular standard. The separation is achieved either by applying the non-parametric or parametric frontier method. The parametric approach includes stochastic frontier analysis,

the free disposal hull, thick frontier and the distribution-free approaches (DFAs), while the non-parametric approach is data envelopment analysis (DEA) (Molyneux et al. 1996).
Though many empirical studies have examined banking efficiency over the years, few have used the bootstrap DEA procedures. Consequently, the results obtained through the use of conventional DEA would need to undergo renewed scrutiny. Matthews et al. (2009) examined the Malmquist productivity (not efficiency) and non-performing loans in Chinese banks using bootstrap procedures. Curi et al. (2013) examined foreign-bank bootstrap DEA efficiency in Luxemburg. Barros and Assaf (2011) and Halkos and Tzeremes (2013) examined bootstrap efficiency of Japanese and Greek banks respectively. Chortareas et al (2013) used bootstrap DEA to examine banking efficiency in the European Union.
As can be seen from the above the bootstrap DEA efficiency studies in banking have largely been confined to developed countries. Examining banking efficiency using bootstrap is important in the context of developing countries since they generally have predominance of public sector banks which are typically known to be saddled with inefficiency (Fry, 1995; Ataullah and He, 2006). Governments in these countries need an efficient banking sector for promoting growth. The starting point of this is to accurately assess the banking efficiency in these countries. We address this gap in the literature using data of Indian banks.
Bhattacharya et al.'s paper (1997) was the first to apply frontier analysis (both DEA and stochastic frontier analysis) to assess the efficiency of 86 Indian banks during the early liberalization period (198̃61991). The study found publicly-owned banks to be most efficient, followed by foreign banks and privately-owned banks. Das (1997) used DEA to examine the efficiency of 65 Indian commercial banks for the year 1995 and compared their technical and allocative efficiency and found the former to be more efficient. Mukherjee et al. (2002) examined the technical efficiency of 68 commercial banks for the period 199̃61999. The findings were similar to those of the Bhattacharya et al. (1997) study□that is, the publicly-owned banks were found to be more efficient than both private and foreign banks. Sathye (2003) examined the impact of ownership on Indian banking efficiency using DEA and found that publicly-owned banks were more efficient than foreign banks and privately-owned banks. Ram Mohan and Roy (2004) also found publicly-owned banks to be more efficient than privately- owned banks, but foreign banks had caught up with them over the years.
Das and Ghosh (2009: 193) examined the banking efficiency during 199̃22002, and found that 'medium-sized public sector banks performed reasonably well and are more likely to operate at higher levels of technical efficiency. A close relationship is observed between efficiency and soundness as determined by bank's capital adequacy ratio. The empirical results also show that technically more efficient banks are those that have, on an average, less nonperforming loans'. Ghosh (2009) studied the cost and profit efficiency of Indian banks during the period 199̃22004. The study found that big state-owned banks performed well in terms of efficiency, and a close relationship was found between efficiency and soundness as determined by a bank's capital adequacy ratio. Ray and Das (2010) examined the cost and profit efficiency of Indian commercial banks during a 7-year period beginning 199̃697. The study found that publicly-owned banks were more profit efficient than were privately-owned banks. Gulati and Kumar (2008) found that when non-traditional activities were accounted for in the output specification, the foreign banks appeared to be more efficient than were public and private sector banks. Kaur and Kaur (2010) used DEA to examine the impact of mergers on the cost efficiency of Indian

banks during the period 1990–91 to 2007–08. These authors found that the average cost efficiency of publicly-owned banks was lower than that of privately-owned banks. Dwivedi and Charyulu (2011) studied banking efficiency for the 5-year period 2005–2006 to 2009–2010 and found that new privately-owned banks and foreign banks were more efficient than were publicly- owned banks

Our study makes several new contributions. None of the above studies have used bootstrap DEA scores. As already stated by Simar and Wilson (2007), conventional DEA approach, that is, without bootstrap can give misleading results. Thereafter we examine how ownership, size, soundness, loan quality variables impact on the bootstrap DEA efficiency scores and thus provide robust analysis of Indian banking efficiency as compared to prior studies. In particular, we examine the important issue of efficiency differences resulting from foreign vs domestic ownership as well as public vs private ownership and contribute to the literature discussing this theme. We examine whether, on average, these ownership types have positive or negative effects on bank efficiency. Furthermore, we analyse Indian banking efficiency in a period subsequent to what prior studies have analysed – especially the post GFC years.

4. Data and Method

The data for the study were drawn from the Reserve Bank of India (RBI) publication A Profile of Banks available online and refer to the 5-year period 2007–2008 to 2011–12.

Table 1 presents the total number of banks in various categories, and, of these, the number included in our sample. The banks for which data as required for the study were not available were excluded from the sample.

Table 1: Distribution of banks in India and banks in the sample

	2007–08	2008–09	2009–10	2010–11	2011–12	Total
Foreign						
total	28	31	32	34	40	
in the sample	9	14	17	14	14	
Private sector banks						
total	23	22	22	21	20	
in the sample	19	19	19	19	19	
Public sector banks						
total	28	27	27	26	26	
in the sample	26	26	26	26	26	
Total	79	80	81	81	86	407
in the sample	54	59	62	59	59	293

DEA efficiency calculation

DEA is a linear programming technique initially developed by Charnes, Cooper and Rhodes (1978) to evaluate the efficiency of public sector non-profit organizations. It involves calculation of relative efficiency scores of decision-making units (DMUs) in the sample. The DMUs could be banks or branches of banks. A major advantage of DEA is the identification of peers with which the efficiency could be compared. For choosing the inputs and outputs to be used in DEA analysis, two major approaches, the production approach and the intermediation approach, are prevalent. The production approach involves use of physical inputs and outputs and relevant processes. The intermediation approach is commonly used and has some variants. The asset approach involves use of labour and capital as inputs and loans as output (Sealy and Lindley 1977). Under the user cost approach, the outputs are where the financial returns on an asset exceed the opportunity cost of the funds and the financial costs of a liability are less than the opportunity cost. If it is vice versa, it is treated as inputs (Hancock 1985). The value-added approach considers as outputs those assets or liabilities that contribute to bank value added□that is, business associated with the consumption of real resources (Berger et al. 1987). According to Jemric and Vujcic (2002), yet another popular approach is the operating or income- based approach. In this approach, interest income and non-interest income are considered as outputs, and interest expenses and non-interest expenses are considered as inputs. The approach has been used in many prior studies□for example, Leightner and Lovell (1998), Avkiran (1999), Sathye (2003) and Das and Ghosh (2006). In the present study, we use this approach.
Charnes et al. (1976) described the original DEA model as follows. There are N units producing J outputs, with I inputs. Efficiency is measured by maximising the ratio weighted outputs to weighted inputs for that unit under following constraints:

$$Max\ e^0 = \frac{\sum_{j=1}^{J} u_j^o y_j^o}{\sum_{i=1}^{I} v_i^o x_i^o} \qquad (1)$$

Subject to

$$\frac{\sum_{j=1}^{J} u_j^o y_j^n}{\sum_{i=1}^{I} v_i^o x_i^n} \leq 1; \quad n = 1, \ldots, N,$$

$$v_i^o, u_j^o \geq 0; \quad i = 1, \ldots, I; \ j = 1, \ldots, J.$$

y_j^n, x_i^n represent the outputs and inputs of the n^{th} unit called a decision making unit (DMU)

and v_i^o, u_j^o are the variable weights. These are determined by solving problem (1).

Given the difficulty in solving the above non-linear problem the objective function is transformed into a linear one as follows:

$$Max h_o^o = \sum_{j=1}^{J} u_j^o y_j^o \qquad (2)$$

Subject to

$$\sum_{i=1}^{I} v_i^o x_i^o = 1, \quad \sum_{j=1}^{j} u_j^o y_j^n - \sum_{i=1}^{I} v_i^o x_i^n \leq 0; \quad n = 1,\dots\dots,N,$$

$$v_i^o \geq \varepsilon, \quad u_j^o \geq \varepsilon, \; i=1,\dots I, \quad j=1,\dots\dots,J.$$

The variables in (2) above are the same as in equation (1) above. Readers interested in knowing the details of the DEA procedure are advised to refer to the original paper by Charnes et al. (1976).

In the present study, we use the variable returns to scale (an input-oriented model) to compute technical efficiency. It shows the extent to which the output could be enhanced by each of the banks in the sample with the existing inputs.

The bootstrap approach

Simar and Wilson (1998, 1999, 2007) stated that the DEA scores calculated above have strong association with each other and using them in second-stage regression may be inappropriate. The scores are relative and not absolute, and as these are calculated and not estimated, it is difficult to obtain statistical properties of DEA. Consequently, these authors proposed a double bootstrap procedure that enables computation of confidence intervals and standard errors for the DEA scores. This computer-based method draws from the theory of re-sampling original data to assign statistical properties to it and also enables accounting for the impact of environmental variables on efficiency (Simar and Wilson 2007). These authors also did not consider the use of ordinary least squares to estimate the relationship between DEA scores and environmental variables as appropriate since regression assumption of no auto-correlation and absence of multi-collinearity get violated, and they suggested instead the use of truncated regression. The procedure for the bootstrap method has been described in detail by Simar and Wilson (2007) and is not repeated here. Descriptive statistics of inputs and outputs used in DEA are presented in Table 2.

Table 2: Descriptive statistics of input and outputs used for DEA

Year/Variable	Obs.	Mean	Std. Dev.	Min	Max
2007–08					
Interest expenses	54	36785.56	54625.04	4	319291
Non-interest expenses	54	13313.89	20515.99	27	126086
Interest income	54	54028.81	79550.46	45	489503
Non- Interest income	54	10247.56	16724.3	36	88108

2008–09					
Interest expenses	59	43938.03	66450.71	6	429153
Non-interest expenses	59	15080.78	23701.45	34	156487
Interest income	59	64497.95	96153.47	14	637884
Non- Interest income	59	12699	20665.51	46	126908
2009–10					
Interest expenses	62	43255.61	68959.56	4	473225
Non-interest expenses	62	15827.39	27866.65	40	203187
Interest income	62	65902.77	102390.4	11	709939
Non- Interest income	62	12537.65	22054.29	1010	149682
2010–11					
Interest expenses	59	50393.9	73581.3	7	488680
Non-interest expenses	59	20619.08	32746.39	43	230154
Interest income	59	82555.22	120504.3	12	813944
Non- Interest income	59	13183.97	23115.34	35	158246
2011–12					
Interest expenses	59	110027	158398.5	23.298	1065215
Non-interest expenses	59	14207.14	22714.62	995.57	143514.5
Interest income	59	72571.31	98984.41	8.479	632303.7
Non- Interest income	59	22960.72	37077.77	49.522	260689.9

Descriptive statistics of the bias-corrected scores for the years 2007̃08 to 2011̃12 are presented in the table below:

Table 3: Descriptive statistics of bias-corrected efficiency scores

Year	Banks	Mean	Std. Dev.	Min	Max
2007–08	54	1.124906	0.097194	1.0212	1.523
2008–09	59	1.158169	0.109709	1.0286	1.5036
2009–10	62	1.193563	0.2211	1.0178	2.1587
2010–11	59	1.125178	0.095275	1.0194	1.4239
2011–12	59	1.159812	0.150925	1.0346	1.8622

It will be seen from the above that outputs could be increased on average for all banks by approximately 12 per cent (2007̃08), 16 per cent (2008̃09), 19 per cent (2009̃10), 13 per cent (2010̃11) and 16 per cent (2011̃12). As can be seen, the post-crisis average efficiency of banks has deteriorated. In 2007̃08, there was scope to increase efficiency by 12 per cent, while in the year 2011̃12, a 16 per cent increase in efficiency could be achieved with the given inputs.

Truncated regression

The environmental variables that we use are drawn from relevant theory and prior empirical studies. We use the following model to assess the link between environmental variables and the bootstrap efficiency score.

$$\theta_i = \beta_0 + \beta_1 ForOwn_i + \beta_2 Soundness_i + \beta_3 StateOwn_i + \beta_4 LoanQuality_i + \beta_5 Size_i + \varepsilon_i$$

When bootstrap procedure followed by truncated regression is used the issue of ‘separability condition’ becomes relevant. Simar and Wilson (2011:207) say that by separability they ‘mean that the support of the output variables does not depend on the environmental variables in Z’ where Z refers to environmental covariates. As the data generation process (DGP) used in our study corresponds to DGP 2 described by the above authors, separability is a reasonable assumption in this study.

ForOwn: Foreign versus domestic ownership is a binary variable. Foreign ownership equals 1, while domestic ownership equals zero. It is intended to detect the influence of foreign ownership on technical efficiency. The variable could have either negative or positive influence on efficiency. Studies such as that of Williams and Strum (2007) found foreign banks more efficient than domestic banks; however, in the Indian context barring Dwivedi and Charyulu (2011), other studies found domestic banks to be more efficient than foreign banks. Consequently, we do not postulate an a priori sign for this variable.

Soundness: The soundness of a bank depends upon the capital it holds vis-à-vis risk-weighted assets. We use the capital-to-risk-assets ratio (CRAR) as a measure of soundness. Many prior studies such as those of Das and Ghosh (2006) and Ghosh (2009) have used CRAR as a measure of soundness. Better capitalized banks are expected to be more efficient because of their ability to attract more business. Fiordilisi et al. (2010) stated that higher capital levels positively impact efficiency. Das and Ghosh (2006) stated that financial soundness reduces uncertainties and systematic risk and thus contribute to lowering inefficiency. Consequently, we expect a positive relationship a priori between soundness and technical efficiency.

StateOwn: State versus private ownership is a binary variable. State ownership equals 1 while non-state ownership equals zero. It is intended to detect the influence of state ownership on technical efficiency. Most prior studies in Indian banking have found that state-owned banks are more efficient than are other banking groups; however, recent study by Dwivedi and Charyulu (2011) already cited above, finds that the case is otherwise. Consequently, we do not postulate an a priori sign for this variable.

LoanQuality: Similar to prior studies (such as Das and Ghosh [2006] and Ghosh [2009]), we capture loan quality by the ratio of non-performing loans to net advances. Inadequate loan monitoring and bad debt control can lead to lesser interest income. Further, bad loans require higher supervision and monitoring, which increase operational expenses. The combined effect would be lower efficiency. This is consistent with the bad management hypothesis of Berger and DeYoung (1997). We expect that a priori this variable will have a negative sign□as non-performing loans increase, efficiency will lower.

Size: As per public choice theory and principal agent framework, different types of ownership impact on efficiency differently. ‘The theoretical argument is straightforward: a lack of capital market discipline weakens owners’ control over management, enabling the latter to pursue their own interests, and giving fewer incentives to be efficient’ (Das and Ghosh, 2006). Prior studies have used assets, deposits, advances, number of ATMs, number of employees, number of branch offices as measures of size. We use number of employees as a measure of size.

As stated by Keuleneer and Leszczynska (2011) ‘Size is claimed by many to bring economies of scale and cost reductions almost per definition.’ In the banking context, studies in the US indicate that economies of scale appear in small banks but not in the large banks (Short, 1979; Miller and Noulas, 1996). However, studies such as Sun and Chang (2011) have found that size impacts efficiency negatively. We postulate a negative sign for this variable a priori.

To run the truncated regression, data from a total of 293 banks were used, and the procedure suggested by Simar and Wilson (2007) was deployed to obtain the following results.

5. Results and discussion

Table 4 provides for the year 2012 (for other years, data are available on request from the authors) output-oriented DEA bootstrap scores and the raw scores. It indicates the extent to which output could be increased with the current input levels. The details of the variable returns to scale (VRS) technical efficiency scores of each of the 68 banks in the sample together with the bias-corrected efficiency scores, the extent of bias and the lower and upper confidence levels are presented.

Following Simar and Wilson (1999), we used 2,000 bootstrap replications (B=2,000). According to these authors, this should provide an adequate coverage of the confidence intervals.

It will be noticed that although 24 out of 68 banks are on the frontier with a score of 1 (when raw efficiency is computed), after the bias is corrected, even these banks have inefficiencies and their output could be increased. For example, in the case of first bank□AB bank□the efficiency could be improved by 9.84 per cent. The bias-corrected column shows that few banks are quite close to the frontier but are not exactly on the frontier, suggesting that there is scope to further increase output with the same inputs. The information could be useful to bank managements to take appropriate strategic actions.

Table 5: Truncated regression results

Variable	Co-eff	Std Error	*p*-value
Foreign-owned=1	-0.06093	0.024	0.01
Soundness	-1.7E-05	0.001	0.99
State-owned=1	-0.09497	0.019	0.00
LoanQuality	-0.0148	0.006	0.02
Size (staff numbers)	-5.93E-07	3.06E-07	0.05
Constant	1.201007	0.023	0.00
Log likelihood: 168.47 (Prob > chi square = 0.000) No. of observations=293, LL=0, Wald chi2(5) = 42.66			

Foreign ownership was found to have significant negative association with efficiency. Berger et al. (2009, 2010) in the context of Chinese banks found that foreign banks were most efficient. In the Indian context, Mohan and Ray (2004) and Das et al. (2005) found that foreign-owned and state-owned banks were not significantly different in efficiency. Our study, however, shows that foreign-owned banks had significantly lower efficiency. Thus, foreign banks in these two countries show divergent results with respect to efficiency. Berger et al. (2009) study, however, refers to the 1994-2003, that is, the pre-GFC period. Our finding is in line with that of Lensink et al. (2008), who found that foreign ownership negatively affects bank efficiency. However, in countries with good governance, this negative effect is less pronounced. Chen et al. (2013) state that efficiency flows through two channels, that is, the monitoring channel and the information channel reducing issues associated with agency problem and information asymmetry. However, corporate governance in Indian banks is wanting. A senior official of

RBI recently stated 'sserious lapses observed in governance framework during the crisis, tilted the balance in favour of more rigorous regulation' (Sinha, 2013).

This could be because many foreign banks suffered badly during the GFC, and their income deteriorated also due to high bad debt provision. Many foreign banks curtailed operations due to problems in their home countries.

The soundness variable is not found to be significant. Earlier studies have found that well capitalized banks are more efficient. During the GFC, most banks were required to beef up capital given the rising bad debts; consequently, it appears that the normal salutary effect that increased capital may have on efficiency through increased business and increased income is not seen. The additional capital was to provide a buffer against bad debts rather than for expanding business because of the unusual circumstances through which the banks were passing.

The state ownership variable shows a negative significant result. This is particularly interesting. Many prior studies of Indian banks have found the relationship to be positive for medium-sized state-owned banks (Kumbhakar and Sarkar 2005; Das and Ghosh 2006; Chatterjee 2006). However, our results are consistent with recent studies such as those by Kaur and Kaur (2010) and Dwivedi and Charyulu (2011), who found that state-owned banks were less efficient than were non-state-owned banks. Lensink et al (2008:841) also found that 'state-owned banks are, in general, less efficient than non-state owned banks'. It appears that after the GFC, the foreign and private sector banks have considerably improved their efficiency vis-à-vis the state-owned banks. Further, given the archaic labour laws in India, it may be hard for state-owned banks to take drastic measures such as curtailing staff, which could be possible for private sector and foreign banks.

The loan quality variable, which measures credit risk, has significant negative association with technical efficiency. Higher credit risk (non-performing loans) implies lower interest income and higher operational expenses in loan collections and monitoring. The result is consistent with prior work of Berger and Mester (1997), who found that poor management of credit portfolio,

has an unfavorable impact on efficiency. Ghosh (2009) also found similar results for Indian banks.

Size has a significant negative influence on efficiency. As the number of employees increases, the operational costs, which include salary and wages, would increase, and unless it is compensated by increased income through increased business, the efficiency would be negatively impacted. The result is similar to those of prior studies such as Sun and Chang (2011), Ghosh (2009) and Das and Ghosh (2006). These studies found that large banks are less efficient than are small banks.

Next we examine if there was significant difference in bootstrap banking efficiency in the pre – GFC years, during GFC years and between GFC years and post GFC years. The impact of GFC (using a decline in GDP as the criteria to define GFC years) on the GDP was felt by India in the years 2008-09 and 2009-2010. The GDP growth rate which showed a rising trend prior to these years showed a sharp decline and stagnancy in these years. Thereafter, the GDP rose significantly in 2010-11 (over 10 per cent from 7 per cent in earlier years) but again sharply declined in 2011-12 to the GFC years' level.

We use Kruskal-Wallis test to assess whether there was significant difference in banking efficiency in the above periods. The computation returned chi square value of 4.889 (with 1 d.f.) and probability of 0.027. This demonstrates that the GFC years did affect banking efficiency. While comparing GFC years with the post-GFC years, an interesting result can be found. When we compare the efficiency scores GFC years with 2010-11 (GDP rose significantly exceeding 10 per cent), we get the chi square value of 5.378 (with 1 d.f.) and a probability of 0.020 indicating that post GFC year there was significant difference in efficiency. However, if we use the year 2011-12 data as well, then the results are not significant. This was because in 2011-12, India's GDP sharply declined to GFC years' level. Overall, when we compare pre-GFC year with post- GFC years, no significant difference in banking efficiency was noticed.

As indicated by Podpiera and Cihak (2005), regular screening of banking efficiency is important as it can serve as early warning system. Indian banking efficiency does show signs of stress in the post GFC years. It appears that the Government of India too is concerned about the inefficiencies that plague the Indian banking system and has taken policy measures like the recent Banking Reforms Bill 2012, which raises limit on foreign capital to 26 per cent from 10 per cent. Hopefully, these measures would help improve Indian banking efficiency over the years. Berger et al. (2009) observation in the context of Chinese banking could be equally applicable to Indian situation. 'The ''real" reward of such reforms may be continued economic growth because an open and flexible banking environment not only provides more credit, but a better allocation of credit, funding more positive net present value projects that contribute to economic growth'.

6. Conclusion

In the current study, we provide a bootstrap efficiency analysis of Indian banks for the 5-year period from 200̃708 to 201̃112 using Simar and Wilson's (2007) method. Such an analysis is being done for a developing country for the first time, to our knowledge. These authors have already demonstrated that DEA analysis using conventional methods (non-bootstrap) may not provide reliable results. In the current paper, we not only rectify the situation in the Indian banking context but also provide results from truncated regression, which has not been employed in prior studies on Indian banking. Consequently, our study provides more appropriate analysis of Indian banking efficiency than found in studies hitherto.

Interestingly, contrary to prior studies, we find that state ownership has a negative impact on efficiency in the Indian context. Similarly, foreign ownership also was found to have negative influence on efficiency. The bad management hypothesis finds support, as the loan quality variable was found to have significant negative impact on efficiency.

The bootstrap scores suggest that there is room for expanding output with current input levels by banks. It is hoped that the study would provide an impetus for similar studies that use bootstrap efficiency analysis and second-stage truncated regression so as to draw valid conclusions.

Besides the above conceptual contributions, the study is expected to help bank managements in further improving efficiency by suitable strategic actions such as reducing inputs or making better use of inputs and to policy makers to continue with banking reforms agenda. Regulatory authorities in developing countries may also like to consider conducting similar studies of banks in their respective countries so that efficiency is accurately measured so as to draw valid conclusions for policy actions.

Labour Unions, Unit Labour Cost and Competitiveness: The Case of Singapore

Chew Soon Beng
Nanyang Technological University, Singapore
ASBCHEW@ntu.edu.sg

In Singapore, we have been able to achieve full employment. Indeed, our natural rate of unemployment is always close to our actual unemployment rate (Groenewold and Tang, 2004). We have been able to achieve this result because our wage costs are fully flexible. During good years, we enjoy wage increases and during a recession, we allow wage costs to fall to protect employment. However, the business cycles are shorter and more extreme. We need more and more foreign workers to act as buffer. Consequently, the low income workers in Singapore suffer even when there is full employment on the account of higher cost of living and depressed wages caused by foreign workers.

The purpose of this paper is to show that with the right kind of labour unions, Singapore economy can recover fast in terms of lower ULC. Of course, low wage workers suffer too when there is a recession because their take-home pay is reduced significantly. In other words, we do not have inclusive growth when there is a negative demand shock. Consequently, the government would have to increase public spending to help the poor. The strategy of relying on foreigners, coupled with globalization has caused the Gini coefficient in Singapore to continue to rise. We need additional instrument to look after low income workers. Our unions can play a role here.

1. Introduction

This paper will present a scenario which shows that besides wages and worker benefits which are provided by the employers, the labour movement can help to mitigate the hardship caused this strategy of relying excessively on foreign workers by providing union benefits to union members. Workers at non-unionized plants are also eligible to join as social union members.

These union benefits can be regarded as country club benefits in the sense that workers joining the union is like joining a country club except this is a big country club. The paper will present evidence of the country club benefits provided by the unions to the workforce in Singapore as part of the inclusive growth strategy.

2. The Economics of Joining the Trade Union

Booth (1984) presents a model of union membership where a worker's decision to acquire trade union membership depends on his wage premium plus non-contractual benefits and his probability of being retrenched. The amount of wage premium is positively related to the probability of retrenchment, as the demand curve for labour has a negative slope. At the same time, effective union strategies can enhance a worker's valuation of non-contractual services (benefits provided by the union) and thereby increase union membership. Unions also provide benefits to members in terms of an insurance scheme (Boyer 1988). This type of union benefits can be regarded as country club benefits as workers join the union in the same way as they join a country club.

However, reliance on the creation of wage premium is not effective in increasing union membership as firms worldwide face intense competition and the market constraint would limit the amount of wage premium a union can effectively command since the number of employed would fall, while country club benefits are not able to reverse the declining union membership trends because these benefits are not substantial owing to job mobility and/or shorter job tenure and most of all, the limited financial resources of a union. In the USA where labor militancy has been strong but the number of strikes has decreased steadily from 1995 to 2005 due to globalization (Borjas, 2009). The traditional labour unions which can be regarded as micro-focused unions need to rethink about union strategy in order to stay relevant.

Macro-focused unions

Contrary to micro-focused unions, a macro-focused union will not trade higher wages for lower level of employment. In other words, a macro-focused union would want to maximize the employment level. But being a labour union, the objective is to raise wages. Hence, a macro-focused union would work with the government to raise the competitiveness of the country and would work with the management to increase profitability of the firm, all with the sole objective of raising purchasing power of the workers (see Chew and Chew (2010) for reference on macro-focused unions). During a recession, wages and employment would fall in the normal economic circumstance. But a macro-focused union would work with the government and the management to reduce labour cost such that the employment can best be protected.

However, as a macro-focused union provides a public good, it has difficulties in inducing workers to join the union. Consequently, the macro-focused union needs to provide country club benefits to induce workers to join the union.

Diagram 1 shows that the labour market is in equilibrium at E. A macro-focused union will set the wage rate at W so that the employment level is maximized. The macro-focused union will work closely with the government to attract foreign investment such that the demand for labour curve will shift to D’. The new equilibrium point is at E’ and the wage rate is at W’. There is no union wage premium for union members. A macro-focused union can provide country club benefits of AE’ to union members. Hence, the macro-focused union can achieve full employment and at the same time increase union membership.

Diagram 1: Demand and Supply curves

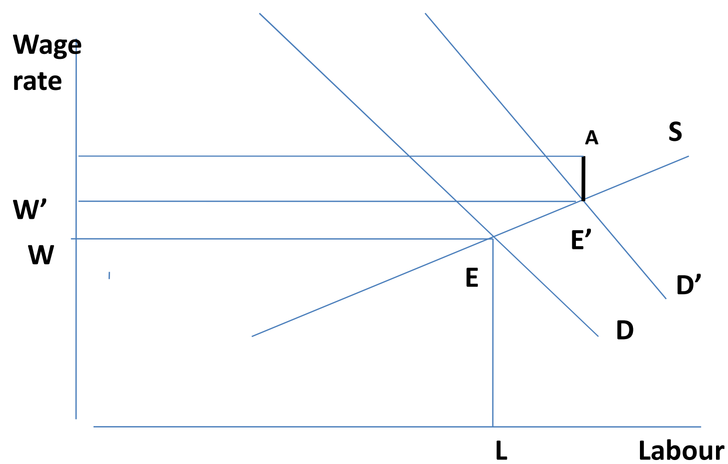

Diagram 2 shows that the original equilibrium was at E in another situation. Suppose a recession has shifted the demand curve to D’ and under normal circumstance, both wage rate and employment will fall and the Gini will be bibber. In order to maintain the level of employment, the new wage rate has to be at W’. Workers will suffer a wage cut in exchange for employment. This is a better outcome for the workers, which is the objective of an inclusive growth strategy.

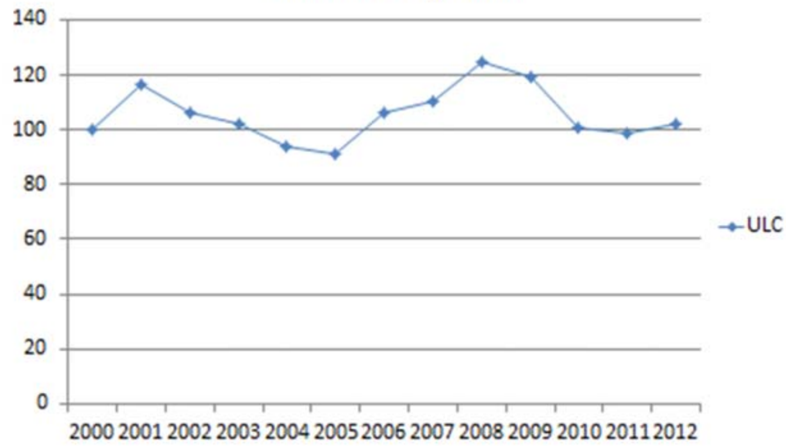
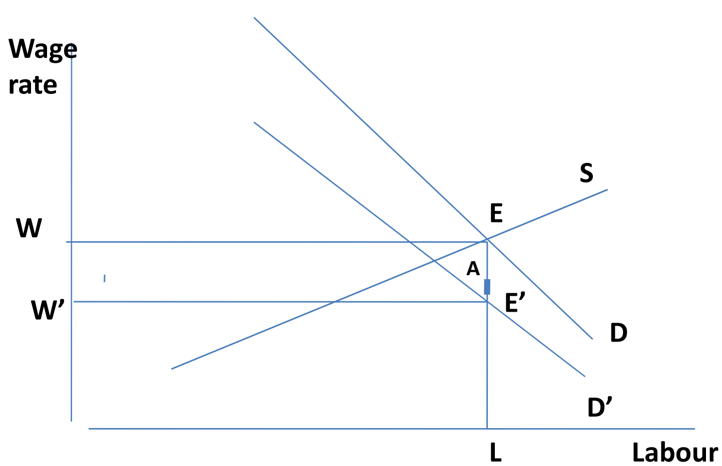
At E’, unit labour cost is lower because employment level and output is the same but wage cost is lower. This will help Singapore to recover from recession. Diagram 1 shows that ULC in Singapore’s manufacturing sector is flexible downward during economic slowdown. In most countries, wage costs cannot be lowered due to unions’ objections but labour unions in Singapore behave differently.

**Diagram 1:
Index of Unit Labour Cost (ULC) within the
Manufacturing Sector**



At the same time, if the union can offer to both union members AE’ in country club benefits, the reduction of wages will be mitigated by the country club benefits of AE’. The purpose of this paper is to provide as estimate of AE’ based on a survey of workers in Singapore.

Diagram 2: Demand and Supply curves



It is not easy for a union to provide a significant amount of country club benefits to the workforce. But the government can help the union in the provision of country club benefits because the union is macro-focused.

Labour Unions in Singapore

The labour movement in Singapore is represented by the National Trades Union Congress (NTUC). NTUC is a macro-focused union as she looks after the interests of all workers in

Singapore. For instance, NTUC provided vouchers worth one million dollars to 10,000 workers for the Family Recreation Fund in 2007。

As a macro-focused union, NTUC also promotes employment and training. This strategy is, as expected, strongly endorsed by the government and the employers. NTUC has also openly supported the government policy of attracting foreign talents and foreign workers as this policy will induce more foreign investment in Singapore and consequently raise standard of living for the locals (See Lim Chong Yah, at al., for an extensive discussion on economic policies in Singapore) . In 1985 and 1998, when Singapore registered negative GDP growth rates, the government had, with the support of the NTUC, used labour cost reductions as an effective solution to prevent retrenchment (see Diagram 1 for reference). In 2008, when the world was crushed by the global financial crisis, the NTUC persuaded the Singapore government to use past reserves to fund wage subsidies in the order of SE' in Diagram 1 in order to stabilize employment.

NTUC has two types of union members. The normal union members are entitled to collective bargaining benefits and of course they enjoy country club benefits. In early 90s, NTUC has set up the General Branch Union for workers in non-unionised firms to join the labour movement (See Chew, 1990 for the theoretical framework of General Branch Union) . Hence, members of the General Branch Union only enjoy country club benefits. As the union due per month is $9 in Singapore, the country club benefits per month have to be worth far more than the $9. Table 1 shows that about 30% of NTUC membership is from the General Branch Union.

Table 1: Union members of NTUC

year	Union Members	Members of General Brach Union	Traditional Union Members
0 1	3 45935	112,009	2 33 926
02	389,676	147,706	241,970
03	417,166	175,383	241,783
04	443,893	206,684	237,209
15	850,000	30%	70%

The extent of union benefits in Singapore

Both 2008 and 2009 were bad for Singapore and the world, the union benefits offered to the Singapore society by the NTUC was around $76 million and $107 million respectively.

However, these benefits are estimated based on NTUC's expenditures. It is not clear to what extent individual members benefited in dollars and cents.

The objective of this paper is to present a survey where we ascertain the preferences of Singapore workers the extent to which they benefit from the union benefits.

Estimation of EE' based on a survey

A survey is conducted to explore the total savings that members can reap, regularity of frequenting the merchant and lastly, the importance of the benefits that is provided.

The first part of the survey looks into gather some basic information of the survey respondents on their age, gender, occupation, marital status and number of dependents (This information will be supplied upon request). Furthermore, the survey also seeks to uncover the preferences of respondents on the importance of the availability of discounts based on broad categories of household expenditures as defined by Singapore Statistics Department. The survey results should reveal the ideal set of benefits that people would need or prefer to have.

The subsequent section of the survey contains the entire list of benefits provided by NTUC for its members, listed by merchants. The collated list of 185 merchants and its listed benefits will also be supplied upon request. Respondents will be asked to disclose how frequent they visit these vendors. The survey is expected to reveal the taste and preference of NTUC members and non-members and that if NTUC is attracting the correct the target audience. Computing the amount of savings / benefits that people will receive as a NTUC member will also be possible.

Cost-Benefit Analysis of union membership

The following section will present and analyse the data collected from the findings. The survey has 70 respondents with 20% of them being NTUC members. Having survey participants' age ranging from 20 to 60, with 58.6% being males, the survey is conducted on a random basis so long they are residing within Singapore.

From the survey, we gathered expenditure data of both union and non-union members. Union members enjoy $52.8 in savings monthly. The total amount of saving is derived using the average savings that can be obtained from the discount tied up NTUC has with its participating merchants. This coupled with survey results used to find out the frequency of visits, allowed the computation of savings that one gets as a union member. Hence, the country club benefits are significant as the monthly union due is only $9.

For non-union members, they are not entitled to discount but if they were union members, based on our calculations, they stand to gain $47.2 in savings per month.

Generally, the monthly wages of workers who are eligible to join the labour movement in Singapore range from $1,000 to $$2,500. This represents an implicit wage increase of 5.3% to 2.1% for union members and 4.7% to 1.9% for would be union members. According to Year Book of statistics of Singapore, the average monthly household expenditures for labourers in 2012 is about $1,925. If both husband and wife will be working and if both are union members, the household savings would exceed $100 a month which would present an increase of 5.2% in purchasing power.

3. Conclusion

Having a macro-focused is desirable for an inclusive growth strategy for the following reasons; we can ensure sustainable employment level and salary level during good times. During a recession, wage costs can be lowered to protect employment level which is the most important aspect of inclusive growth strategy.

Regardless of economic situations, low income workers can benefit from country club benefits. If unions know the preferences of the workforce, the country club benefits can increase significantly.

However, it is not easy to have a macro-focused union. It depends on the leadership of the labour movement and also the leadership of the ruling party. We will discuss this in another paper.

This paper examines whether and to what extent a firm's performance pricing loans provide an incentive for managers to manipulate earnings more aggressively. We find that firms with a higher slope of the performance pricing schedule have significantly larger discretionary accruals, which is consistent with the prediction of the positive accounting theory (Watts and Zimmerman, 1986, 1990). However, the positive relationship between the slope of performance pricing schedule and discretionary accruals is significantly attenuated in firms borrowing from high reputation banks or banks with a prior lending relationship. These results suggest that bank reputation and prior lending relation serve as an effective monitoring mechanism, which in turn mitigates managers' incentive and ability to manipulate earnings.

Keywords: Performance pricing, debt contracting, earnings management, discretionary accruals, performance pricing schedule.

JEL Classifications: G21, G32

1. Introduction

Performance pricing is a provision in bank loan contracts that ties loan spread with a borrower's performance, e.g., credit rating or accounting ratios like debt-to-EBITDA ratio. A typical performance pricing loan charges lower (higher) interest rates as borrower’s performance becomes better (poorer). The use of performance pricing provision has become increasingly popular in the last two decades. Hu, Mao, and Naveen (2014) document that about 1% of bank loans were performance priced in 1991 and the usage goes up to 49% in 2006.

In this study, we examine the contractual role of the performance pricing provision in resolving the conflicts of interest problem that arises between lenders and borrowing firms, and its potential impact on firms’ earnings management. Jensen and Meckling (1976) and Myers (1977) recognize the conflicts of interest that exist between a firm’s shareholders and debt-holders, and debt covenants and other provisions can be used to mitigate the conflicts (Smith and Warner, 1979; Bradley and Roberts, 2004). Covenants impose constraints on managers’ actions and prevent them from taking actions that will hurt debt-holders. Since many debt covenants involve accounting measures, the positive accounting theory suggests that managers have an incentive to change accounting method or make financial reporting decisions that reduce the likelihood of violating accounting-based covenants in debt contracts (Watts and Zimmerman, 1986, 1990). Empirical studies provide evidence supporting the existence of such incentives (DeFond and Jiambalvo, 1994).

While debt covenants regulate the allocation of control rights between shareholders and debt-holders via covenant thresholds (specific levels of performance), performance pricing provisions provide a continuous and direct link between accounting measures and interest payments on bank loans. Prior studies show that performance pricing provision is used in a debt contract to lower renegotiation costs (Beatty, Dichev, and Weber, 2002; Asquith, Beatty, and Weber, 2005), to reduce moral hazard between managers and shareholders (Tchistyi, 2013), and to reduce information asymmetry (Manso, Strulovici, and Tchistyi, 2010). In particular, a scheme that punishes bad performance with higher interest rates could serve as an additional incentive for the manager to exert effort. As a result, performance pricing would better align the interests of shareholders and debt-holders. Since performance pricing grids usually have multiple levels, a small improvement in a borrower’s performance will result in a decrease in interest payments. In the same spirit of positive accounting theory, performance pricing may give managers additional incentives to manage accounting information so as to achieve a lower cost of debt, even when the firms are in compliance with debt covenants. Hu, Mao and Naveen (2014) show that a manager’s incentive to manipulate earnings is indeed a determinant for whether a firm is able to obtain a performance pricing loan.

In this study, we aim to address the following questions: Do performance pricing loans encourage managers to manipulate earnings more aggressively? Does bank monitoring curtail the extent of earnings manipulation associated with performance pricing loans? We use discretionary accruals as measures of earnings management because they are able to reveal subtle manipulation strategies related to revenue and expense recognition (DeFond and Jiambalvo, 1994). We use the slope of the performance pricing schedule in the loan contract as a proxy for managers’ incentive to manipulate earnings. A steeper performance pricing schedule (a steeper slope) implies a larger decrease (increase) of interest rate given a fixed level of firms' performance improvement (deterioration). Therefore, a steeper pricing schedule (a steeper slope) would offer greater savings in interest payments through inflated accounting performance, which hence provides a greater incentive for managers to manipulate earnings. Based on dollar weighted average slope of all loans for each firm in a given year, we find that firms with steeper performance pricing schedules have significantly larger discretionary accruals, and the results are robust with various measures of discretionary accruals adopted in the literature. The findings are consistent with the prediction of the positive accounting theory.

Previous research suggests that bank reputation and prior lending relationship serve as an effective monitoring mechanism (Pichler and Wilhelm, 2001; Haubrich, 1989), because higher reputation banks and relationship banks have greater incentive to monitor borrowers and an expertise to monitor effectively. Therefore, borrowing from high reputation bank or banks with prior lending relationship potentially constraints managers' incentive and abilities to manage earnings. We document evidence supporting this conjecture. We find that discretionary accruals are less positively related to the slope of performance pricing loans in firms borrowing from banks with high reputation or with prior lending relationship.

Our study contributes to the literature on debt contracting and earnings management. It is the first study that directly examines the effect of performance pricing provision on earnings management. This study also shed light on how banks assert their monitoring effects to mitigate borrowers' incentive and ability to manipulate accounting information related to performance pricing loans.

The rest of paper proceeds as following. Section 2 provides a literature review and develops hypotheses. Section 3 describes our sample, variables construction, and summary statistics. Section 4 reports empirical results and section 5 concludes the paper.

2. Literature Review and Hypotheses Development

2.1. *Debt Contracting and Earnings Management*

Agency theory in Jensen and Meckling (1976) and Myers (1977) recognize the conflicts of interest problem that exists between shareholders and debt-holders. Debt covenants and other provisions are in place to impose constraints on managers' actions and prevent them (in the interest of shareholders) from taking actions that will hurt debt-holders, e.g., investing in higher risk project (Smith and Warner, 1979; Bradley and Roberts, 2004). Many debt covenants and provisions are based on accounting variables, e.g., EBITDA. The positive accounting theory suggests that managers have an incentive to make financial reporting decisions that reduce the likelihood of violating accounting-based covenants in debt contracts (Watts and Zimmerman, 1990). Several empirical studies suggest that managers do respond to such incentives. DeFond and Jiambalvo (1994) document that managers use abnormal accruals to avoid debt covenant violation. Sweeney (1994) finds that managers make income-increasing accounting changes during periods prior to technical default. Jaggi and Lee (2002) also show that managers of financial distressed firms use income-increasing discretionary accruals if they are able to obtain waivers for debt covenant violations. Dichev and Skinner (2002) document an unusually small number of observations with financial measures just below covenant thresholds and an unusually large number of observations with financial measures at or just above covenant thresholds.

Compared to covenants that restrict managerial actions at a particular threshold stipulated by the contract, performance pricing provisions provide a direct and continuous link between firm performance and loan spread since lower (higher) interest rate would be charged if the borrower's performance becomes better (worse). In contrast to loan covenants, in which firms would manipulate earnings only when they are close to the covenant threshold, the performance pricing provisions offer firms an incentive to manipulate earnings more frequently, since even relatively small changes in earnings could be translated into substantial savings in interest payments. Consistent with this argument, Beatty and Weber (2003) document that the performance pricing provisions give managers additional incentives to make income-increasing changes in accounting method. Hu, Mao and Naveen (2014) find that firms with poorer accounting quality are less likely to receive performance pricing loans. The likelihood of receiving performance pricing loans is significantly reduced after borrowers' accounting quality deteriorates.

In this study, we examine the effect of the performance pricing provision on earnings management. The provision often includes a pricing schedule that stipulates the level of loan spread for each performance level. In the same spirit of the positive accounting theory, we expect that firms with a steeper slope of performance pricing schedule would manage earnings upward to a greater extent. This is because a steep performance pricing schedule implies a rapid decrease of interest payments when a firm improves its performance and a rapid increase of interest payments when firm's performance deteriorates. As such, a larger slope of the performance pricing provision provides greater reduction in interest payments for each unit change of performance, thereby provides a greater incentive for managers to manipulate earnings. Therefor we propose the following hypothesis:

H1: Steeper performance pricing schedules are associated with higher levels of earnings management.

2.2. *Banks' Monitoring Role: Bank Reputation and Lending Relationship*

As 'informed lenders' and delegated monitors, lead banks in syndicated loans have an incentive to monitor borrowers due to their large holding in the loan syndicate, as well as their long-run reputation consideration. Since banks are aware of borrowers' incentive to manipulate earnings so as to reduce interest payments on performance pricing loans, they would exert effort to monitor borrowers' performance and accounting information to restrict firms' opportunistic behavior. For example, Beck, Lin, and Ma (2014) find that firms in countries with higher bank branch penetration are less likely to evade taxes. In addition, bank monitoring makes manipulation of accounting information more costly to firms. Graham, Li, and Qiu (2008) document a significant increase in the cost of bank loans due to illegal misconduct, e.g., corporate misreporting. More reputable banks in the lending market will have a stronger incentive (to preserve their reputation) and better skills (due to greater experience) to monitor their borrowers effectively. Billett, Flannery and Garfinkel (1995) find that stock market reaction to bank loan announcements is more positive as the lenders of bank loans have a higher credit rating. Pichler and Wilhelm (2001) argue that lead arrangers' reputation could serve as

an effective monitoring mechanism. As a result, we expect that bank monitoring is essential to mitigate the moral hazard problem of borrowers in managing earnings. Thus, we have the following hypothesis:
H2: All else equal, borrowing from high reputation lead banks will mitigate the effect of the performance pricing schedule on earnings management.

In addition to lender reputation, prior lending relationship could mitigate information asymmetry between borrowers and lenders hence reduce monitoring costs. Through close and repeated interaction over time, relationship lending allows a bank to acquire information through screening and monitoring the borrower at a lower cost. Therefore, banks having repeated relationship with their borrowers are able to monitor the borrowers more effectively. Haubrich (1989) argue that in a repeated relationship between a bank and a borrower, the bank can keep track of reports from the borrower and penalize it if too many reports are bad. While firms have an incentive to manipulate earnings as a result of the performance pricing loans, the incentive will be significantly reduced as they borrow from relationship banks. This is because relationship banks “know” the borrower well through previous lending relationship, and would monitor the borrowers' performance and accounting information closely and intensively. Therefore, firms borrowing from banks with which they have a prior lending relationship have less chance to manage earnings even if they want to save interest payments. Thus, we have the hypothesis below:
H3: All else equal, existence of a prior lending relationship with the lead bank will mitigate the effect of performance pricing schedule on earnings management.

3. Data and Summary Statistics

3.1. *Data Source*

We start with all loans of U.S. borrowers from 1993 to 2007 recorded in the Dealscan database. Dealscan contains detailed information on bank loans worldwide, such as borrower and lender identity, loan amount, loan spread, issue and maturity date, financial and general covenants, etc. About 60% of loan data in Dealscan are collected from SEC filings and the rest are obtained from direct contact with borrowers and lenders.

There are more than eight performance measures used in performance pricing loan contracts, such as debt-to-EBITDA ratio and senior debt rating. Hu, Mao and Naveen (2014) find that the most commonly used measure is debt-to-EBITDA ratio, which accounts for about half of the performance pricing loans. The second widely used performance measure is senior debt rating, which accounts for about 22.3% of the performance pricing loans. All other types of performance measures account for a much smaller portion of the sample. Therefore, we focus on performance pricing loans based on debt-to-EBITDA based ratio or senior debt rating for which we can clearly and uniformly quantify the slope of the performance pricing schedule of each loan facility. Accounting data of borrowers are obtained from the Compustat database. Firms in Dealscan are linked to the Compustat database using the Dealscan-Compustat link file that was kindly provided by Michael Roberts (Chava and Roberts, 2008). We exclude borrowers that cannot be linked to Compustat, as well as those observations with missing values in relevant firm characteristic variables. This leaves us with about 22,120 firm-year observations of 4,070 firms.

3.2. *Definition of Key Variables*

Below we define the main variables used on our study. More details are provided in Appendix A and B.

3.2.1. Slope of the Performance Pricing Schedule

As we discussed above, the slope of the performance pricing schedule is related to managers' incentive to manipulate earnings. A pricing schedule with a steeper slope implies a larger decrease (increase) of interest rate given a fixed level of firms' performance improvement (deterioration). As a result, a pricing schedule with a steeper slope will provide greater savings in interest payments through inflated accounting performance, which hence creates a greater incentive for managers to manipulate earnings. We compute the slope of the two types of performance pricing loans a bit differently. For debt-to-EBITDA based performance pricing loans, we compute the slope as the interest rate change of each debt-to-EBITDA increment in the pricing schedule divided by the difference of debt-to-EBITDA ratio over the same increment. Average slope is calculated as the average of all slopes across all debt-to-EBITDA segments between the upper and lower limits of the debt-to-EBITDA ratio specified in each performance pricing loan contract. Local slope is calculated as the average of the two slopes immediately above and immediately below the firm's debt-to-EBITDA ratio at the time of loan issuance. In appendix A, we present an example of the performance pricing schedule of a loan issued by Chemed Corp. on February 24, 2004 in which interest rate is tied to the debt-to-EBITDA ratio. We illustrate in details the way we compute average slope and local slope in the example. Non-performance pricing loans are assigned with a slope of zero.

As for senior debt rating based performance pricing contracts, we follow Tchistyi, Yermack and Yun (2011) to construct the slope of the performance pricing schedule. For each performance pricing loan facility, we identify interest rate change of each credit rating increment, and then divide it by the difference of market yields of corporate bonds over the same rating increments during the same time period. Slope of rating based performance pricing loan is computed as follows:

$$\text{Slope} = \frac{Spread(i-1) - Spread(i)}{MarketSpread(i-1) - MarketSpread(i)}, \tag{1}$$

where Spread(i) is a firm's loan spread above the LIBOR at rating i, MarketSpread(i) is the average yield spread above the LIBOR for corporate bonds with rating i, and rating i is a credit rating listed in the pricing schedule. We construct two measures of the slope of a performance pricing contract, the "average slope" and the "local slope." An average slope is calculated as the average of all slopes across all rating segments between the upper and lower limits of the credit ratings specified in each performance pricing loan contract. Local slope is defined as an average of the two spread ratios of the rating increments immediately below and above the borrower's rating at the time of loan issuance as shown below:

$$\text{Local slope} = 0.5\left\{\frac{Spread(i-1) - Spread(i)}{MarketSpread(i-1) - MarketSpread(i)} + \frac{Spread(i) - Spread(i+1)}{MarketSpread(i) - MarketSpread(i+1)}\right\}, \tag{2}$$

where Spread(i) is a firm's loan spread above the LIBOR at rating i, MarketSpread(i) is the average yield above the LIBOR for corporate bonds with rating i, rating i is the borrower's credit quality at the time of loan issuance, and rating i-1 and rating i+1 are the borrower's credit ratings one notch below and one notch above its rating at the time of loan issuance, respectively. Under such a scaling, non-performance pricing loans are assigned with a slope of zero. Slope is greater (smaller) than one if the interest rate change in performance pricing contract is larger (smaller) than the change of prevailing market yields.

After we compute the slope of each loan contract, we next aggregate the slopes of all bank loans outstanding for a particular borrower in a given year. However some borrowers have both rating based and debt-to-EBITDA based performance pricing loans outstanding, we cannot add up the slopes of both types of loans because their slopes are on different scales. To circumvent this problem, we adopt the idea in Anderson, Duru and Reeb (2009) and assign rank scores to the slope of each type of performance pricing loans, and then sum up the slope rank scores among loans with different performance measures. In particular, we every year assign rank scores to the average (local) slope of each type of debt-to-EBITDA based or senior debt rating performance pricing loans into quartiles, with the top 25% taking a value of 4 and the bottom 25% taking a value of 1. In this step we do not include non-performance pricing loans since more than 50% of our sample loans are not performance priced. Instead we assign a rank score of zero for non-performance pricing loans. Next, we compute firm level aggregated average (local) slope of all performance pricing loans in a particular year as the weighted average rank scores of all the outstanding loans with the weight equal to the facility amount divided by the total outstanding facility amount of the firm in that year, i.e.,

$$\text{Aggregated slope score}_j = \frac{\sum_i AMT_i * \text{Slope rank score}_i}{\sum_i AMT_i}, \tag{3}$$

where AMT_i is the outstanding amount of facility i, $\text{Slope rank score}_i$ is the slope rank score of a performance pricing facility i, $\sum_i AMT_i$ is the total amounts of all outstanding facilities of firm j.[1] The aggregated score of slope captures the relative steepness of the performance pricing schedule. A higher slope score implies a larger decrease (increase) of interest rate given a fixed level of firms' performance improvement (deterioration).

3.2.2. Measures of Discretionary Accruals

To measure earnings management, we construct discretionary accrual measures following Daniel, Denis and Naveen (2008). Total accrual is defined as income before extraordinary items (EBEXTRA) minus operating cash flows (OCF). There are two components of total accruals: non-discretionary and discretionary accruals, which are estimated using the following cross-sectional model of Jones (1991):

$$\frac{Total\ accruals_{j,t}}{Assets_{j,t-1}} = \varphi_0 \frac{1}{Assets_{j,t-1}} + \varphi_1 \frac{\Delta Sales_{j,t}}{Assets_{j,t-1}} + \varphi_2 \frac{PPE_{j,t}}{Assets_{j,t-1}} + \varepsilon_{j,t}, \tag{4}$$

where total accruals are regressed on annual change in sales and property, plant and equipment, with all variables scaled by lagged total assets. We estimate equation (4) using all

[1] For those facilities with missing maturity date, we set facility maturity date as the facility start date plus the sample median of years to maturity.

Compustat firms in each two-digit SIC coded industry for each year. Residual and predicted values from the above regression are the discretionary and non-discretionary components of total accruals, respectively. The discretionary components are then multiplied by the firm's lagged assets to retrieve the dollar value of discretionary accruals, which is used for our analysis. This measure is called 'discretionary accrual Modified Jones (1991)'.

We also compute 'discretionary accrual Modified KLW (2005)' based on modified Kothari, Leon, Wasley (KLW) model, which is an extension of 'Modified Jones (1991)', and attempts to improve the power and specification by developing a discretionary accrual model that is adjusted for a performance-matched firm's discretionary accruals. Specifically, we first calculate asset-scaled discretionary accruals for each firm based on equation (4) with ROA as an additional regressor. Then we compute the discretionary accruals of a sample firm and its matched partner based on ROA, industry and calendar year. The difference between these two discretionary accruals is our 'discretionary accrual Modified KLW (2005)'.

In addition, we construct three alternative measures of discretionary accruals following various models in the literature. We compute 'discretionary accrual TWW (1998)' based on Teoh, Welch, and Wong (1998), where discretionary accruals are estimated from equation (4), however total accruals are computed as net income minus operating cash flows. 'Discretionary accrual BS (2006)' is based on Ball and Shivakumar (2006). Ball and Shivakumar (2006) show that accrued loss recognition is more prevalent than accrued gain recognition. Therefore, we include variables that capture the asymmetric timely loss recognition of firms in the regression, which are cash flow from operation (CF), a dummy variable (DCF) that equals one if cash flow from operation implies a loss and the interaction term DCF*CF. Residuals from such a regression model are the discretionary component of total accruals 'Discretionary accrual Modified DD (2002)' is based on the Dechow and Dichev (2002) model. We augment the Dechow and Dichev (2002) model with variables from the Jones (1991) model, and 'Discretionary accruals Modified DD (2002)' are residuals estimated from the model below:

$$CA_{j,t} = \alpha_1 + \beta_1 CFO_{j,t-1} + \beta_2 CFO_{j,t} + \beta_3 CFO_{j,t+1} + \beta_4 \Delta Sales_{j,t} + \beta_5 PPE_{j,t} + \varepsilon_{j,t}. \quad (5)$$

where $CA_{j,t}$ is total current accrues and $CFO_{j,t}$ is cash flow from operation.

3.2.3. Other Firm Characteristic Control Variables

We construct firm specific variables that might affect the level of discretionary accruals, including firm size, market-to-book ratio, leverage and retained earnings. We measure firm size using the natural logarithm of total assets. The effect of firm size on the discretionary accruals is not clear. Larger firms are in general more transparent because of greater disclosure and more analyst coverage. Therefore, larger firms are less likely to manipulate earnings. On the other hand, Kim, Liu and Rhee (2003) find that both large and small firms manage earnings aggressively. While small firms are more likely to manage earnings to avoid reporting losses, large- and medium-sized firms exhibit more aggressive earnings management to avoid reporting earnings decreases. Market-to-book ratio is defined as the ratio of market value of assets (book value of debt plus market value of equity) and book value of total assets. Leverage is defined as the ratio of total amount of debt and book value of assets. Retained earnings are used to control for the potential inventory of payable funds. The effect of retained earnings on discretionary total accruals is also not clear. Daniel, Denis and Naveen (2008) find that retained earnings have a positive effect on discretionary accruals in some regression and negative effect in others.

3.2.3. Bank Reputation and Prior Lending Relation

To assess how bank reputation and prior lending relationship affects the extent of earnings manipulation, we construct variables to measure banks' reputation in the lending market and the existence of prior lending relationship between a lead bank and a borrower. While most loans in Dealscan involve several lenders, it is the lead arrangers' responsibilities to negotiate directly with the borrowers and monitor contractual terms. Our analysis on lender characteristics is thus focused on lead arrangers. To make data collection manageable, we follow Sufi (2007) and focus on the top 100 lead arrangers. This selection results in little bias, because according to Sufi (2007), the top 100 lenders represent about 96% of the total number of loans. To take into account bank mergers during our sample period, we track all mergers and acquisitions of financial institutions, and allow the acquiring banks to inherit all the lending history of the acquired bank after the acquisition date. For example, in April 1998, First Union Corp. acquired CoreStates Financial Corp. with the merged entity being called 'First Union Corp.' Thus for the purpose of computing lead bank-borrower relation after April 1998, we assume that First Union Corp. inherited CoreStates' entire lending history prior to April 1998.

Following previous literature (e.g., Bharath et al., 2007), we construct a lead bank's market share in lending during the previous five years as a proxy for bank reputation. It is computed as the dollar amount of loans arranged by a particular lead bank during the previous five years divided by the total amount of loans issued in the market in the same period. In addition, we create a dummy variable 'existence of prior lending relation' to capture whether the firm has a prior lending relationship with the current lead bank. It is equal to one if the firm has borrowed from the same lead bank of the current loan during the previous five years, and zero otherwise.

4. Empirical Results

4.1. Summary Statistics

We present summary statistics of our sample of firm year observations in Table 1. Our sample consists of a total of 4,070 firms (18,809 loan facilities and 22,120 firm-year observations) during 1993 to 2007. An average firm in our sample has over \$2.5 billion in total assets, retained earnings of \$498 million, leverage ratio of 0.276, and market-to-book ratio of 1.89. While discretionary accruals are on average negative, the median values of discretionary accruals are close to zero. Since about 62.5% of loans are non-performance priced (Hu, Mao and Naveen, 2014), are thus assigned with a slope rank score of zero, it is not surprising that the median values of average slope score and local slope score are zero. Lender characteristics show that about 52% of lead banks have a high reputation, and 49% firms are borrowing from lead banks with which they had a prior lending relationship.

4.2. The Slope of Performance Pricing Schedule and Discretionary Accruals

As we discussed above, based on the positive accounting theory, a steeper slope of the performance pricing loans provides a greater incentive for managers to manipulate earnings upward. To examine the effect of the slope of performance pricing contracts on earnings management, we estimate the following regression model:

$$Discretionary\ Accruals_{j,t} = \alpha_1 + \beta_1 Slope\ score_{j,t} + \sum_i \gamma_i Control\ variables_{j,t\text{-}1} + \varepsilon_{j,t} \quad (6)$$

Here, we use five different measures of discretionary accrual as described above. Control variables include firm characteristics as presented in Appendix B, dummies for each two-digit SIC code and each calendar year. The variable of our interest is Slope score, which captures the aggregated slope rank scores of all outstanding loans at each year end for a firm. OLS regression results of equation (6) are presented in Table 2.

In Panel A, we examine the effect of average slope of performance pricing loans on various measures of discretionary accruals. In column (1), the coefficient estimate of Average slope score is positive and statistically significant at 1% level. It suggests that discretionary accruals will increase by \$13.34 million if the average slope score increases from the sample median to the top quartile. The result indicates that the effect of Average slope score on earnings management is also economically significant. We use alternative measures of discretionary accruals in columns (2) – (5), and obtain similar results. The coefficient estimates of Average slope score are all positive and statistically significant, except in column (5) using discretionary accrual from the model 'Modified DD (2002)'. These results are consistent with our hypothesis H1, suggesting that a steeper pricing schedule provides greater incentive for managers to manipulate earnings upward.

Results on the control variables are in general consistent with Kim, Liu and Rhee (2003) and Daniel, Denis and Naveen (2008). Firm size and retained earnings have significant effect on discretionary accruals, although the size of their effect varies, depending on the type of discretionary accrual used in the regressions.

In Panel B, we investigate the effect of Local slope score of performance pricing schedule on different measures of discretionary accruals. The coefficient estimates of Local slope score are mostly positive, and statistically significant in two out of five columns. The results are again consistent with our hypothesis H1, although they are not as strong as those in Panel A.

Tchistyi, Yermack and Yun (2011) suggests that average slope measures CEO's desire of risk over a long horizon, and local slope measures CEO's desire of risk over a short horizon. One caveat with the local slope is that it is measured at the time of loan issuance rather than in a given sample year. As a firm's financial condition changes after issuance, the local slope at issuance becomes a poor measure of CEO's desire of managing earnings. In contrast, in a sample year after loan issuance, even if a firm's financial condition has changed, the average slope of the entire performance pricing schedule remains a better measure of the CEO's desire of managing earnings since it captures the slopes of the entire spectrum of performance. This potentially explains why our results in Table 2 are stronger with the average slope score than with the local slope score.

In summary, the findings in Table 2 support the predictions of the positive accounting theory that a steeper slope of performance pricing schedule provides managers a larger incentive to manage earnings upwards, which leads to a high level of discretionary accruals.

4.3. Does Bank Reputation Limit Earnings Manipulations Resulted from Performance Pricing Loans?

As shown above, we document a positive relationship between the slope of performance pricing schedule and earnings management. As a delegated monitor, lead banks have an incentive and ability to monitor borrowers closely after loans are issued, which in turn reduces the extent of earnings manipulations by managers. Thus we examine whether bank reputation will mitigate managers' incentive to manipulate earnings, as suggested in our hypothesis H2. For that purpose, we include a High bank reputation dummy and its interaction with Slope score in the regression columns as shown below:

$$\begin{aligned} &Discretionary\ Accruals_{j,t} \\ &= \alpha_1 + \beta_1 High\ bank\ reputation\ dummy_{j,t} + \beta_2 Slope\ score_{j,t} \\ &+ \beta_3 Slope\ score_{j,t} \times High\ bank\ reputation\ dummy_{j,t} + \sum_i \gamma_i Control\ variables_{j,t-1} + \varepsilon_{j,t}. \end{aligned} \tag{7}$$

In equation (7), captures the effect of performance pricing slope score on discretionary accruals for banks with low reputation. The impact of performance pricing slope score on discretionary accruals for banks with high reputation is captured by , while measures the differential effect of slope score on discretionary accruals between banks with high and low reputation.

The regression results are reported in Table 3. In Panel A, we examine the effect of Average slope score of performance pricing loans on discretionary accruals conditional on bank reputation. In column (1), the coefficient estimate of Average slope score is positive and significant, suggesting that as firms borrow from low reputation banks, discretionary accruals are higher as they have a larger Average slope score of performance pricing loans. However the coefficient estimate of the interaction term, Average slope score*High bank reputation dummy is negative and significant, which leads to an insignificant coefficient estimate of based on a F-test reported at the bottom of Table 3 Panel A. Since captures the impact of average slope score on discretionary accruals for banks with high reputation, this result indicates that as firms borrow from high reputation banks, discretionary accruals are not significantly related to the average slope score of performance pricing loans. Put another way, a steeper performance pricing slope does not lead to greater extent of earnings manipulation in the presence of higher reputation banks. This finding is robust with respect to alternative measures of earnings management. As shown in columns (2) - (5), we document a consistent pattern that the coefficient estimates of are all insignificant.

Panel B presents results regarding the effect of Local slope score of performance pricing schedule on discretionary accruals conditional on bank reputation, and the findings are similar to those in Panel A. While the coefficient estimates of Local slope score are positive and mostly significant, the coefficient estimates of are generally insignificant based on a F-test reported at the bottom of Table 3 Panel B, except in column (5). Collectively, we find evidence supporting our hypothesis H2 that the association of the slope of performance pricing schedule and discretionary accruals is significantly weakened in firms borrowing from high reputation banks. This is because banks with high reputation would monitor borrowers more diligently and effectively, which in turn curtails borrowers' incentive and ability to manipulate earnings.

4.4. Does Prior Lending Relationship Mitigate Earnings Manipulations Resulted from Performance Pricing Loans?

Above we find evidence that high bank reputation can mitigate borrowers' incentive and ability to manipulate earnings. Next we will examine whether the prior lending relationship between the borrowers and the lenders would mitigate the effect of performance pricing schedule on earnings management, as suggested in our hypothesis H3. To test the hypothesis, we estimate the following regression model:

$$\begin{aligned}&Discretionary\ Accruals_{j,t}\\&=\alpha_1+\beta_1 Existence\ of\ prior\ lending\ relation_{j,t}+\beta_2 Slope\ score_{j,t}\\&+\beta_3 Slope\ score_{j,t}\times Existence\ of\ prior\ lending\ relation_{j,t}+\sum_i \gamma_i Control\ variables_{j,t\text{-}1}+\varepsilon_{j,t}.\end{aligned}$$

(8)

Similarly, captures the effect of performance pricing schedule on discretionary accruals for banks without any prior lending relationship, measures the differential effect of slope score on discretionary accruals between banks with prior lending relation and banks without prior lending relation, and measures the effect of performance pricing schedule on discretionary accruals for banks with a prior lending relation.

Table 4 presents the OLS regression results of equation (8). As shown in Panel A, the coefficient estimate of Average slope score is positive and significant in three out of five columns. In contrast, the coefficient estimates of are insignificant in all five models. Panel B presents results regarding the effect of Local slope score of performance pricing schedule on discretionary accruals conditional on prior lending relationship. The results in Panel B are qualitatively similar as those in Panel A, except that is significant when we use Modified DD as dependent variable. These results suggest that when firms borrow from banks without any prior lending relationship, discretionary accruals increase significantly as the slope of performance pricing schedule becomes higher. In contrast, as they borrow from banks that have lent them in the past, discretionary accruals are not significantly related to the slope of performance pricing schedule. Consistent with our hypothesis H3, relationship banks monitor the borrowers more effectively, which alleviates managers' incentive and ability to manipulate earnings.

4.5. Endogeneity Issue

Our results above are consistent with our hypotheses H2 and H3 that relationship banks and high reputation banks monitor the borrowers more effectively, which alleviates managers' incentive and ability to manipulate earnings. It is noteworthy that banks are not randomly assigned to firms. It is possible that banks with good monitoring mechanism only lend money to firms which are less likely to manipulate earnings. For example, Dinc (2000) suggests that banks offer relationship lending only to borrowers of the highest credit quality. To address the selection issue between borrowers and banks, we employ a two-stage instrumental variable approach. In the first stage, we regress the existence of prior lending relation / high bank reputation dummy on borrower characteristics, including firm size, ROA, asset tangibility, and a rating dummy variable for whether the firm has access to the public debt market:

$$\begin{aligned}&(High\ bank\ reputation\ dummy\ or\ Existence\ of\ \ prior\ lending\ relation\ dummy)_t\\&= \lambda_0 + \lambda_1 FirmSize_{t-1} + \lambda_2 ROA_{t-1} + \lambda_3 AssetTangibility_{t-1}\\&+ \lambda_3 RatingDummy_{t-1} + \varepsilon_t .\end{aligned} \tag{9}$$

The choice of these instruments is based on Bharath et al. (2007), who show that borrowers' size, credit rating, and tangibility of assets are significantly related to a firm's use of a relationship bank for future loans. In the second stage, we estimate the following model in which the predicted value of bank reputation or prior lending relation from the first stage is used to explain whether banks' monitoring mechanism would mitigate the effect of performance pricing schedule on earnings management:

$$\begin{aligned}&Discretionary\ Accruals_{j,t}\\&= \alpha_1 + \beta_1 Predicted\ value\ of\ bank\ monitoring_{j,t} + \beta_2 Slope\ score_{j,t}\\&+ \beta_3 Slope\ score_{j,t} \times Predicted\ value\ of\ bank\ monitoring_{j,t}\\&+ \sum_i \gamma_i Control\ variables_{j,t-1} + \varepsilon_{j,t} .\end{aligned} \tag{10}$$

Table 5 and 6 report the results of the second stage regressions of equation (10). As shown in Panel A of Table 5 and Table 6, the coefficient estimate of Average slope score is positive and significant in three out of five columns. The coefficient estimate of interaction term is negatively and significant in three out of five models, suggesting a mitigating effect of bank monitoring on managers' incentive to manipulate earnings resulted from the performance pricing schedule. For the effect of local slope as shown in Panel B of Table 5 and Table 6, the coefficient estimate of Local slope score is mostly positive and significant and the coefficient estimate of interaction term is significantly negative. Those results are consistent with our findings in Table 3 and Table 4, supporting our hypotheses that stronger bank monitoring via higher bank reputation or prior lending relation alleviates managers' incentive and ability to manipulate earnings. Our results appear robust after controlling for the endogeneity issue.

5. Conclusion

Positive Accounting Theory (Watts and Zimmerman, 1986, 1990) suggests that managers have the incentive to change accounting method or make financial reporting decisions to reduce the likelihood of violating accounting-based covenants in debt contracts. Compared to debt covenants, the performance pricing provision provides a more continuous and direct link between accounting information and interest costs. In this study, we examine whether performance pricing loans encourage managers to manipulate earnings more aggressively. We find that firms with steeper slopes in their performance pricing loans have significantly higher discretionary accruals. We further investigate whether high lender reputation and relationship lending will curtail firms' extent of earnings management associated with performance pricing loans. We find that in firms borrowing from high reputation banks or from banks with prior lending relationship, discretionary accruals are not related to the slope of performance pricing schedule. In contrast, discretionary accruals is significantly and positively related the slope of performance pricing loans for firms borrowing from low reputation banks or from banks without any prior lending relationship. These results suggest that bank reputation and prior lending relation serve as an effective monitoring mechanism, which in turn mitigates managers' incentive and ability to manage earnings.

Compared with previous research on performance pricing loans, we directly examine the effect of performance pricing provision on earnings management, and investigate the role of high bank reputation and prior lending relationship on this effect. One interesting venue for future research is to investigate whether and how firms manage earnings when their performance measure is close to the performance threshold in the pricing schedule.

Appendix A: An Example of the Performance Pricing Schedule

Below is an example of the performance pricing schedule of a loan contract from Chemed Corp. in which interest rate is tied to debt-to-EBITDA ratio. This loan was issued on February 24, 2004, with an amount $35 million. The initial interest rate is LIBOR+350 basis points. The pricing schedule specifies how the interest rate on the loan will change with respect to the firm's debt-to-EBITDA ratio.

	Debt-to-EBITDA	**LIBOR Margin**	**Slope**
LEVEL I	Less or equal to 2.5	225 Basis Points	
LEVEL II	Between 2.5 and 3	275 Basis Points	(275-225)/(3-2.5)=100
LEVEL III	Between 3 and 3.5	300 Basis Points	(300-275)/(3.5-3)=50
LEVEL IV	Between 3.5 and 4	325 Basis Points	(325-300)/(4-3.5)=50
LEVEL V	**Between 4 and 4.75**	**350 Basis Points**	**(350-325)/(4.75-4)=33.3**
LEVEL VI	Between 4.75 and 5	375 Basis Points	(375-350)/(5-4.75)=100
LEVEL VII	Larger than 5	400 Basis Points	

$$Average\ slope = \frac{100+50+50+33.33+100}{5} = 66.7,$$

$$Local\ slope = 0.5\left(\frac{375-350}{5-4.75} + \frac{350-325}{4.75-4}\right).$$

Appendix B: Variable Definitions

Variable	Definition
Discretionary Accruals	
Modified Jones (1991)	We first regress following model: $\frac{Total\ accruals_{j,t}}{Assets_{j,t-1}} = \varphi_0 \frac{1}{Assets_{j,t-1}} + \varphi_1 \frac{\Delta Sales_{j,t}}{Assets_{j,t-1}} + \varphi_2 \frac{PPE_{j,t}}{Assets_{j,t-1}}$, where total accruals = income before extraordinary items (EBEXTRA) – operating cash flows (OCF). Regression is estimated using all Compustat firms in each two-digit SIC industry for each year. Residuals from the above regressions are the discretionary components of total accruals. The discretionary components are multiplied by firm's lagged assets to obtain the dollar value of discretionary accruals, which are used in our analysis.
Modified KLW (2005)	Based on modified Kothari, Leon, Wasley (KLW) model. We first calculate asset-scaled discretionary accruals for each firm based on Jones (1991), in which ROA is included as an additional regressor. Then we compute the discretionary accruals of a firm matched based on ROA, industry and year. The difference between these two discretionary accruals is our discretionary accrual measure 'Modified KLW (2005)'.
TWW (1998)	Based on Teoh, Welch, and Wong (1998) model, where total accruals = net income – operating cash flows.
BS (2006)	Based on Ball and Shivakumar (2006) model. This method includes variables that capture the asymmetric timely loss recognition of firms, including cash flow from operation (CF), a dummy variable (DCF) that equals one if cash flow from operation implies a loss and an interaction term DCF*CF in the model.
Modified DD (2002)	Based on Dechow and Dichev (2002) model. We augment the Dechow and Dichev (2002) model with variables from Jones (1991): $CA_{j,t}=c+\varphi_1 CFO_{j,t-1}+ \quad \varphi_2 CFO_{j,t}+\varphi_3 CFO_{j,t+1}++$

	$\varphi_4 \Delta Sales_{j,t}$++ $\varphi_5 PPE_{j,t}$ $+\upsilon_{j,t}$, where $CA_{j,t}$ is total current accrues and $CFO_{j,t}$ is cash flow from operation.

Borrower Characteristics

Retained earnings	Data item 'RE' from Compustat
Firmsize	Natural logarithm of book value of total assets
Leverage	Total debt divided by total assets
Market-to-book	The sum of market value of equity and book value debt divided by book value of total assets
ROA	Net income divided by total assets
Rating dummy	A dummy variable that equals one if any type of S&P debt rating of a firm is available in Compustat.
Tangibility	Net PP&E divided by total assets.

Lender Characteristics

High bank reputation dummy	A dummy variable taking a value of one if a lead bank's market share in lending in the previous five years is above the sample median, and zero otherwise
Existence of prior lending relationship dummy	A dummy variable taking a value of one if the lead bank of the current loan has acted as a lead bank of a loan issued by the same firm during the previous five years, and zero otherwise

Slope of the Performance Pricing Schedule

Average slope of a debt-to-EBITDA based performance pricing loan facility	Slope is computed as the interest rate change of each debt-to-EBITDA increment in the pricing schedule divided by the difference of debt-to-EBITDA ratio over the same increment. Average slope is calculated as the average of all slopes across all debt-to-EBITDA segments between the upper and lower limits of the debt-to-EBITDA ratio specified in each performance pricing loan contract.

Local slope of a debt-to-EBITDA based performance pricing loan facility	Local slope is calculated as the average of the two slopes immediately above and immediately below the firm's debt-to-EBITDA ratio at the time of loan issuance.
Average slope of a senior debt rating based performance pricing loan facility	Slope is computed as the interest rate change of each credit rating increment in the pricing schedule divided by the difference of market yields of corporate bonds over the same rating increments during the same time period, i.e., $\frac{Spread(i-1)-Spread(i)}{MarketSpread(i-1)-MarketSpread(i)}$, where *Spread(i)* is a firm's loan spread above the LIBOR at rating *i*, *MarketSpread(i)* is the average yield spread above the LIBOR for corporate bonds with rating *i,* and rating *i* is a credit rating listed in the pricing schedule. Average slope is calculated as the average of all slopes across all rating segments between the upper and lower limits of the credit ratings specified in each performance pricing loan contract.
Local slope of a senior debt rating based performance pricing loan facility	$0.5\{\frac{Spread(i-1)-Spread(i)}{MarketSpread(i-1)-MarketSpread(i)} + \frac{Spread(i)-Spread(i+1)}{MarketSpread(i)-MarketSpread(i+1)}\}$, *Spread(i)* is a firm's loan spread above the LIBOR at rating *i*, *MarketSpread(i)* is the average yield spread above the LIBOR for corporate bonds with rating *i,* rating *i* is the borrower's credit quality at the time of loan issuance, and rating *i-1* and rating *i+1* are the borrower's credit ratings one notch below and one notch above its rating at the time of loan issuance, respectively.
Average (Local) slope score of a firm in a given year	We aggregate the slopes of all bank loans outstanding for a particular borrower in a given year. First, every year we assign rank scores to the average (local) slope of each type of debt-to-EBITDA based or senior debt rating performance pricing loans into quartiles, with the top 25% taking a value of 4 and the bottom 25% taking a value of 1. In this step we do not include non-performance pricing loans since more than 50% of our sample loans are not performance priced. Instead we assign a rank score of zero for non-performance pricing loans. Second, we compute firm level aggregated average (local) slope of all performance pricing loans in a particular year as the weighted average rank scores of all the outstanding loans with the weight equal to the facility

	amount divided by the total outstanding facility amount of the firm in that year, i.e., $\text{Aggregated slope}_j = \frac{\sum_i AMT_i * \text{Slope rank score}_i}{\sum_i AMT_i}$, where AMT_i is the outstanding amount of facility i, $\text{Slope rank score}_i$ is the slope rank score of a performance pricing facility i, $\sum_i AMT_i$ is the total amounts of all outstanding facilities of firm j.

Table 1: Sample statistics

This table reports summary statistics of our sample. The sample includes 22,120 firm year observations of 4,070 firms during 1993 - 2007. We require the observations to have non-missing values in relevant firm characteristic variables listed in the table. Borrower characteristics and discretionary accruals are computed using the *Compustat* database. Slope variables of the performance pricing schedule and lender characteristics are constructed using the Dealscan database. We focus on debt-to-EBITDA based and senior debt rating based performance pricing loans to quantify the slope of the performance pricing schedule of each loan facility, since these two types account for more than 77% of all performance pricing loans. Variable constructions are detailed in Appendix B.

Table 2: Effect of the slope of performance pricing schedule on discretionary accruals

These tables report regression results examining the effect of performance pricing schedule on discretionary accruals. We use five different accrual measures. 'Modified Jones (1991)' is based on the modified Jones (1991) model; 'Modified KLW (2005)' is based on the modified Kothari, Leon, Wasley (KLW) model; 'TWW (1998)' is based on the Teoh, Welch, and Wong (1998) model; 'BS (2006)' is based on the Ball and Shivakumar (2006) model; 'Modified DD (2002)' is based on the Dechow and Dichev (2002) model. We examine the effect of average slope in Panel A and the effect of local slope in Panel B. All variables are as defined in Appendix B. P-values are reported in parentheses below each coefficient estimate. ***, **, and * indicate significance at the 1%, 5%, and 10% level, respectively.

Table 3: Bank reputation, performance pricing schedule, and discretionary accruals

These tables report regression results examining how bank reputation affects the relationship between the performance pricing schedule and discretionary accruals. We use five different accrual measures. ‘Modified Jones (1991)’ is based on the modified Jones (1991) model; ‘Modified KLW (2005)’ is based on the modified Kothari, Leon, Wasley (KLW) model; ‘TWW (1998)’ is based on the Teoh, Welch, and Wong (1998) model; ‘BS (2006)’ is based on the Ball and Shivakumar (2006) model; ‘Modified DD (2002)’ is based on the Dechow and Dichev (2002) model. High bank reputation dummy is equal to one if the lead bank's lending market share is above the sample median, and zero otherwise. We examine the effect of average slope in Panel A and the effect of local slope in Panel B. All other variables are as defined in Appendix B. P-values are reported in parentheses below each coefficient estimate. ***, **, and * indicate significance at the 1%, 5%, and 10% level, respectively.

Table 4: Prior lending relationship, performance pricing schedule, and discretionary accruals

These tables report regression results examining how prior lending relationship affects the relation between the performance pricing schedule and discretionary accruals. We use five different accrual measures. 'Modified Jones (1991)' is based on the modified Jones (1991) model; 'Modified KLW (2005)' is based on the modified Kothari, Leon, Wasley (KLW) model; 'TWW (1998)' is based on the Teoh, Welch, and Wong (1998) model; 'BS (2006)' is based on the Ball and Shivakumar (2006) model; 'Modified DD (2002)' is based on the Dechow and Dichev (2002) model. *Existence of prior lending relation* is a dummy that equals one if the lead bank of the current loan has acted as a lead bank of a loan issued by the same firm during the previous five years, and zero otherwise. We examine the effect of average slope in Panel A and the effect of local slope in Panel B. All other variables are as defined in Appendix B. P-values are reported in parentheses below each coefficient estimate. ***, **, and * indicate significance at the 1%, 5%, and 10% level, respectively.

Table 5: Bank reputation, performance pricing schedule, and discretionary accruals: A two-stage instrumental variable approach

In the first stage, we regress the *high bank reputation dummy* on borrower characteristics, including firm size, ROA, asset tangibility, and a rating dummy variable for whether the firm has access to the public debt market. In the second stage, the *predicted vale of bank reputation* from the first stage is used to explain how it affects the relation between the performance pricing schedule and discretionary accruals. We examine the effect of average slope in Panel A and the effect of local slope in Panel B. All other variables are as defined in Appendix B. P-values are reported in parentheses below each coefficient estimate. ***, **, and * indicate significance at the 1%, 5%, and 10% level, respectively.

This study mainly explores price discounts of Chinese public listed companies which have issued ADRs (overseas shares in the U.S. market), H-shares (shares traded in the Hong Kong market) and A-shares (shares traded in the China market). We use time-varied panel data models to investigate the effect of different market share prices are affected by the long-term centrally planned economy and financial policies of the Chinese government, and not like other countries, share prices are much influenced by share liquidity, investors sentiment and other factors.

Keywords: ADRs; H-shares; A-shares; Cross-listing; Financial crisis; China's Five-Year Plan; financial policies; China.

JEL classification: C12; C33; F23; F31; F51; G01; G18.

I. Introduction

This study focuses on the Chinese market rather than developed markets as we observe that the Chinese market has some unique and promising characteristics. Specifically, China is a fast growing economic with high economic growth rate 30 years in a row (average 10%). China has become the largest economy country in the world by nominal GDP in 2015. The China's capital market grow fast and the total equity market value of the Shanghai stock exchange (SHSE) reached USD 2,479 billion in 2013. The total market value, turnover of equity market, and overall capital raised rank No. 7, No.5 and No.6 respectively in the world. It was the leading FDI recipients, receiving almost USD 34.8 billion in 2013[1]. How the Chinese government attracts international funds and international know-how to accomplish its high economy growth is an important issue, and we would investigate the Chinese equity market behavior and Chinese companies' overseas listings.

Special attention should be given to that China is a planned economy country, without considering that, studies would have misinterpreted the valuation of share prices of Chinese companies in different markets. A planned economy is an economic system that all major decisions are under the control of the government and that

[1] The economic growth rate, nominal GDP, forecasting nominal GDP, exporting amounts, and importing amounts of China are according to the International Monetary Fund (IMF). The total market value, turnover of equity market, and overall capital raised ranking data are according to Fact Book of the SHSE. The FDI data is according to World Bank statistics.

securities prices are not mainly decided by the market. Therefore, the decision made by Chinese companies are different from companies of other countries which always list their company on their home market first, and then turn to foreign markets. The Chinese government plays a dominate role in choosing selective companies to be listed on markets. For example, when Chinese government wants to attract international capital, Chinese companies are listed in the Hong Kong market first, and later, for showcasing Chinese companies on the international stage and introduce international capital, some profitable and stable Chinese companies are chosen by the Chinese government, to use H-shares as underlying shares to list ADRs[2]. Chinese government want further Chinese companies to learn from international experience and to solidify the A-shares market, so most Chinese companies go back to list in the home market after listing in the foreign markets (see. *e.g.*, Malkiel *et al.*, 2008)[3].

Accordingly, Chinese companies can issue A-shares, B-shares, H-shares, and ADRs simultaneously. According to the law of one price, under no investment barriers of market, security price in the cross-listed stock markets should equal to each other if evaluated under the same currency. In other words, there is a parity between each shares. In recent years, there are a number of researches documenting that, when the

---

[2] H-shares represent those shares which are registered in China and traded in Hong Kong stock exchange (HKSE).ADR is one kind of negotiable security that represents securities of non-US companies traded in the U.S. financial market. It provides the unique investment channel for Americans to invest in foreign companies.

[3] A Chinese company could issue A-shares or B-shares on the SHSE. A-shares are only available to Chinese investors, whereas B-shares are only accessible to foreign investors.

same or equivalent securities are traded in multiple markets, the law of one price is often violated with global data (see. *e.g.*, Rosenthal and Young, 1990; Froot and Dabora, 1999; Kim *et al.*, 2000; Chan *et al.*, 2003; Eun and Sabhereal, 2003; Chan *et al.*, 2008; Foucault and Gehrig, 2008; Moulton and Wei, 2009; Gagnon and Karolyi, 2010; Kehrle and Peter, 2013). Security price in the cross-listed stock markets might also not equal in the Chinese market by two reason. First, to protect fledging China's securities market, China controls its capital inflows, capital outflows, exchange rate, and foreign currency exchange. Chinese residents and institutions cannot freely exchange Renminbi (RMB) to foreign currencies. Chinese investors (mostly individuals) can only trade A-shares in RMB and foreign investors (mostly institutions) can only trade B-shares, H-shares and ADRs in foreign currency[4]. Second, there are fundamental difference of investment considerations between Chinese investors and foreign investors; for example, different tax regimes, different stock liquidity, and different market sentiment. leads to different stock prices in different markets. Several researches have shed some lights on the subject of price deviations of the Chinese companies in different markets in recent years. (see. *e.g.*, Sun and Tong, 2000; Wang and Jiang, 2004; Chiang *et al.*, 2008; Gul *et al.*, 2010; Cai.

[4] ADR are traded in U.S. dollars on the United Stated stock exchanges, and H-shares are traded in HK dollars on the HKSE.

et al., 2011; Eichler, 2011; Chung *et al.,* 2013)[5].

This study does not only discuss whether Chinese companies have different prices in different markets; we do several extended investigations and have some findings which are different from previous literatures. First, we extend Arquette *et al.* (2008) which examine price deviations between ADRs and A-shares and price deviations between ADRs and H-shares, for all underlying stocks of cross-listed level 2 and level 3 ADRs are H-shares, with no ADR can be converted to A-share (home market shares). It is due to A-shares and ADRs cannot transfer into each other[6]. It can explain why there are a big price deviation between A-shares and ADRs. And because H-shares and ADRs can transfer into each other, the price of H-share and the price of ADR should get close to each other by the law of one price. Second, China is a planned economy country. A planned economy is policy-oriented and share prices and transactions are under the direct influence of the government's policies. Long-term planning and government policies are important factors when we research on the China's securities market. Chinese Five-Year Plan is an important guidance of economic growth and helps establish principles and direction to the China's securities

[5] Wang and Jiang (2004) examined a group of stocks cross-listed as A-shares and H-shares. They found that the price discount of H-shares relative to A-shares is highly correlated with the domestic and foreign stock market indices, the relative market illiquidity and the expected devaluation of the Chinese currency. Chung *et al.* (2013) showed that price deviations between A-shares and H-shares are inevitable as long as the presence of information asymmetry and limited arbitrage, which leads to investors have different assessments of the stock value and involved risk.

[6] Due to restrictive capital flow policy, Chinese investors (mostly individuals) can only trade A-shares and foreign investors (mostly institutions) can only trade H-shares and ADRs.

market. The timetable of the deregulation of the China's securities market can be separated into three periods: limitation period (the early limitation period after security market was established), the period of the progressive openness of investment limitation, and the period of encouraging Chinese companies to list in the home market. In the early limitation period (the eighth and ninth Five-Year Plan), the protection of the Chinese government to the fledgling China's securities market and the overexcited sentiment of Chinese investors have contributed to the much higher prices of A-shares to prices of H-shares and ADRs of the same Chinese company. In the period of the progressive openness of investment limitation (the tenth Five-Year Plan), the Chinese government gradually deregulate the China's securities market, and we could find that prices of A-shares, H-shares and ADRs of the Chinese companies gradually get closed to each other in different markets. In the period of encouraging Chinese companies to list in the home market (the eleventh and twelfth Five-Year Plan), there were more listed companies in the China's securities market, and deviations between prices of Chinese companies in different markets are fluctuated again. Third, previous studies focus on the relationship between pricing factors (liquidity, dividend taxes, *etc.*) and share prices in different markets, but without considering plans and regulations of China's government, the studies would have misinterpreted the impact estimation of share prices of Chinese companies in different markets. We collect important government policies through annual Fact Books from the SHSE and Chinese government's news releases published between 1991 and 2012, and factor the collective information into our research. And find that those policies are important factors to prices of the Chinese companies. Forth, China is experiencing the transition from a planned economy to a market economy today. Market economy is described which prices and transactions are determined by consumers and producers. This research further discusses on the progressive openness of the Chinese market, we investigate the impact of openness of the capital inflow and outflow, and the reform of the currency exchange rate on the China's securities market. Our research also indicates that prices of Chinese companies in different markets get close to their implied values with the effect of progressive openness of the Chinese market. Fifth, China's hybrid economy features a mixture of government-owned and privately owned enterprises. Most Chinese companies have significant government ownership, but also trade in the open market. We include the proportion of state-owned shares (relative to outstanding shares) in our research, and we predict the share prices of companies which have higher government ownership would be higher for more price support by the government, and higher confidence from Chinese investors. Sixth, for we can comprehensively interpret different prices of Chinese companies in different markets, our research also considers financial crises. We discover that price deviations are enlarged during financial crisis period for the Chinese government would protect the Chinese securities; for example, the limitation of the range of currency exchange rate volatility, price limit, *etc*.

The rest of the paper proceeds as follows. Section II introduces the data; Section III presents discounts and discusses the empirical results of discounts. Section IV investigates the effects of government ownership, government policies, China's Five-Year Plans, and financial crises on discounts. Finally, Section V summarizes the main conclusions.

II. **Data description**

A Chinese company could issue its stock in China, Hong Kong, and the United Stated markets at the same time by issuing A-shares and/or, B-shares, H-shares, and ADRs respectively[7]. The research only focuses on A-shares, H-shares, and ADRs[8].

[7] Our research involves three main stock exchange markets: New York, Hong Kong, and Shanghai. NYSE is by far the world's largest stock exchange by market capitalization of its listed companies, and one of the oldest developed markets. HKSE is one of the oldest liberal emerging stock markets in Asia. The SHSE is the first stock market in China. It is among the youngest emerging stock markets with ownership restrictions imposed by government. Because of these special market characteristics, we can see different performance of the underlying shares in different markets.

We exclude B-shares in this study for that the Chinese government is currently considering to terminate the B-shares trading[9]. We find that all underlying stocks of cross-listed level 2 and level 3 ADRs are H-shares, with no ADR can be converted to A-share[10].

In our analysis, we use daily firm stock data from Datastream to examine the dynamic behavior of price deviations at firm level. We also use SEC documents (20-F and 424A-B[11]) to get the ADR conversion ratio and other information related to our research, including: taxes, underlying stock companies.

III. Definition, investigation, and the cross-sectional panel data analysis of discounts

In this section, we definite and investigate ADR-A discount, H-A discount and

---

[8] Our samples are constructed from the initial list of 292 ADRs (based on the databases of the Bank of New York, Datastream, and corrected by SEC documents), 176 H-shares (151 in the Main-Board Market (Main Board) and 25 in the Growth Enterprises Market (GEM)) and 2468 A-shares (943 in the SHSE and 1525 in the Shenzen stock exchange (SZSE)) which are listed by Chinese companies between December 1990 and December 2012. It is because of that China reopen it stock markets in the early 1990s. The current SHSE is re-established on Nov. 26, 1990 and is in operation on Dec. 19 of the same year. From this list, we exclude 170 144A and Level 1 firms for the liquidity of 144A and LEVEL 1 ADRs are too low, it would affect the outcome of the research. And 122 ADRs remain (53 in the NASDAQ Stock Market (NASDAQ) and 69 in the NYSE). We exclude 108 ADRs (include all ADR in the NASDAQ), 84 H-shares (include all H-shares in the GEM) and 2406 A-shares (include all A-shares in the SZSE) for they are not cross-listed. We further exclude one firm that has extremely high price discount. For shares in NASDAQ, GEM, and SZSE are excluded, we find that Chinese companies list in NASDAQ, GEM, and SZSE all list in the single market, that is, most Chinese small- and medium-sized enterprises and Chinese growth companies are listed in the single market. The common factor of NASDAQ, GEM, and SZSE is that they establish the Small- and Medium-sized Enterprise Board to facilitate the growth of start-up companies. Chinese companies list in NASDAQ, GEM, and SZSE all list in single market.

[9] The investment restriction of A-shares to foreign investors was deregulated in December 2002 which significantly diminished the importance of B-shares market.

[10] The example could see in the appendix 2.

[11] 424 is preliminary prospectus filed or pricing supplement filed. 20-F is an integrated form used both as a registration statement for purposes of registering securities of qualified foreign private issuers or as an annual report.

ADR-H discount, respectively. And we employ a general cross-sectional panel regression model which refers Arquette *et al.* (2008) to explain the variations in ADR-A discount, H-A discount and ADR-H discount[12].

III.1 ADR-A, H-A, and ADR-H discounts

We refer Arquette *et al.* (2008) to formulate ADR-A discount and H-A discount. According to the law of one price in a perfect market, the implied ADR price that it is the fundamental price in the home market (the Chinese market) after translated by a conversion ratio and translated into US dollar in comparison with other studies, and to examine evidences in the Chinese market. The difference between the ADR price and the implied ADR price (from the home market) is a premium or discount, which is denoted as $ER_{i,t}^{ADR-A}$. We define that there is a ADR-A discount when $ER_{i,t}^{ADR-A}<0$, and there is a ADR-A premium when $ER_{i,t}^{ADR-A}>0$. The ADR-A discount means that the ADR market price prevailing in the US market is lower than its implied value calculated by the fundamental price in the home market.

The implied ADR price which is transferred by the price of stock in the home market and the ADR-A discount (or premium) are expressed as equations (1) and (2), where *i*, *t* denotes the *i*-th sample company in the period *t*. The definitions are as

---

[12] Arquette *et al.* (2008) examine the differential between the share prices of Chinese securities traded on their home market of Shanghai versus prices observed offshore in New York and Hong Kong to make basic model.

follows:

$$IP_{i,t}^{ADR(A)} = (P_{i,t}^{A-share} \times FX_{i,t}^{\$/RMB}) \times Ratio_i, \quad (1)$$

$$ER_{i,t}^{ADR-A} = (P_{i,t}^{ADR} - IP_{i,t}^{ADR(A)}) / IP_{i,t}^{ADR(A)}, \quad (2)$$

where $IP_{i,t}^{ADR(A)}$ is the implied ADR price for firm i on day t. $P_{i,t}^{A-share}$ is the A-share price in RMB for firm i on day t. $FX_{i,t}^{\$/RMB}$ is the exchange rate between US dollars and RMB (US dollars to RMB) for firm i on day t. $Ratio_i$ is the ADR conversion ratio for firm i. $P_{i,t}^{ADR}$ is the ADR price in dollars firm i on day t. $ER_{i,t}^{ADR-A}$ is the ADR-A discount (premium) for firm i on day t. Similarly, we define that the H-A discount to reflect the differences in the actual and the implied prices of securities cross-listed in Hong Kong and China.

Based on what we found, all underlying stocks of cross-listed level 2 and level 3 ADRs are H-shares, with all 13 ADRs can be converted to H-shares by 424B and 20-F SEC documents[13]. We extend Arquette et al. (2008) to explain the variations in the ADR-H discount[14].

To have a better understanding on the three discounts, we construct market-value

---

[13] With no ADR can be converted to A-share.

[14] According to the law of one price in a perfect market, the implied ADR price is the fundamental price in the underlying stock market (the Hong Kong market) after translated by a conversion ratio and translated into US dollar, and the ADR price is the market price prevailing in the US market.

weight average portfolios of ADR-A discount, H-A discount, and ADR-H discount, shown in Figure 1. By eyeballing the figures, we find that both ADR-A discount and H-A discount tend to move close to zero as time advanced prior to 2007. This result is similar to the studies of Arquette *et al.* (2008) and Eichler (2011), and it is also consistent with the market integration hypothesis and the relaxation of the investment restrictions. We find that ADR-H discounts fluctuate around zero for all 13 ADRs which can be converted to H-shares[15]. During the financial crises, we can find both ADR-A discount and H-A discount became profound and ADR-H discount had higher volatility than ordinary time. After 2009, we can find that both ADR and H-share prices move close to their implied values in home market shares again. This result shows the elimination of market segmentation, and the effect of the financial crisis. We will examine those phenomena in the next section

[Please insert Figure 1 about here]

Further analysis is given to the dynamic relation between the ADRs, H-shares and A-shares, we refer Chiang *et al.* (2007) to apply a bivariate VAR(2)-GARCH(1,1)- DCC model to study the variances of ADR-A, H-A, and ADR-H

[15] The volatility of ADR-H discounts in the end of 1997 comes from the new ADR listing.

discounts, and also their correlations among A-shares, H-shares, and ADRs. We report the results of time-varying dynamic correlations in the empirical results in Figure 2 and Figure 3.

[Please insert Figure 2 about here]

[Please insert Figure 3 about here]

In figure 2, there are higher variances during financial crisis period than normal time, especially the average variance of the ADR-H discount is 2.44 during normal time, which is enlarged to 10.5 during financial crises[16]. The average variance of the ADR-A discount is 2.42 during normal time, and is enlarged to 4.2 during financial crises; the average variance of the H-A discount is 1.77 during normal time, and is enlarged to 3.04 during financial crises. We would examine ADR-A, H-A, and ADR-H discounts under the period of financial crises and discuss variances of discounts during financial crises in the later chapter.

In figure 3, the correlation between ADR and H-shares are mostly from 0.6 to 0.8. The correlation between H-shares and A-shares obviously increases from 0.29 to 0.72 after restrictions on Chinese investors' buying H-shares are liberated[17]. We split the

[16] We take off data in the end of 1997 for large volatility of ADR-H discounts by new ADR listing.

[17] Chiang *et al.* (2007) find that the correlation between A-share and B-share markets has increased

cross-section panel model by the time point of the investment's restriction relaxation and the currency exchange rate reform and further estimate the impact of China's policy change from the planned economy to free market economy.

III.2 Empirical model: a cross-sectional panel model of discounts

To examine the phenomena in Figure 1, we refer Arquette *et al.* (2008) to employ time-varied panel data models and study ADR-A discount, H-A discount, and further extend to ADR-H discount of the companies at each specific time. Furthermore, we study the correlations among the three mentioned discounts, the change of expected exchange rate, dividend taxes, illiquidity, and sentiment, and the models are as follows:

$$ER_{i,t}^{ADR-A} = \alpha + \beta_1 \Delta S_t^{\$/RMB} + \beta_2 DIV_{i,t} + \beta_3 DILLIQ_{i,t}^{ADR-A} + \beta_4 DSENT_t^{S\&P/SSECI} + \beta_5 SENT_{i,t} + \nu_{i,t}, \quad (5)$$

$$ER_{i,t}^{H-A} = \alpha + \beta_1 \Delta S_t^{HKD/RMB} + \beta_2 DIV_{i,t} + \beta_3 DILLIQ_{i,t}^{H-A} + \beta_4 DSENT_{i,t}^{HSI/SSECI} + \beta_5 SENT_{i,t} + \gamma_{i,t}, \quad (6)$$

$$ER_{i,t}^{ADR-H} = \alpha + \beta_1 \Delta E_t^{\$/HKD} + \beta_2 DIV_{i,t} + \beta_3 DILLIQ_{i,t}^{ADR} + \beta_4 DSENT_t^{S\&P/HSI} + \beta_5 SENT_{i,t}^{Com} + \varepsilon_{i,t}, \quad (7)$$

where $ER_{i,t}^{ADR-A}$, $ER_{i,t}^{H-A}$, and $ER_{i,t}^{ADR-H}$ are the ADR-A discount (premium), H-A discount (premium), and ADR-H discount (premium) for firm *i* on day *t*. $\Delta S_t^{\$/RMB}$,

---

since the relaxation of the restriction on B-share market investments by domestic investors.

$\Delta S_t^{HKD/RMB}$, are the change of expected exchange rate (US dollars to RMB, HK dollars to RMB and US dollars to HKD) on day *t*. $DIV_{i,t}$ is the dividend yield for firm *i* on day *t*. $DILLIQ_{i,t}^{ADR-A}$, $DILLIQ_{i,t}^{H-A}$, and $DILLIQ_{i,t}^{ADR-H}$ are relative illiquidity for firm *i* on day *t*. $DSENT_t^{S\&P-SSECI}$, $DSENT_t^{HSI-SSECI}$, and $DSENT_t^{S\&P-HSI}$ is the relative market sentiment on day *t*. $SENT_{i,t}$ is the company sentiment for firm *i* on day *t*.

The first major factor contributes to discounts is the change of the expected exchange rate. According to relative purchasing power parity (RPPP), higher inflation of China promotes the expectation of RMB appreciation which leads to a higher ADR discount (see. *e.g.*, Wheatley, 1988; Sarno and Valente, 2006; Eichler *et al.*, 2009). Eichler (2011) summarized several expected exchange rate theories, and applied Chinese cross-listed stocks to reconfirm those theories. The empirical results support that RMB depreciation would induce the increase of ADR discount[18]. The change of expected exchange rate is proxied by the 3-month forward premium [19]. Furthermore, tax structures in the cross-list market also play an important role in discounts.[20] Due to foreign investors cannot invest in the Chinese market before 2007, the tax structure would not affect the decisions of investors. After 2008, the dividend tax in A-share,

[18] For example, according to Harrod-Balassa-Samuelson effect, countries with a higher productivity growth will have a relative currency appreciation (Chinn, 2006); Follow uncovered interest rate parity states that the returns on risk-less assets are equal when adjust for exchange rate (Eichler *et al.*, 2009).
[19] We also use S_{t+1}-S_t, AR model -time series data for robustness.
[20] Arquette *et al.* (2008) showed that high dividend stocks tend to have ADR premium since tax rate in the United Stated market was lower than the Chinese market. (In a market that has higher tax rate, higher dividend paying stocks would be expected to sell at a discount for the reason of avoiding dividend tax.)

H-share and ADR are at about 10%, the tax structure still do not affect the decisions of investors[21]. Our research result might be more closer to dividend clientele effect that investors will invest by their preference for dividends; for example, investors think that getting cash earlier can reduce the investment risk (see. *e.g.*, Bekart *et al.*, 2007). Illiquidity is also a major factor to explain the discounts, which implies that the observed foreign share discounts are due to their lower liquidity[22]. The illiquidity proxy, according to Amihud (2002), is the daily ratio of absolute stock return to its dollar volume averaged over some period. These measures not only extend liquidity ratio, but also follow Kyle's (1985) concept of illiquidity[23] and Silber's (1975) measure of thinness[24]. These measures don't require a lot of microstructure data and could cover long periods of time. In our analysis, we use *ILLIQ* measure as the illiquidity proxy. It can consider the illiquidity effect of volume and price at the same time:

---

[21] Before Jun 13, 2005, dividend income of A-share was part of the individual income and was taxed at about 20% rate. After Jun 13, 2005, the dividend tax was halved to 10%. Individual U.S. investors face dividend tax rate at about 30% in the United States of America but that ADR and H-share dividend taxes are based on Chinese withholding taxes and applicable tax treaties. A Chinese withholding tax levied at a flat rate of 20%, but it can be reduced by an applicable tax treaty. After Aug. 13, 2006, the deduction of the applicable tax treaty of H-shares decreased 10%-15%, and the dividend tax was at about 5%-10%. After Mar. 1, 2008, the deduction of the applicable tax treaty of ADRs decreased 10%, and the dividend tax is at about 10%.

[22]. For example, Chan *et al.* (2008) used the Amihud (2002) illiquidity measure to test the relationship between ADR premium and liquidity. They showed that a higher ADR premium is associated with a higher ADR liquidity and lower home share liquidity. (see. *e.g.*, Alexander *et al.*, 1988[22]; Ma, 1996; Domowitz *et al.*, 1998; Foerster *et al.*, 1999; Kadiyala and Subrahmanyam, 2004; Wang and Jiang, 2004; Chan *et al.*, 2008; Silva and Chavez, 2008; He and Yang, 2011; He and Yang, 2012)

[23] Kyle (1985) proposed that because market makers cannot distinguish between orders flows that are generated by informed traders and by liquidity (noise) traders, they set prices that are an increasing function of the imbalance in the order flows which may indicate informed trading.

[24] It is defined as the ratio of absolute price change to absolute excess demand for trading.

$$DILLIQ_{i,t}^{ADR-A} = \ln\left(1/D_{i,y}\sum_{t=1}^{Diy}\left|R_{i,y,t}^{ADR}\right|/Volume_{i,y,t}^{ADR}\right) - \ln\left(1/D_{i,y}\sum_{t=1}^{Diy}\left|R_{i,y,t}^{A-share}\right|/Volume_{i,y,t}^{A-share}\right), \quad (8)$$

$$DILLIQ_{i,t}^{H-A} = \ln\left(1/D_{i,y}\sum_{t=1}^{Diy}\left|R_{i,y,t}^{H-share}\right|/Volume_{i,y,t}^{H-share}\right) - \ln\left(1/D_{i,y}\sum_{t=1}^{Diy}\left|R_{i,y,t}^{A-share}\right|/Volume_{i,y,t}^{A-share}\right), \quad (9)$$

$$DILLIQ_{i,t}^{ADR-H} = \ln\left(1/D_{i,y}\sum_{t=1}^{Diy}\left|R_{i,y,t}^{ADR}\right|/Volume_{i,y,t}^{ADR}\right) - \ln\left(1/D_{i,y}\sum_{t=1}^{Diy}\left|R_{i,y,t}^{H-share}\right|/Volume_{i,y,t}^{H-share}\right), \quad (10)$$

where $ILLIQ_{i,t}$ is illiquidity for firm i on day t. $DILLIQ_{i,t}^{ADR-A}$, $DILLIQ_{i,t}^{H-A}$, and $DILLIQ_{i,t}^{ADR-H}$, are relative illiquidity for firm i on day t. $R_{i,y,t}^{ADR}$, $R_{i,y,t}^{H-share}$ *and* $R_{i,y,t}^{A-share}$ are the return for firm i on day t of year y in the US market, the Hong Kong market and the Shanghai market. $Volume_{i,y,t}^{ADR}$, $Volume_{i,y,t}^{H-share}$ and $Volume_{i,y,t}^{A-share}$ are the daily volume for firm i on day t of year y in the US market, the Hong Kong market and the Shanghai market. This ratio gives the absolute price change per dollar of daily trading volume. $D_{i,y}$ is the number of days for which data are available for firm i in year y. That is, $DILLIQ_{i,t}^{ADR}>0$ means that the ADR is more illiquidity relative to the H-share. The last important factor for discounts is sentiment[25]. Following Arquette *et al.* (2008), we separate sentiment into market sentiment and company sentiment by

[25] Lee *et al.* (1991) are the first ones to use the word "investor sentiment". After that, a considerable number of studies have been made on investor sentiment. Garbade and Silber (1979) tested the behavior of the prices of identical assets that are traded in different markets, and concluded that home market prices and ADR prices are relevant to both the United States market and the home market. Bodurtha *et al.* (1995) called it the country-specific sentiment. Suh (2003) first used a time series analysis and found that ADR premium movements are associated with changes in investor's sentiment over time. Wang and Jiang (2004) suggested that H-shares behave more reflected to Hong Kong market sentiment than the Chinese market sentiment. Wang *et al.* (2004) found the overreaction effect is most profound in the Chinese market than in the United Stated market. Baker and Wurgler (2006) separated investors' sentiment into optimistic and pessimistic. They concluded that when market sentiment is considered at higher level, investors would require relatively lower return. (see *e.g.*, Chen *et al.*, 1993; Swaminathan, 1996; Neal and Wheatley, 1998; Kim *et al.*, 2000).

using daily P/E ratios as a proxy of sentiment. The company sentiment variable is measured by the (one period) lagged natural log of each individual company's P/E ratio relative to the nature log of market's P/E ratio. In using the one period lagged value, we avoid the contemporaneous problem.

The sentiments are defined as:

$$DSENT_t^{S\&P/SSECI} = \ln(P/E)_t^{S\&P} - \ln(P/E)_t^{SSECI}, \tag{11}$$

$$DSENT_t^{HSI/SSECI} = \ln(P/E)_t^{HKMarket} - \ln(P/E)_t^{ChineseMarket}, \tag{12}$$

$$DSENT_t^{S\&P/HSI} = \ln(P/E)_t^{S\&P} - \ln(P/E)_t^{HSI}, \tag{13}$$

$$SENT_{i,t} = \ln(P/E)_{i,t-1} - \ln(P/E)_t^{Market}, \tag{14}$$

where $DSENT_t^{S\&P-SSECI}$, $DSENT_t^{HSI-SSECI}$, and $DSENT_t^{S\&P-HSI}$, is the relative market sentiment on day t. $SENT_{i,t}$ is company sentiment for firm i on day t. $P/E_t^{S\&P}$, P/E_t^{HSI}, and P/E_t^{SSECI} are the S&P 500 P/E ratio, the HANG SENG price index P/E ratio, the Shanghai index P/E ratio for time t. $(P/E)_{i,t-1}$ is the company P/E ratio for time $t-1$. $(P/E)_t^{Market}$ is the underlying market index trading volume for time t. The expected exchange rate fluctuations which represent the volatility change of exchange rate are measured by square of the change of expected exchange rate.

[Please insert Table 1 about here]

The positive coefficients in equation (5), (6), and (7) indicate that the variables make price larger than its implied value. On the contrary, the negative coefficients indicate that the variables make price lower than its implied value[26]. Table 2 represents the results to explain the price deviation by cross-sectional panel approach at different points of time.

[Please insert Table 2 about here]

Evidence from Table 2 show that there are similar results to Arquette *et al.* (2008), almost all variables play important roles in determining both ADR-A discount and H-A discount and almost all findings are consistent with hypotheses in 1996-2006. However, some results in ADR-H discount are not consistent with hypothesis[27].

[26] According to theories and existing evidence, the following is our anticipation: According to relative purchasing power parity (RPPP), higher inflation of China promotes the expectation of RMB appreciation which leads to a higher share price than its implied value. (positive in β_1); The relationship among ADR discount, ADR-A discount, H-A discount and dividend yield depends on the preference of known investors. (β_2 is unknown); When one market has lower liquidity than other markets, investors are reluctant to invest and induce the price to be lower than the implied value (negative in β_3); The higher market sentiment represents that investors in this market are optimistic or this market is in good prospect. Investors will be willing to invest and lead to a price premium (positive in β_4). Higher company sentiment represents that the companies or industries have good performance. Investors who focus on company performance will be willing to invest and lead to a higher share price (β_5 is unknown).

[27] For example, the result should find a positive correlation between ADR-H discount and relative market sentiment, and a positive correlation between ADR-H discount and changes of the expected exchange rate.

We further expand the cross-sectional panel model to 2012, the testing results show that the capability of explanation of models decrease, and several outcomes are different from hypotheses; for example, ADR-A discount and H-A discount should be negatively related to relative illiquidity, and ADR-H discount should be positively related to relative market sentiment between 1996 to 2012. We also revise the cross-sectional panel model to examine the data from 2007 to 2012 while China's security market became more liberal after 2007[28]. The testing result also shows that the capability of explanation of models decrease, and several outcomes are different to hypothesis[29].

IV. The effects of non-pricing factors on discounts

Previous literatures on China focus on the relationship between pricing factors (liquidity, dividend taxes, *etc.*) and share prices in different markets (see. *e.g.*, Sun and Tong, 2000; Wang and Jiang, 2004). However, without considering the impact of non-pricing factors, such as government ownership, government policies, Five-Year Plans, and financial crises, there would have misinterpreted the impact estimation of

[28] There is lower investment restriction in the Chinese market after 2007 (restrictions on foreign investors' entry into the A-share, restrictions on Chinese investors' entry into the H-share market are liberated, there are lower non-tradable shares).

[29] For example, there should be a positive significant relation between ADR-A discount and changes of the expected exchange rate, so does ADR-H discount and H-A discount. The relationship between ADR-A discount and relative illiquidity should be negative. The result should find a positive and significant relationship between ADR-A discount and relative market sentiment.

share prices of Chinese companies in different markets. In order to comprehensively examine the effect of the Chinese market transferring from a planned economy market to a free economy market (gradually opening in the Chinese market), our research extends the model of Arquette *et al.* (2008) with those non-pricing factors respectively to investigate the effects on discounts.

Ⅳ.1 Empirical evidences of government ownership, government policies and financial crises on discounts

We add three key non-pricing factors, government policies, government ownership, and financial crises, into our models. The first key factor is China's government policies. China is a planned economy country and its policies relating to the financial market would affect prices of Chinese companies in the China market and in overseas markets. There are three Chinese financial policies which affect the China's securities market tremendously[30]. First, The China Securities Regulatory Commission (CSRC) announced three bailout policies in August 1994 to save the stock market decrease between 1992 to July 1994 (the first bailout policy in the China's securities market)[31]. Three bailout policies included that Chinese companies

---

[30] Those financial policies and events are mainly summarized from annual Fact Book published by the SHSE, decrees enacted by the Chinese government and news and events which are related to China's securities market from 1991 to 2012. The impact of those financial policies to the China's securities market could refer to the price index of the SHSE in appendix 2.

[31] China tightening monetary and fiscal policies in 1993 , and the Shanghai Composite Index decline from 1558 in Feb. 1993 to 325 in Jul. 1994, more than 70%.

are suspended from initial public offering in the market, CSRC controlled the financing scale of existing listing companies, and introduce foreign funds into the A-share market gradually. The price index of the SHSE soared from 325 to 1050 (increased 323%) in a month after the announcement of three bailout policies. Second, Department of State announced that whenever the state-owned enterprises had initial public offering or capital raising, 10% of the financing amount should be sold to the public. After the announcement, prices in the SHSE and SZSE plunged by about 32% in four-month time. This policy was paused temporary in October 2001, and the stock market rose 10% in a single day, and later was terminated in June 2002. Third, A-shares include tradable and non-tradable shares[32]. Measures for the Administration of Initial Public Offering and listing of stocks promulgated by CRSC became effective, which heralded the resumption of shares following the non-tradable share reform in June 2005. Shareholders in government-owned enterprises (companies in A-share) can get compensation when a non-tradable share transfers to a tradable one. For example, shareholders in China Petroleum and Chemical got the dividend compensation, RMB 0.28 per share, after the non-tradable share reform. All companies completed the reform before 2007. Prices in the SHSE skyrocketed by about 500% during the period of the non-tradable shares reform. It clearly

[32] Non-tradable shares mainly refer state-owned shares and institutional shares that do not trade on the securities market, where state-owned shares are transferred when restructured into listed shares and institutional shares are a raising capital by company's promoters at the beginning of the listing.

demonstrates that even an announcement not the actual implementation can stir the A-shares market. We assimilate those policies into our research to investigate the impact of Chinese policies to the share prices of Chinese companies.

The second factor affecting price discounts is state-owned enterprise (SOE). Total 273 companies, namely 33.58% companies of all Chinese companies, have more than 50% of shares are state-owned in the SHSE and SZSE. Among them, 70% of companies have their company's share value over RMB 400 million and more than 50% company's shares are state-owned.[33] We suppose enterprises that have more state-owned shares would be affected less by investors sentiment, the price of enterprises that have more state-owned shares would be influenced closely by the government policies and be inefficient (see e.g., Dewenter and Malatesta, 1999; Chen, 2009). We add the proportion of state-owned shares, which is comparative to outstanding shares, into our model and examine this special factor.

The third factor that would affect price discounts is financial crises. The importance of financial crises to ADR-A, H-A, ADR-H discounts has already indicated in figure 2. During crises, we assume that herding behavior causes individual investors joining the crowd in a rush to get out of the market, the behavior of ADR and H-share investors tends to be more sentiment than A-share investors due

[33] The proportion of China's state-owned shares are going down with the gradual reduction of financial planning and policy, and therefore we cite the previous year (1998) to express the importance of state-owned shares of Chinese companies in the past.

to government control such as foreign currency exchange control, price limits, and limitation of transaction numbers. Therefore, there would be large price deviation between A-shares and H-shares or ADRs. Recent research has suggested that there is a large ADR discount during the financial crisis (see *e.g.*, Mitton, 2002; Mervin, 2003). Auguste *et al*. (2006) showed that Argentine and Venezuelan ADR discounts were 55 percent during the Argentina financial crisis, it indicated that investors are willing to pay significant price differences in order to move their funds abroad and to hedge the dollar value of their assets during the Argentina financial crisis. We also add financial crises into our research.

We extend equations (5), (6) and (7) by adding the proportion of state-owned shares and dummy variables of events and financial crises:

$$\begin{aligned} ER_{i,t}^{ADR-H} &= \alpha + \beta_1 \Delta S_t^{\$/HKD} + \beta_2 DIV_{i,t} + \beta_3 DILLIQ_{i,t}^{ADR-H} + \beta_4 DSENT_t^{S\&P/HSI} \\ &+ \beta_5 SENT_{i,t}^{Com} + \beta_6 SOE\%_{i,t} + \beta_7 D_t^{EVENT2} + \beta_8 D_t^{EVENT3} + \beta_9 D_t^{CRISIS1} \\ &+ \beta_{10} D_t^{CRISIS2} + \beta_{11} D_t^{CRISIS3} + \varepsilon_{i,t} \end{aligned} \quad (15)$$

$$\begin{aligned} ER_{i,t}^{ADR-A} &= \alpha + \beta_1 \Delta S_t^{\$/RMB} + \beta_2 DIV_{i,t} + \beta_3 DILLIQ_{i,t}^{ADR-A} + \beta_4 DSENT_t^{S\&P/SSECI} \\ &+ \beta_5 SENT_{i,t}^{Com} + \beta_6 SOE\%_{i,t} + \beta_7 D_t^{EVENT2} + \beta_8 D_t^{EVENT3} + \beta_9 D_t^{CRISIS1} \\ &+ \beta_{10} D_t^{CRISIS2} + \beta_{11} D_t^{CRISIS3} + v_{i,t} \end{aligned} \quad (16)$$

$$\begin{aligned} ER_{i,t}^{H-A} &= \alpha + \beta_1 \Delta S_t^{HKD/RMB} + \beta_2 DIV_{i,t} + \beta_3 DILLIQ_{i,t}^{H-A} + \beta_4 DSENT_{i,t}^{HSI/SSECI} \\ &+ \beta_5 SENT_{i,t}^{Com} + \beta_6 SOE\%_{i,t} + \beta_7 D_t^{EVENT1} + \beta_8 D_t^{EVENT2} + \beta_9 D_t^{EVENT3} + \\ &\beta_{10} D_t^{CRISIS1} + \beta_{11} D_t^{CRISIS2} + \beta_{12} D_t^{CRISIS3} + \gamma_{i,t} \end{aligned} \quad (17)$$

where $SOE\%_{i,t}$ is the proportion of state-owned shares (relative to outstanding shares). $D^{EVENT1}{}_{t}$ is the three bailout policies in 1994. $D^{EVENT2}{}_{t}$ is the announcement of the sale of all sate shares in 2001. $D^{EVENT3}{}_{t}$ is the non-tradable share reform in 2005. $D^{CRISIS1}{}_{t}$ is the dummy variable for the 1997-1998 Asia financial crisis, $D^{CRISIS2}{}_{t}$ is the dummy variable for the 2000-2001 dotcom bubble. $D^{CRISIS3}{}_{t}$ is the dummy variable for 2007-to-2008 Subprime Mortgage Crisis (D_t= 1 during the crisis periods, otherwise=0). Other variables are defined above.

The results are shown in Table 3.

[Please insert Table 3 about here]

Evidence from Table 3 shows that after control variables are added, the capability of explanation of models rises. For example, the cross-section panel model of ADR-A discount can explain 17.38% of the total variation before control variables are added, but the cross-section panel model of ADR-A discount can explain 75.35% of the total variation after control variables are added.[34] It means that we can see effects of impact factors much more clearly and correctly, for example, the

[34] The cross-section panel model of ADR-H discount can explain 0.34% of the total variation before control variables be added, but the cross-section panel model of ADR-H discount can explain 0.55% of the total variation after control variables be added. The cross-section panel model of H-A discount can explain 24.21% of the total variation before control variables be added, but the cross-section panel model of H-A discount can explain 29.51% of the total variation after control variables be added.

relationship between H-A discount and relative illiquidity or relative market sentiment turns to be negative, and H-A discount has significant relation to state-owned shares. The relationship between ADR-H discount and relative market sentiment turns to be positive, and they are consistent with our hypotheses.

There are significant relations between all ADR-H discount, H-A discount, and ADR-A discount and China's government policies. There are significant relationship between all ADR-H discount, H-A discount, and ADR-A discount and the 2007-to-2008 Subprime Mortgage Crisis, except only ADR-A discount and H-A discount are related to the 1997-1998 Asia financial crisis. There are also significant relations between all ADR-H, H-A, and ADR-A discounts and the non-tradable reform in 2005, H-A discount are significant related to the three bailout policies in 1994, and only ADR-A discount and H-A discount are related to the sale of state-owned shares in 2001 for they related to the investors in the Chinese market.

Many relationship between variables and discounts turn to be non-significant after adding the proportion of state-owned shares (relative to outstanding shares) and controlling the impact of China's government policies and financial crises. There is only a positive and strong relationship between the ADR-H discount and dividend yield. It can be explained that investors in the U.S. market prefer dividend taxes compared to investors in Chinese market. All relationships between variables and

ADR-A discount turn to be non-significant. The result indicates that the discount occurs because of the impact of China's government policies and financial crises and not variables.

ADR-A discount and H-A discount are negative related to the proportion of state-owned shares (relative to outstanding shares), it is due to investors in the Chinese market are more confident in state-owned shares; investors in the Chinese market prefer to invest and induce the price to become higher than the implied value (see *e.g.*, Dewenter and Malatesta, 1999; Chen, 2009). The relationship between ADR-H discount and the proportion of state-owned shares (relative to outstanding shares) is non-significant, it is due to no direct relation to investors in China.

Ⅳ.2 Empirical evidences of China's Five-Year Plans on the discounts

Five-Year Plans of the China are a series of social and economic development guidelines. The Communist party plays a leading role in establishing the foundations and principles, they map out strategies for economic development, set growth targets, and launch reforms every five years. Our research contains from the eighth Five-Year Plan to the twelfth Five-Year Plan[35]. The eighth and ninth Five-Year Plans

---

[35] In 1991, the National People's Congress (NPC) approve the State Council's Report entitled "The eighth Five-Year Plan." In 1996, NPC approve the ninth Five-Year Plan. In 2001, NPC approve the tenth Five-Year Plan. In 2006, NPC approve the eleventh Five-Year Plan. In 2011, NPC approve the twelfth Five-Year Plan.

(1991-2000) emphasized the needs to establish the security markets, and to lead the enterprises by plans and to regulate and adjust the market step by step and finally transform the market. To protect the China's stock market, China restricts its stock market on capital flows at the beginning of the establishment of security markets. This is because when the financial system and the financial institutions in a country are not strong enough to cope with capital flows of the liberalization on the capital accounts and cause financial instability and even lead to a crisis. The tenth Five-Year Plan (2001-2005) emphasized that the financial market needs to restructure and reform as the preparation of gradually transformation to free market. During the tenth Five-Year Plan period, the Chinese government accomplished the Qualified Foreign Institution Investor Program (QFII) which permits a limited number of qualified institutional investors, on an annual renewal basis, to participate directly in China's domestic stock markets in 2002 (Capital inflows). The Chinese government also prepared the Qualified Domestic Institutional Investing (QDII) which allows local institutions to exchange RMB into foreign currencies (Capital outflows). Chinese government also achieved the reform of currency exchange rate mechanism for; therefore, RMB exchange rate is no longer pegged to the U.S. dollar, instead it is a collective reflection to a basket of several major currencies. We could focus on the comprehension and research of gradual openness of China's capital market. The original eleventh Five-Year Plan (2006-2010) was named the eleventh Five-Year Program in Chinese, and it means that the planned economy is formally transformed into free market economy. The eleventh and twelfth Five-Year Plans (2006-2015) emphasized that China determined to build a global financing platform to allow large enterprises to list their shares in the SHSE. China introduced listing experiences from overseas markets to improve the quality of listing in the SHSE. For example, the Chinese government encouraged that shares, which were listed in the HKSE, returned to the SHSE and helped solve the problem of over-valuation in A-shares. Therefore, many Chinese companies which had initial public offering were listed as H-shares, and later were listed as ADRs with H-shares as underlying shares, and finally returned to China and listed A-share. We can find that China gradually open its security market by attracting international capital and international know-how under Five-Year Plans.

We can also find the effects of Five-Year Plans in figure 1. In the eighth and ninth Five-Year Plans, China's securities market just opened and there were many restrictions in order to protect China's securities markets. Therefore, there were large deviations between A-shares and H-shares or ADRs. In the tenth Five-Year Plans, we find the price deviations between A-shares and H-shares or ADRs were diminishing gradually because of the continuing openness of China's securities market. In the eleventh Five-Year Plans, China encouraged Chinese companies return to A-shares market for introducing international experience and the permission of big enterprises were listed in A-shares market, consequently, more companies listed in Chinese market and price deviations were volatile again. Five-Year Plans are too important to Chinese companies and Chinese markets, therefore we spilt our cross-sectional model by the timeframe of Five-Year Plans to estimate the impact of different price changes from the planned economy to free market economy.

The results are shown at Table 4, the positive coefficients indicate that the variables make the share price higher than its implied value. On the contrary, the negative coefficients indicate that the variables make the share price lower than its implied value.

[Please insert Table 4 about here]

The result in Table 4 shows that in the earliest period (1996-2000), there are too many restrictions in the Chinese market, therefore investors can only invest in a single market, under this circumstance, many results are significant but differ from our hypotheses, for example, ADR-H discount is significant and negative related to relative market sentiment. In the second period (2001-2005), while the Chinese market was globalizing, arbitragers led prices to converge in two markets. For ADR prices are always lower than their implied values calculated by their home market (the result illustrates in Figure 1), increasing in those coefficients can reduce the magnitude of the discount. In other words, coefficients should become larger to let discounts close to zero. Our statistic results are in agreement with this point. Our results show that most coefficients on ADR-A discount (5 of 6 variables) become larger while Chinese market keeps globalizing. We can also find some variables turn to be non-significant in the relationship between impact factors and discounts. In the last period (2006-2012), the Chinese market is more liberal than the pre-2007 period on foreign investors' entry into the A-share, Chinese investors' entry into the H-share market, and there are lower non-tradable shares. We find more variables turn to be non-significant in the relationship between impact factors and discounts, for example, half coefficients on ADR-H discount turn to be non-significant, most coefficients (5 of 6 variables) on ADR-A discount turn to be non-significant. It means that most ADR-A discounts, ADR-H discounts and H-A discounts are no longer affected by those variables. With the Chinese market keeps globalizing, investors can invest in their favorite market for their own purposes such as liquidity, tax purpose, and their risk attitude. It means that the relationship between impact factors and all discounts are getting close to our hypotheses. In the last period, all statistic results are consistent with our hypotheses. With the Chinese market keeps globalizing, arbitragers lead prices converge in two markets. In other words, all discounts should get close to zero. Our statistic results are in agreement with this point. Our results show that all coefficients on ADR-H discount get close to zero with the Chinese market keeps globalizing, most coefficients on ADR-A discount (5 of 6 variables) get close to zero with the Chinese market keeps globalizing, half coefficients on H-A discount (3 of 6 variables) get close to zero with the Chinese market keeps globalizing, and the other three variables which do not get close to zero are becoming larger. For ADRs are always lower than their implied value calculated by its home market (the result illustrates in Figure 1), increasing in those coefficients can reduce the magnitude of the discount. It is the affirmation to our hypothesis again. We further use Wald test to test the equality of coefficients in different periods, and find almost all coefficients are significant different in different periods. It indicates that the effects of each variable are different by Five-Year Plans.

IV.4 Further investigation by bivariate model

We conduct several cross-sectional panel models of returns to further investigate results in equation (5), (6), and (7), and the model is as follows:

Sample: listing in ADR and H-share in the same time

$$\begin{aligned} R_{i,t}^{ADR} &= \alpha + \beta_1 \Delta S_t^{\$/HKD} + \beta_2 DIV_{i,t} + \beta_3 ILLIQ_{i,t}^{ADR} + \beta_4 ILLIQ_{i,t}^{H} + \beta_5 SENT_t^{S\&P} \\ &+ \beta_6 SENT_t^{HSI} + \beta_7 SENT_{i,t} + \beta_8 SOE\%_{i,t} + \beta_9 D_t^{EVENT2} + \beta_{10} D_t^{EVENT3} \\ &+ \beta_{11} D_t^{CRISIS1} + \beta_{12} D_t^{CRISIS2} + \beta_{13} D_t^{CRISIS3} + \varepsilon_{i,t} \end{aligned} \quad ,(18)$$

$$\begin{aligned} R_{i,t}^{H} &= \alpha + \beta_1 \Delta S_t^{\$/HKD} + \beta_2 DIV_{i,t} + \beta_3 ILLIQ_{i,t}^{ADR} + \beta_4 ILLIQ_{i,t}^{H} + \beta_5 SENT_t^{S\&P} \\ &+ \beta_6 SENT_t^{HSI} + \beta_7 SENT_{i,t} + \beta_8 SOE\%_{i,t} + \beta_9 D_t^{EVENT2} + \beta_{10} D_t^{EVENT3} \\ &+ \beta_{11} D_t^{CRISIS1} + \beta_{12} D_t^{CRISIS2} + \beta_{13} D_t^{CRISIS3} + \mu_{i,t} \end{aligned} \quad , (19)$$

Sample: listing in ADR and A-share in the same time

$$\begin{aligned} R_{i,t}^{ADR} &= \alpha + \beta_1 \Delta S_t^{\$/RMB} + \beta_2 DIV_{i,t} + \beta_3 ILLIQ_{i,t}^{ADR} + \beta_4 ILLIQ_{i,t}^{A} + \beta_5 SENT_t^{S\&P} \\ &+ \beta_6 SENT_t^{SSECI} + \beta_7 SENT_{i,t} + \beta_8 SOE\%_{i,t} + \beta_9 D_t^{EVENT2} + \beta_{10} D_t^{EVENT3} \\ &+ \beta_{11} D_t^{CRISIS1} + \beta_{12} D_t^{CRISIS2} + \beta_{13} D_t^{CRISIS3} + \nu_{i,t} \end{aligned} \quad , (20)$$

$$\begin{aligned} R_{i,t}^{A} &= \alpha + \beta_1 \Delta S_t^{\$/RMB} + \beta_2 DIV_{i,t} + \beta_3 ILLIQ_{i,t}^{ADR} + \beta_4 ILLIQ_{i,t}^{A} + \beta_5 SENT_t^{S\&P} \\ &+ \beta_6 SENT_t^{SSECI} + \beta_7 SENT_{i,t} + \beta_8 SOE\%_{i,t} + \beta_9 D_t^{EVENT2} + \beta_{10} D_t^{EVENT3} \\ &+ \beta_{11} D_t^{CRISIS1} + \beta_{12} D_t^{CRISIS2} + \beta_{13} D_t^{CRISIS3} + \omega_{i,t} \end{aligned} \quad , (21)$$

Sample: listing in H-share and A-share in the same time

$$\begin{aligned} R_{i,t}^{H} &= \alpha + \beta_1 \Delta S_t^{HKD/RMB} + \beta_2 DIV_{i,t} + \beta_3 ILLIQ_{i,t}^{H} + \beta_4 ILLIQ_{i,t}^{A} + \beta_5 SENT_t^{HSI} \\ &+ \beta_6 SENT_t^{SSECI} + \beta_7 SENT_{i,t} + \beta_8 SOE\%_{i,t} + \beta_9 D_t^{EVENT1} + \beta_{10} D_t^{EVENT2} \\ &+ \beta_{11} D_t^{EVENT3} + \beta_{12} D_t^{CRISIS1} + \beta_{13} D_t^{CRISIS2} + \beta_{14} D_t^{CRISIS3} + \gamma_{i,t} \end{aligned} \quad , (22)$$

$$\begin{aligned} R_{i,t}^{A} &= \alpha + \beta_1 \Delta S_t^{HKD/RMB} + \beta_2 DIV_{i,t} + \beta_3 ILLIQ_{i,t}^{H} + \beta_4 ILLIQ_{i,t}^{A} + \beta_5 SENT_t^{HSI} \\ &+ \beta_6 SENT_t^{SSECI} + \beta_7 SENT_{i,t} + \beta_8 SOE\%_{i,t} + \beta_9 D_t^{EVENT1} + \beta_{10} D_t^{EVENT2} \\ &+ \beta_{11} D_t^{EVENT3} + \beta_{12} D_t^{CRISIS1} + \beta_{13} D_t^{CRISIS2} + \beta_{14} D_t^{CRISIS3} + \upsilon_{i,t} \end{aligned} \quad , (23)$$

where $R_{i,t}^{ADR}$ is the return for firm i on day t (calculated by price of ADRs). $R_{i,t}^{A}$ is the return for firm i on day t (calculated by price of A-Shares). $R_{i,t}^{H}$ is the return for firm i on day t (calculated by price of H-shares). $ILLIQ_{i,t}^{ADR}$, $ILLIQ_{i,t}^{A}$, and $ILLIQ_{i,t}^{H}$ are illiquidity for firm *i* on day *t*. $SENT_t^{S\&P}$, $SENT_t^{SSECI}$, and $SENT_t^{HSI}$ is the market sentiment on day *t*.[36] Other variables are defined above.

The results are shown at Table 5.

[Please insert Table 5 about here]

In Table 5, we find there is a significant relationship between China's government policies and the return of A-share; however, there is no significant relationship between China's government policies and the return of ADR. In addition, we also find that there is a significant relationship between the 1997-1998 Asia financial crisis and the return of A-share, and on the contrary, there is no significant relationship between the 1997-1998 Asia financial crisis and the return of ADR. There are significant relationship between the 2007-2008 Subprime Mortgage Crisis and the return of A-share and ADR, but the 2007-2008 Subprime Mortgage Crisis effect the return of ADR more than the return of A-share for investors in the Chinese market because of the protection of exchange rate mechanism during financial crises; there are significant relationship between financial crises and the return of A-share and H-share, but financial crises affect the return of H-share more than the return of

[36]Illiquidity and market sentiment variables are made by:

$ILLIQ_{i,t}^{ADR} = 1/D_{i,y}\sum_{t=1}^{Diy}\left|R_{i,y,t}^{ADR}\right|/Volume_{i,y,t}^{ADR}$, $ILLIQ_{i,t}^{A} = 1/D_{i,y}\sum_{t=1}^{Diy}\left|R_{i,y,t}^{A}\right|/Volume_{i,y,t}^{A}$, $ILLIQ_{i,t}^{H} = 1/D_{i,y}\sum_{t=1}^{Diy}\left|R_{i,y,t}^{H}\right|/Volume_{i,y,t}^{H}$.

$SENT_t^{S\&P} = \ln(P/E)_t^{S\&P}$, $SENT_t^{SSECI} = \ln(P/E)_t^{SSECI}$, $SENT_t^{HSI} = \ln(P/E)_t^{HSI}$.

A-share for investors in the Chinese market who were protected by exchange rate mechanism in Chinese market during financial crises. It supports that in the light of Figure 1, ADR-A discount and H-A discount become larger during the financial crises. We can also indicate that the capability of explanation of models rises after control variables are added.

V. Conclusions

We make several contributions in this paper. First, this study mainly inspects price discounts of Chinese public listed companies which have issued ADRs (overseas shares in the U.S. market), H-shares (shares traded in the Hong Kong market) and A-shares (shares traded in the China market). Our data are selected from the databases of the Bank of New York, Datastream, and compare with the SEC documents. We find that all underlying stocks of cross-listed level 2 and level 3 ADRs are H-shares, with no ADR can be converted to A-share (home market shares). It is due to A-shares and ADRs cannot transfer into each other. It can explain why there are a big price deviation between A-shares and ADRs before 2007. And because H-shares and ADRs can transfer into each other, the price of ADR gets close to the implied price of H-share by the law of one price.

Second, China is a planned economy country. For Chinese government wants to attract international capital, most Chinese companies are listed in the Hong Kong market first, and later, using H-shares as underlying shares to list ADRs. Chinese government want further Chinese companies to learn from international experience and to solidify the A-shares market, so most Chinese companies go back to list in the home market after listing in the foreign markets.

Third, long-term planning and government policies are important factors when we research on the China's securities market. Chinese Five-Year Plan is an important guidance of economic growth and helps establish principles and direction to the China's securities market. The timetable of the deregulation of the China's securities market can be separated into three periods. In the early limitation period (the eighth and ninth Five-Year Plan), the protection of the Chinese government to the fledgling China's securities market and the overexcited sentiment of Chinese investors have contributed to the much higher prices of A-shares to prices of H-shares and ADRs of the same Chinese company. In the period of the progressive openness of investment limitation (the tenth Five-Year Plan), the Chinese government gradually deregulate the China's securities market, and we could find that prices of A-shares, H-shares and ADRs of the Chinese companies tally in different markets. In the period of encouraging Chinese companies to list in the home market (the eleventh and twelfth Five-Year Plan), there were more listed companies in the China's securities market, and deviations between prices of Chinese companies in different markets are fluctuated again.

Fourth, previous studies focus on the relationship between pricing factors (liquidity, dividend taxes, *etc.*) and share prices in different markets, but without considering plans and regulations of China's government, the studies would have misinterpreted the impact estimation of share prices of Chinese companies in different markets. We collect important government policies through annual Fact Books from the SHSE and Chinese government's news releases published between 1991 and 2012, and factor the collective information into our research. And find that those policies are important factors to prices of the Chinese companies.

Fifth, for we can comprehensively interpret different prices of Chinese companies in different markets, our research also considers financial crises. We discover that price deviations are enlarged during financial crisis period for the Chinese government would protect the Chinese securities; for example, the limitation of the range of currency exchange rate volatility, price limit, *etc*.

The estimates of this table are based on the following equations.

$$ER_{i,t}^{ADR-A} = \alpha + \beta_1 \Delta S_t^{\$/RMB} + \beta_2 DIV_{i,t} + \beta_3 DILLIQ_{i,t}^{ADR-A} + \beta_4 DSENT_t^{S\&P/SSECI} + \beta_5 SENT_{i,t} + v_{i,t},$$

$$ER_{i,t}^{H-A} = \alpha + \beta_1 \Delta S_t^{HKD/RMB} + \beta_2 DIV_{i,t} + \beta_3 DILLIQ_{i,t}^{H-A} + \beta_4 DSENT_{i,t}^{HSI/SSECI} + \beta_5 SENT_{i,t} + \gamma_{i,t},$$

$$ER_{i,t}^{ADR-H} = \alpha + \beta_1 \Delta S_t^{\$/HKD} + \beta_2 DIV_{i,t} + \beta_3 DILLIQ_{i,t}^{ADR-H} + \beta_4 DSENT_t^{S\&P/HSI} + \beta_5 SENT_{i,t} + \varepsilon_{i,t},$$

where $ER_{i,t}^{ADR-A}$ is the ADR-A discount (premium) for firm i on day t. $ER_{i,t}^{H-A}$ is the H-A discount (premium) for firm i on day t. $ER_{i,t}^{ADR-H}$ is the ADR-H discount (premium) for firm i on day t. $\Delta S_t^{\$/RMB}$ is the change of expected exchange rate (US dollars to RMB) on day t. $\Delta S_t^{HKD/RMB}$ is the change of expected exchange rate (HK dollars to RMB) on day t. $\Delta S_t^{\$/HKD}$ is the change of expected exchange rate (US dollars to HKD) on day t. $DIV_{i,t}$ is the dividend yield for firm i on day t. $DILLIQ_{i,t}^{ADR-A}$, $DILLIQ_{i,t}^{H-A}$, and $DILLIQ_{i,t}^{ADR-H}$ are relative illiquidity for firm i on day t . $DSENT_t^{S\&P/SSECI}$, $DSENT_t^{HSI/SSECI}$, and $DSENT_t^{S\&P/HSI}$ is the relative market sentiment on day t. $SENT_{i,t}$ is the company sentiment for firm i on day t. ***, **, and * indicate significant at 1%, 5%, and 10% levels, respectively.

The risk measures (such as VaR and CVaR) often rely an assumption about the return distribution of the underlying risky assets. Different distributional assumption may produce widely different computed VaR values. When measuring risk for intra-daily equity returns, the question arises as to what assumption should be made about the return distribution due to the huge amount of market microstructure noise. Because of the difficulty of decom- posing such noise, it is very hard to measure high-frequency market risk. In this paper, we circumvent the inefficiency of distributional assumption of intra-daily market fluctuations, by specifying approaching the issue using wavelet based adaptive separation method. With this approach, we can deconstruct optimally the data into the true efficient information and the noise. Using this approach, we forecast VaR and CVaR and implement them in portfolio selection using high frequency data of the US DJIA stocks. Our results suggest that the performance of the wavelet approach in VaR computation and portfolio selection dominates that of the competitive models investigated in this study.
Keywords: DWT, High-frequency data, Portfolio, Value at Risk, Wavelet.

JEL Classifications: C02, C10, C63

1 Introduction

The standard VaR computation (e.g., delta-normal VaR) requires that the underlying return-generating processes for the risky assets be normally distributed, where the moments are time invariant and can be estimated with historical data. Despite the increased use of the VaR methodology, it does have well-known drawbacks. VaR is not a coherent risk measure and does not provide insight into the risk beyond the quantile.[1] The empirical work by Beder (1995) clearly demonstrates how different VaR models can lead to dramatically different VaR estimates. More- over, when employing the VaR methodology, it is possible for a decision maker, unintentionally or not, to decrease portfolio VaR while simultaneously increasing the expected losses beyond the VaR (i.e., by increasing the "tail risk" of a portfolio or position).[2] There are superior measures to VaR for measuring market risk, such as average value at risk (AVaR). This risk measure – also called conditional value at risk (CVaR) and, for continuous distributions called expected tail loss (ETL) – is a coherent risk measure that overcomes the conceptual deficiencies of VaR.[3] Even with these well-known limitations, however, VaR remains the most popular measure of market risk employed by risk managers [4].

Different arguments about the distributional assumption of the underlying risky assets have been proposed in the literature. Neftci (2000) points out that extreme events are structurally different from the return-generating process under normal market conditions. Höchstötter et al. (2005) and Rachev et al. (2005, 2007) make the same argument, focusing on the stylized fact that returns are heavy tailed. Brooks et al. (2005) argue that heavy tailedness might lead to an underprediction of both the size of extreme market movements and the frequency with which they occur. Sun et al. (2009) propose a methodology for computing VaR based on the fractional stable model.

With the development of algorithmic trading techniques, increasingly financial institutions have implemented high frequency trading. High-frequency trading narrows spreads and improves market liquidity. As a consequence, the market volatility changes instantaneously. As a result, fi- nancial institutions require a methodology that can be easily applied to monitoring instantaneous market risk. With the availability of real-time tick-by-tick data (i.e., high-frequency data), risk managers can measure market risk at a high-frequency level. For example, hedge funds with large position involving high frequency trading can measure their market risk every minute. When performing risk management with high-frequency data, one has to take into account that the high-frequency data are known to exhibit the complex structure of irregularities and roughness that have been described as multifractal phenomena, that is, different fragments of the data have different fractal properties (see ?). The major characteristic of high-frequency data is that they

[1]See Artzner et al. (1999).
[2]See Martin et al. (2003) and the references therein.
[3]See, for example, Acerbi and Tasche (2002) and Rachev et al. (2005a).
[4]See Dowd (2002) for the characteristics of VaR that make it appealing to risk managers

exhibit erratic arrival that contains several distinct types of market microstructure noise. Such noises reflect the trading behavior and information flows in the market. Due to the difficulty of decomposing the different types of noises, an intelligent pattern recognition method is desired.

Wavelet method has been shown as one of a multifractal spectrum computing methods and proven to be a reliable tool in econometric analysis, (see, for example, Fan and Gençay (2010), Fan and Wang (2007), and Hong and Kao (2004)). Particularly, it is suitable for time series analysis, for example, smoothing, denoising, and jump detection (see, for example, Gençay et al. (2010), In et al. (2011), Donoho and Johnstone (1998), and Sun and Meinl (2012), among others). The advantage of wavelet method is that it performs a multiresolution analysis, that is, it allows us to analyze the data at different scales (each one associated with a particular frequency passband) at the same time. In this way, wavelets enable us to identify single events truncated in one frequency range as well as coherent structures across different scales. Several studies have applied wavelet methods in mining financial data, for example, Ramsey and Lampart (1998) and Kim and In (2008) apply wavelets to analyze relationships and dependencies among key macroeconomic and financial variables. Laukaitis (2008) applies wavelet transforms for high frequency data denoising in the study of credit card intraday cash flow and intensity of transactions. Sun et al. (2011) propose a wavelet method for analyzing currency market with high-frequency data. Meinl and Sun (2012) investigate the local linear scaling approximation (LLSA) in denoising high-frequency data and show its robustness in empirical application under statistical goodness-of-fit tests.

A classic assumption for data mining is that the data is generated by certain systematic patterns plus random noise. Denoising big data provides a fundamental tool to extract the systematic patterns conveyed in the data. As Sun and Meinl (2012) point out a specific problem arises when trend component exhibits occasional jumps that are in contrast to the slow evolving long-term trend. These occasional jumps are often caused by, for example, unexpected large transaction or extreme prices and should not be contributed to the normal short-term variations (since jumps are often considered as noises) but indeed to the long-run trend. Traditional linear denoising methods (e.g., moving average) usually fail to capture this information accurately as these linear methods tend to blur out jumps, while nonlinear filters are not appropriate to smooth out high-frequency fluctuations sufficiently since the trends extracted by these methods are not smooth enough (i.e., usually with kicks) to present the long-run dynamic information (see Sun and Meinl (2012) and references therein).

Several works have been done to overcome the above-mentioned problem. For example, Con- nor and Rossiter (2005) estimate the wavelet variance by using non-decimated wavelet transforms. Haven et al. (2012) show the efficiency of wavelet method in dnoising option price data. Studies of applying wavelets in denoising data and coefficient construction can be found in Gençay et al. (2002), Keinert (2004), Mallat and Hwang (1992), and Percival and Walden (2006) among oth- ers. Ramsey (2002) highlights some research areas where wavelet analysis might be applied in economics and Crowley (2007) provides a survey about how wavelet methods have been used in

the economics and finance literature. Gençay et al. (2003) propose a method based on a wavelet multiscaling approach for decomposing time series data. Lada and Wilson (2006) develop a wavelet-based spectral method for steady-state simulation analysis. Gençay and Gradojevic (2011) introduce a wavelet approach to estimate the parameters of a linear regression model. Among these methods, both DWT and MODWT need to decide the wavelet function, level of decomposition, and thresholding rule. A common approach in choosing the wavelet function is to use the shortest wavelet filter which can provide reasonable results, see Percival and Walden (2006). The level of decomposition leads to the choice which considers "the higher the better" in general. The thresholding rule, which is a function identifying the wavelet coefficients to be deleted, has also been investigated in academic research, see, for example Gençay et al. (2002). The remaining challenge is how to determine the combination of wavelet function, level of de- composition, and thresholding rule to reach an optimal smoothness that generally improve the performance of classic models after denoising the data.

The algorithm (named GOWDA) proposed in this paper can optimally determine the wavelet function, level of decomposition, and thresholding rule by using smoothness as a regularization variable. The goal of our method is to denoise the data and obtain the trend that (1) contains as much information as possible, (2) exhibits a certain degree of smoothness which can utilize the classic model, and (3) preserves as less artifact (i.e., undesired structures, like oscillating nature, generated through the denoising process) as possible. In our method, we define measures for smoothness. Intuitively, these measures for smoothness describe the characteristics of the denoised data with wavelet transform that optimally provide output for further analysis with classical model. We show the resulting difference sequence between the denoised data and the original signal must converge in probability at a predetermined confidence level. This requires
(1) the structural change (e.g., jumps) of the denoised data and the original signal should be synchronous, (2) there is no outliers in the denoised data, and (3) the local extremum in the denoised data should be bounded. We show that the method we proposed leads to an optimal choice with respect to these requirements.

We investigate the performance of GOWDA with numerical simulations that consider some typical patterns often observed in big financial market data, e.g., excessive volatility and regime switching. With comparison, GOWDA results in better performance than the alternative meth- ods and the numerical results coincide with the analytical properties we have shown. From the results in this paper, we see that GOWDA maintains the original wavelet transform's compu- tational complexity and its approximation errors are bounded. In order to confirm the compu- tational reliability and consistency that we have shown in the simulations, we further perform an empirical investigation by applying GOWDA with 5-minute data of German DAX 30 stocks. The results we obtained from such large sample investigation coincide with the previous sim- ulation results. When using the denoised data generated by GOWDA for forecasting with the high-frequency data, we find that the performance (i.e., accuracy of forecasting) of classic models e.g., AR, ARMA, and ARMA-GARCH, has been significantly improved which confirms the robustness of GOWDA.

We then apply GODWA for two financial implementations, i.e., market risk assessment and portfolio selection for day trading. We compute the Value at Risk (VaR) and conditional Value at Risk (CVaR) measures with GOWDA based on our big financial market data. We found when using the data denoised by GOWDA, we can improve the accuracy of VaR and CVaR measures significantly. In this paper, we formulate three day trading strategies, i. e., first, sorting stocks with Sharpe ratio and risk-reward ratio with VaR and CVaR; second, ranking them as the top and bottom groups, then conduct long-short strategy for buying the top and shorting the bottom group at hourly frequency and keep the position only for one day. We estimate the transaction cost at tick-by-tick level and formulate a index (market) portfolio as the benchmark. The annualized return of the trading strategy based on ranking with GOWDA denoised data is overwhelmingly larger than that with ranking of original data.

We organized the paper as follows. In Section 2, we describe the methodology in details, summarize it with an algorithm chart. In Section 3, we show the analytical properties of our algorithm. In Section 4, we do an empirical study of applying our method for measuring risk and portfolio selection. We summarize our conclusions in Section 5.

2 The Methodology

In this section, we describe the wavelet based adaptive seperation algorithm (WASA) and analytically show its computational properties.

2.1 Wavelet and wavelet transform

Assume that the observed data X can be decomposed as follows:

$$X_t = S_t + N_t,$$

where S_t is the true signal and $\tilde{S}$ is its estimation. N_t is the additive noise sampled at time t.

Let $W(\cdot;\omega,\zeta)$ denote the wavelet transform operators with certain wavelet function ω for ζ level of decomposion. $W^{-1}(\cdot)$ denotes the inverse wavelet transform. Let $D(\cdot;\gamma)$ denotes the denoising operator with thresholding rule γ. We intend to wavelet denoise $X(t)$ in order to recover $\tilde{S}(t)$ as an estimate of $S(t)$. Then the procedure is summarized as follows:

$$\begin{aligned} Y &= W(X;\omega,\zeta), \\ Z &= D(Y;\gamma), \\ \tilde{S} &= W^{-1}(Z). \end{aligned}$$

This summary of procedure does not reveal the details involving implementation of the operators

$W(\cdot)$, $D(\cdot)$, and selection of ω, ζ, and γ. Donoho et al. (1994, 1995) address details about implementation of the operators and selection of thresholding rules.

Wavelets are bases of $L^2(\mathrm{R})$ first developed to analyze geophysical signals (see Morlet (1983)). In contrast to Fourier transformation they enable a localized time-frequency analysis with wavelet

functions that usually have either compact support or decay exponentially fast to zero. In ad- dition, wavelets provide a multiresolution of a signal that allows to analyze the signal simulta- neously on different (usually dyadic) scales. To achieve these desirable properties, the wavelet transformation is subject to the following conditions, i.e., the admissibility condition and or- thonormality,

$$\sum_{l=0}^{L-1} h_l = 0, \qquad \sum_{l=0}^{L-1} h_l^2 = 1 \quad \text{and} \quad \sum_{l=0}^{L-1} h_l h_{l+2n} = 0$$

for all $n \in \mathrm{N}^*$, where $h_l = (h_0, h_1, \cdots, h_{L-1})$ be a finite length discrete wavelet filter.

The idea of the wavelet transform W is to translate and dilate a single function (the mother wavelet) $\psi(t)$:

$$\psi_{a,b}(t) = \frac{1}{\sqrt{|a|}}\,\psi\left(\frac{t-b}{a}\right), a, b \in \mathrm{R}, a \neq 0. \tag{1}$$

The degree of compression is determined by a and the time location of the wavelet is set by b, where a is said the scaling parameter and b the translation parameter. $|a| < 1$ leads to compression and therefore to higher frequencies. The opposite (lower frequencies) is true for $|a| > 1$, leading to time-widths adapted to their frequencies, see Percival and Walden (2006).

The degree of compression is determined by a and the time location of the wavelet is set by b, where a is said the scaling parameter and b the translation parameter. $|a| < 1$ leads to compression and therefore to higher frequencies. The opposite (lower frequencies) is true for $|a| > 1$, leading to time-widths adapted to their frequencies, see Percival and Walden (2006).

In this paper, we focus on the discrete wavelet transform (DWT). A discrete wavelet transform (DWT) is an orthogonal transform of a vector (discrete signal or time series data) X of length N (which must be a multiple of 2^J) into J wavelet coefficient vectors $W_j \in \mathbb{R}^{N/2^j}$, $1 \leq j \leq J$ and one scaling coefficient vector $V_J \in \mathbb{R}^{N/2^J}$, that is,

$$[W_1, \ldots, W_J, V_J] = WX, \tag{2}$$

with the transformation matrix W determined by the wavelet filter banks h, it is more convenient to use the pyramid algorithm developed by Mallat (1989), with a computational complexity of $O(N)$. Applying the inverse transform on these vectors yield

$$[W_1, \ldots, W_J, V_J]W^T = S_J + \sum_{j=1}^{J} D_j = X, \tag{3}$$

that is, an additive decomposition of the original signal. As

$$S_{j_0-1} = S_J + \sum_{j=j_0}^{J} D_j \tag{4}$$

holds, S_j, approximations (i. e., moving weighted averages) of X at different dyadic scales, and D_j, the detail vectors which are the details we loose at each approximation level, result in a multiscale decomposition. For each scale j we can separate the signal into high and low frequencies by a wavelet filter with the bandwidth determined by j.

Wavelet denoising might result in different outcomes due to different choice of input variables. As we pointed out, wavelets are oscillating functions and transform the signal orthogonally in the Hilbert space, consequently we do not have any trouble from reconstruction based on wavelet transform. However, there are many wavelet functions that can suffice the requirement for transform. In practice, different wavelets are used for different reasons. For example, the Haar wavelet has very small support and wavelets of higher orders such as Daubechies ($D4$) and least asymmetric (LA) have also bigger support. Bigger support can ensure a smoother shape of S_j, $1 \leq j \leq J$ with each wavelet and scaling coefficient carrying more information due to the increased filter width. The optimal band-pass filter which dictates the capacity to isolate features to specific frequency intervals is determined by the length of a wavelet function in approximation. In addition, the wavelet function must be able to mimic the features contained in the signal of interest in order to optimally represent the conveyed information. Therefore, the choice of wavelet basis function turns to be important when analyzing a given signal.

After choosing the wavelet, we can then decompose the signal into several levels. In general, we use the pyramid algorithm to accomplish this, see Gençay et al. (2002). This algorithm decomposes the signal into detail and approximation coefficients in its first iteration. Each following iteration applies the same procedure on the approximation coefficients from the iteration one step ahead.[5] We can do this at a maximum $\log_2(N)$ times (N is the number of observations). The quality of the denoising process varies with the number of iterations. The resulting outcome also critically depends on the thresholding rule which decides all wavelet coefficients less than a fixed constant in magnitude to be zero. The coefficients obtained in each iteration are subject to the thresholding rule before we reconstruct the denoised signal. This rule identifies the coefficients that represent noise.

Therefore, we have three factors that influence the quality of denoising based on wavelet transform: wavelet function (or mother wavelet), number of maximal iterations (or level of decomposition), and thresholding rule. However, there is no straight-forward method to determine these three factors simultaneously. In this paper, we propose a new method that can optimally determine the choice of wavelet function, number of maximal iterations, and thresholding.

2.2 Wavelet based adaptive seperation algorithm (WASA)

In order to evaluate the DWT performance, i.e., to see how close $\tilde{S}_t$ toward S_t, we introduce the wavelet adaptive seperation algorithm (WASA) as follows. First, we name a seperation factor

[5] For DWT, we down sample the coefficients, i. e., in each iteration we halve the number of detail coefficients.

θ that is the combination of wavelet function, number of maximal iterations, and thresholding rule and a factor space $\Theta \subseteq \mathbb{R}^p$, $p \geq 0$, then $\theta \in \Theta$. Different θ will lead to different DWT performance. We then define a random variable X and $X = S - \tilde{S}$. X is in fact the approximation error and determined by a real value approximating function $m(X, \theta) \in R$ and $E(m(X, \theta)) = 0$.

Definition 1. *Let $X_t \in \mathbb{R}^d$ be i.i.d. random vectors, and given $\theta \in \mathbb{R}^p$ that is uniquely determined by $E(m(X, \theta)) = 0$, where $m(X, \theta)$ is called the approximating function and takes values in $\mathbb{R}^{p+q}$ for $q \geq 0$. WASA determines $\tilde{\theta}$ such that $\tilde{\theta} = \operatorname{argmax}_\theta R(\theta)$, where*

$$R(\theta) = \min \left\{ \prod_{i=1}^{n} n\omega_i \,\middle|\, \sum_{i=1}^{n} \omega_i m(X, \theta),\ \omega_i \geq 0, \sum_{i=1}^{n} = 1 \right\}.$$

In other words, WASA is to minimize the resulting difference sequence between $\tilde{S}_t$ and S_t based on choosing an optimal combination of approximating functions $m(\cdot)$. Therefore, WASA needs to determine the approximating function $m(\cdot)$ and its corresponding weight. If we only use one type of approximation, that is, a single criterion, then the weight is one. If we need to apply multivariate criteria for approximation, we need to determine the associated weight for each approximating function.

2.2.1 Model selection criteria

In this paper, for WASA we suggest six model selection criteria (i.e., $m_1, \ldots, m_6$) to evaluate $m(\cdot)$. The first one is the traditional root mean square error, such that,

$$m_1 = \sqrt{\frac{\sum_{t=1}^{T} \left(S_t - \tilde{S}_t\right)^2}{T}}, \tag{5}$$

where T is the data length.

Then we use the Akaike Information Criterion (AIC) and the Bayesian Information Criterion (BIC):

$$m_2 = \ln\left(\frac{\sum_{t=1}^{T} \left(S_t - \tilde{S}_t\right)^2}{T}\right) + \frac{2p}{T}, \tag{6}$$

$$m_3 = \ln\left(\frac{\sum_{t=1}^{T} \left(S_t - \tilde{S}_t\right)^2}{T}\right) + \frac{p \ln T}{T}, \tag{7}$$

where p is the number of parameters and T is the data length.

We use two measures suggested by Sun and Yu (2013) to detect artifacts and jumps: one considers artifacts (m_4, based on an outliers test) and the other considers jumps (m_5, based on local extrema). In other words, we use m_4 to detect the global extrema and m_5 the local extrema. Both of them have ability to detect boundary problems, that is, inefficient approximation at the beginning and end of the signal.

We suggest to apply Grubbs test for identifying artifacts, which is an iterative test for outliers based on an approximately normal distributed sample, see Grubbs (1969). Let $\mu = \frac{1}{T}\sum_{t=1}^{T} X_t$ be the sample mean of vector X and $s^2 = \frac{1}{T-1}\sum_{t=1}^{T}(X_t-\mu)^2$ its sample variance. The test statistics is then given by

$$G = \frac{\max |X_i-\mu|}{s}.$$

G can be assumed to be t-distributed and a test for outliers with significant level α (e.g. $\alpha = 0.05$) can easily be performed by rejecting the null hypothesis of no outliers if

$$G > z_\alpha = \frac{T-1}{\sqrt{T}} \times \sqrt{\frac{t^2_{\frac{\alpha}{2\times T},T-2}}{T-2+t^2_{\frac{\alpha}{2\times T},T-2}}}.$$

When an outlier (i.e., the global extremum) is detected, it is removed from the data and the test will proceed. As a measure of the amount of artifacts (or jumps of high magnitude), we can identify the number of iterations to run the test until it confirms there is no outlier. We apply the test until $g(x) = 0$ and count the number of outliers as a measure of structure.

Let $C(x)$ be a function determining whether there is one outlier in vector X:

$$C(x) = \begin{cases} 1, & if \quad G > z_\alpha \\ 0, & if \quad otherwise \end{cases}$$

$$m_4 = \frac{1}{T}\sum_{t=1}^{T} 1 \times *_{C(x)=1}, \tag{8}$$

where T is the data length.

In order to control all structural changes to be bounded, our proposed method investigates the local extrema (maxima or minima, respectively) at certain magnitude. In order to avoid redundant computation (since τ_1 controls the outlier detection), we can only run the test procedure for the output data after wavelet transform. The local extrema here we referred to, are the largest and smallest values that a function takes at a point within a given neighborhood.

If there exists a $\Lambda \in \mathrm{R}$, such that $\lim\sup_{n\to N} x_n < \Lambda$ and there exists a subsequence x_{k_n} of x_n for which we have that $x_{k_n} < \Lambda$, $\forall n$, then Λ is the local maxima. If there exists a $\lambda \in !R$, such that $\lim\inf_{n\to N} x_n > \lambda$, and there exists a subsequence x_{k_n} of x_n for which we have that $x_{k_n} > \lambda$, $\forall n$, then λ is the local minima.

Let $D(x)$ be a function that detects local maxima

$$D(x) = \begin{cases} 1, & if \quad x_i = \Lambda \\ 0, & if \quad otherwise, \end{cases}$$

and $D^*(x)$ detects local minima.

$$D^*(x) = \begin{cases} 1, & if \quad x_i = \lambda \\ 0, & if \quad otherwise. \end{cases}$$

$$m_5 = \frac{1}{T} \sum_{t=1}^{T} 1 \times \left(\mathbb{1}_{D(x)=1} + \mathbb{1}_{D^*(x)=1} \right), \tag{9}$$

where T is the sample size.

Let $A(x)$ be a function that detects comovement

$$A(x) = \begin{cases} 1, & if \quad (S_{t+1} - S_t)(\tilde{S}_{t+1} - S_1) > 0 \\ 0, & if \quad otherwise, \end{cases}$$

$$m_6 = \frac{1}{T} \sum_{t=1}^{T} 1 \times \mathbb{1}_{A(x)=1}, \tag{10}$$

2.2.2 Determining the factor scores

The algorithm we proposed in this paper is then to solve and optimal problem to determine the weights ω_i, that is,

$$\min \sum_{i=1}^{6} \omega_i m_i, \text{ s.t. } \omega_i \geq 0, \quad \sum_{i=1}^{6} \omega_i = 1.$$

2.2.3 The algorithm: summary

Given a set of wavelet functions F, a set of maximal levels of decomposition L, a set of thresholding rules S, and a input data vector X_t as input variables, $W(F, L, S, X_t)$ determines the output of wavelet transform. We define a score function $T(\tau_1, \tau_2)$ as the criterion to determine the combination of denoising factors (i.e., F, L, and S). The function $\min\{T(\tau_1, \tau_2)\}$ will lead to the optimal combination of denoising factors when its score value is minimized. If two parameter sets $\{F(i), L(i), S(i)\}$ and $\{F(j), L(j), S(j)\}$, $(i < j)$, yield the same score value of $\min\{T(\tau_1, \tau_2)\}$, the algorithm determines the first set (i.e., i) as the optimal one. After the optimal combination of denoising factors has been determined, our algorithm applies the denoising approach based on wavelet transform $W(\cdot)$ to generate the final output vector $\hat{X}_t$. Pseudo code for this smoothness-oriented wavelet denoising algorithm is provided in Algorithm chart 1.

3 Computational Properties of WASA

3.1 Complexity

The wavelet based adaptive seperation algorithm (WASA) can implement DWT and the computational complexity critically depends on the implemented algorithms of DWT.

Algorithm 1 *Generalized Optimal Wavelet Decomposing Algorithm (GOWDA)*

```
X ← input data vector
F ← a set of wavelet functions
L ← a set of maximal levels of decomposition
S ← a set of thresholding rules
W(·) ← wavelet transform
η_H ← upper tail synchronousness defined by Eq.(5)
η_L ← lower tail synchronousness defined by Eq.(??)
for F ← i do
    for L ← j do
        for S ← k do
            Apply W(·) using {F(i),L(j),S(k)} : X → X̃      (see Eq.(2) - Eq.(5))
            if η_L /= η_H then
                Compute T(τ1,τ2) (see Eq.(??))
            else
                Compute T(τ1,τ2) = τ1 + τ2 (see Eq.(??) and Eq.(??))
            end if
        end for
    end for
end for
for run(l) ← l do
    Compute T(τ1,τ2)
end for
Evaluate W(F(l),L(l),S(l)) ← arg min T(τ1,τ2)
Decompose X based on W(F(l),L(l),S(l)): X → X̃.
Reconstruct X̂  from X̃ with W^-1(·)
Output X̂  for X
```

Corollary 1. *The computational complexity of WASA is $O(n)$ when applied with DWT.*

Proof. Percival and Walden (2006) show that the computational complexity of DWT is $O(N)$. WASA computes DWT $(i \times j \times k) + 1$ times, where i stands for the number of wavelet functions, j the number of maximal levels of decomposition, and k the number of thresholding rules. For $i \times j \times k << T$ and the quantity of $i \times j \times k$ is countable, therefore we preserve the computational complexity of DWT. □

When executing WASA, several measures are computed. It is easy to see that the time complexity of τ_2 and η is $O(N)$. For τ_2, we need n times to go through a vector X_n to evaluate the local extrema condition. To compute η, we count changes of tails in vector X_n then have a complexity of $O(N)$ as well. τ_1 implements the Grubbs test for outliers. For each run, we have to compute the new test statistic of the t-distribution. That is, we have n runs, each of complexity $O(N)$. For $n << T$, leads to $O(N)$.

3.2 Consistency

The following theorem provides an upper bound for the error of the estimated trend to the real one. We now show the asymptotic convergence of the proposed method towards DWT.

Theorem 1. *Given any signal X of length N with the trend $\vartheta(X)$, the error generated by WASA approximation S^{WASA} is bounded, that is, for any choice of (F, L, S) there exists a constant $c > 0$ such that*

$$\sum_{t=1}^{N} |\vartheta_t(X) - S_J^{\text{WASA}}| < c \tag{11}$$

holds. Furthermore, for F fixed and $N \to \infty$ we have

$$\lim_{N\to\infty} \frac{1}{N} \sum_{t=1}^{N} |S_J^{\text{DWT}} - S_J^{\text{WASA}}| = 0. \tag{12}$$

i. e., WASA converges asymptotically towards the estimated trend of the DWT.

Proof. Let (F, L) be fixed, we can directly obtain $S_J^{\text{WASA}} = S_J^{\text{DWT}}$. For any other choice of (F, L, S), more details will be added to the estimator S^{WASA}, according to $T(\tau_1, \tau_2)$. After the reconstruction (see Eq. (5)) these additional details correspond to the estimator S_J^{DWT} are therefore bounded as well. For the refinement process, several wavelet coefficients are set to zero by S, this match only holds approximately, i. e., no exact description of $S_{J,t}^{\text{WASA}}$ is available, as this procedure causes the information carried by the wavelet coefficients at different levels to be intermixed. However, knowing that the DWT approximation of any level is bounded by the signal itself, we can set up an ε-tube around the initially estimated trend by

$$\varepsilon := |\max_t X_t - \min_t X_t|. \tag{13}$$

As we have

$$\min_t X_t \leq S^{\mathrm{DWT}}_{J,t} \leq \max_t X_t,$$

for all $1 \leq j \leq J$. It follows that

$$|\vartheta_t(X) - S^{\mathrm{DWT}}_{J,t}| \leq \varepsilon.$$

This must also hold for WASA, i. e.,

$$\min_t X_t \leq S^{\mathrm{WASA}}_{J,t} \leq \max_t X_t, \qquad \text{and} \quad |\vartheta_t(X) - S^{\mathrm{WASA}}_{J,t}| \leq \varepsilon.$$

We then can estimate an upper bound for the error by $c = N \cdot \varepsilon$, which suffices Eq.(11). To prove the asymptotic consistency we assume that for fixed F and L the wavelet coefficients $\Omega^{W}_{j,k}$ are ordered in time, that is

$$\omega_{j,k+1} \geq \omega_{j,k}$$

for all $1 \leq j \leq J$ and $1 \leq k \leq K-1$. With

$$t_K := \max_{t_j}\{t \in \Omega^{S}_{j,K}\}$$

we have $S^{\mathrm{WASA}}_{J,t} = S^{\mathrm{DWT}}_{J,t}$ for all $t > t_K$. As the prior deviations between both estimators were bounded, e. g., by the same ε as in Eq.(13). We then obtain,

$$\sum_{t=1}^{N} |S^{\mathrm{DWT}}_{J} - S^{\mathrm{WASA}}_{J}| = \sum_{t=1}^{t_K} |S^{\mathrm{DWT}}_{J} - S^{\mathrm{WASA}}_{J}| \leq t_K \cdot \varepsilon.$$

for all N, which lead to Eq.(11) and Eq.(12).

4 Empirical Study

In this empirical study, we investigate the performance of our proposed algorithm (WASA) working with a big financial data of US DJIA 30 component stocks. In this study, we are going to conduct three tasks: (1) use WASA to improve the performance of some classic models (i.e., AR, ARMA, and ARMA-GARCH) for in-sample estimation and out-of-sample forecasting; (2) use WASA for market risk management, i.e., assessment of Value at Risk (VaR) and conditional Value at Risk (CVaR) ; and (3) use WASA to improve the performance of portfolio selection based on risk-reward ranking.

4.1 The data

The analysis is performed based on the high-frequency German DAX 30 component stock prices from January to December 2005. In our empirical study, the homogeneous (i. e., equally spaced) time series data is aggregated at 5-minute level by the linear interpolation method (see Meinl and Sun (2012)). That is, the inhomogeneous series with times t_i is given by $x(t_i)$, while fixed. As every regular τ_j is bounded by two times of the irregularly spaced series, i. e.,

$$t_{I_j} \le \tau_j < t_{I_j+1},$$

with

$$I_j := \max\{i \mid t_i \le \tau_j\},$$

data point τ_j is interpolated between t_{I_j} and t_{I_j+1} by

$$\underline{x}(\tau_j) = x_{I_j} + \frac{\tau_j - t_{I_j}}{t_{I_j+1} - t_{I_j}}(x_{I_j+1} - x_{I_j}).$$

In our sample, the 5-minute data contains 26,686 data points for each DAX stock in 2005.

4.2 The methodology

In our simulation study we choose Haar, Daubechies (DB), Symlet (LA) and Coiflets (Coif) as wavelet functions (see Percival and Walden (2006)). We apply the pyramid algorithm in our empirical study. With each iteration of the pyramid algorithm, we increase the scaling level. That is, given a signal of length $N = 2^J$, the j-th iteration computes detail coefficients associated with changes on a scale of length $\lambda_j = 2^{j-1}$, see Gençay et al. (2002).

In this simulation, we consider several thresholding rules. Donoho and Johnstone (1994) suggest the universal thresholding based on the following equation:

$$\vartheta^U = \hat{\sigma}_E \sqrt{2 \log n}.$$

The idea behind this selection rule is that for a sequence of n independently and identical distributed (i.i.d.) $N(0, \sigma^2)$ random variables it holds that the probability that the largest value in absolute terms is smaller than $\hat{\sigma}_E \sqrt{2 \log n}$ converges to one for large n. Donoho and Johnstone (1998) suggest the minimax. Donoho (1994) proposed a method based on minimizing Steins unbiased estimate of risk (i.e., SURE). Suppose there is a sequence of k i.i.d. random variables $z_i \sim N(\mu_i, 1)$. Let $\hat{\mu}$ be an estimator of $\mu = (\mu_1, ..., \mu_k)$. Given a weakly differentiable function g, an unbiased estimator of μ, $\hat{\mu} = z + g(z)$ is given by

$$E\|\hat{\mu} - \mu\|^2 = k + [E\|g(z)\|^2 + 2\nabla g(z)],$$

where $\nabla g(z) = \sum_i \partial g_i(z)$. With soft thresholding we obtain

$$SURE(z, \vartheta) = k - 2 \cdot \#(i : |z_i| \le \vartheta + \sum_{i=1}^{k} min^2(|z_i|, \vartheta).$$

where $\#S$ equals the cardinality of a given set S. The SURE thresholding is the one minimizing the estimated risk:

$$\vartheta^S = \arg min_{\vartheta \ge 0} SURE(z, \vartheta).$$

Donoho and Johnstone (1995) suggest the heuristic thresholding which applies the SURE thresholding rule to some levels of decomposition and universal thresholding to the others. The decision which rule to use on which level is made heuristically. Birgé and Massart (1998) suggest a thresholding rule based on the Birgé-Massart strategy using a penalized projection estimator

(PPE). For each level i, q_i is calculated as

$$q_i = m \cdot (j + 2 - i)^{\alpha},$$

where j is the maximal level of decomposition, m is a constant proposed to equal the length of the data (i.e., the number of observations) and α is a controlling constant. On each level i the q_i largest coefficients are kept. The larger the α value, the more coefficients remain. Typical choice for α value is 1.5 for compression and 3 for denoising.

Based on the above-mentioned thresholding rules, wavelet coefficients are thresholded term by term on the basis of their individual magnitudes. Information on other coefficients has no influence on the treatment of particular coefficients. Cai and Silverman (2001) propose a block thresholding method which is a shrinkage method capturing information on neighboring coef- ficients. When applying block thresholding rule, the coefficients are considered in overlapping blocks and the treatment of coefficients in the middle of each block depends on the data in the whole block.

The candidates of denoising factors of GOWDA in our simulation are:

- $F \in \{$Haar, DB(2), DB(4), DB(8), LA(2), LA(4), LA(8), Coiflet(4), Coiflet(6), Coiflet(8)$\}$;
- $L \in \{i : i = 1, 2, 3\}$;
- $S \in \{$ Block, Universal, SURE, heuristic Sure, Minimax, Birgé-Massart$\}$. The

linear score function $T(\cdot)$ of τ_1 and τ_2 has following form:

$$T(\tau_1, \tau_2) = 0.5 \times \tau_1 + 0.5 \times \tau_2.$$

When we compute τ_1, we set $\alpha = 0.05$ for the Grubbs t-statistic. When we compute τ_2, one- sigma rule is applied to detect the local extrema, that is, an observation is considered to be as

the local extrema (of a given sequence) if it lies in the region at a distance from its mathematical expectation of more than the standard deviation.

In this simulation, the alternative methods we compare with GOWDA are five single wavelet function, i.e., Haar, DB(4), DB(8), LA(8), and Coiflet(6), worked with DWT.

We run the simulation for the two different data patterns described in Section 3.1. We use our algorithm to identify the best denoising method that optimally combines wavelet function, level of decomposition, and thresholding rule. For each pattern, we conduction the simulation based on a moving window design following Sun and Meinl (2012). We investigate our algorithm for both in-sample approximation and out-of-sample forecasting. For the out-of-sample forecasting, we work for one-step and two-step forecasting. Since the true trend (for both in-sample and out-of-sample) of the simulated stylized data is known, we then use GOWDA and alternative methods to denoise the simulated data and compare the approximated trend and forecasted trend with their true counterparts. Obviously, the smaller the difference compared with the true trend, the better the performance of the underlying algorithm.

4.3 Computation of VaR and CVaR

We now present the GOWDA application related to the risk measures, i. e., Value at Risk (VaR) and conditional Value at Risk (CVaR). Let A_i be any asset that is assigned a synthetic return R_i and $r(A_i)$ a rating function. Defualt of an asset occurs if its synthetic return falls below (or equals) a threshold value of the rating function $\rho(r(A_i))$, that is, $R_i \leq \rho(r(A_i))$.

Let R be a random variable with a cumulative distribution function denoted by F_R, the VaR at confidence level $\alpha \in (0, 1]$, also referred as the α-quantile, is defined as

$$\mathrm{VaR}_\alpha(\mathrm{R}) = \inf\{\rho : \mathrm{F_R}(\rho) \geq \alpha\},$$

and the CVaR at confidence level α is defined as

$$\mathrm{CVaR}_\alpha(\mathrm{R}) = \sup\{\rho - \frac{1}{\alpha}\mathrm{E}([\rho - \mathrm{R}]_+)\},$$

where $[\rho - R]_+ = \max(\rho - R, 0)$ denotes the positive part of $\rho - R$. If $VaR_\alpha(R)$ is finite, the supremum in the above equation is attained at $\rho = VaR_\alpha(R)$. Then we have

$$\mathrm{CVaR}_\alpha(\mathrm{R}) = \mathrm{VaR}_\alpha(\mathrm{R}) - \frac{1}{\alpha}\mathrm{E}([\mathrm{VaR}_\alpha(\mathrm{R}) - \mathrm{R}]_+).$$

Following Sun et al. (2009), we apply both the nonparametric method and parametric method. For the nonparametric method, we use the bootstrapping to formulate the confi- dence interval. For the parametric method, we use the AR(2), ARMA(2,1), and ARMA(2,1)- GARCH(1,1). We report our results in Table 4 and Figure 3. As we know from the VaR and

CVaR definition given in Section 4.3, the ideal violation rate for VaR and CVaR is α, i. e., the confidence level. We see that the VaR measure based on the nonparametric method with original data turns to be more conservative as its violation rate is more less than 5%, the confidence level

α in our study. On the contrary, the parametric methods (i.e., AR, ARMA, and ARMA-GARCH models) provide more aggressive VaR measures based on the original data as they are far greater than 5%. For both the nonparametric and parametric methods, GOWDA denoised data can im- prove the performance of both nonparametric and parametric methods by driving the violation

rate close the confidence level α, i.e., 5%.

4.4 Portfolio Selection

Technological innovation has improved the trading capacity of financial assets. Many market participants are now employing algorithmic trading (AT) that uses computer algorithms to automatically complete the trading process that involves making trade decision, order submission, and order management after submission. High frequency trading (HFT) is a special class of al- gorithmic trading (AT) that uses computer algorithms making elaborate trading decision based on the electronically received information before human traders are capable of processing same information they observe. Much attention has, and continues to be, focused on the impact of high frequency trading, particularly due to the tremendous increases in volumes of HFT and the
U.S. May 6, 2010 flash crash.

One of the trading style of HFT is hourly trading that is buying and selling financial instru- ments within one hour, such that all positions are usually closed no longer than one hour after they have been established. In this section, we formulate an active portfolio trading strategy based on allocating asset with respect to the measure of reward to risk.

We consider three measures of reward to risk. The first one is the Sharpe ratio (see Sharpe (1994)), which is the ratio between the expected excess return and its standard deviation:

$$\text{Sharpe} = \frac{E[R - R_f]}{\sigma[R]}.$$

where R_f is the risk-free asset and $\sigma[R]$ is the standard deviation of R.

The second one is the VaR ratio, which is the ratio between the expected excess return and its value at risk:

$$\text{VaR Ratio} = \frac{E[R - R_f]}{\text{VaR}_{(1-\alpha)100\%}(R - R_f)}.$$

The third one is the CVaR ratio, also called STARR ratio (see Martin et al. (2003)), is the ratio between the expected excess return and its conditional value at risk:

$$\text{STARR} = \frac{E[R - R_f]}{\text{CVaR}_{(1-\alpha)100\%}(R - R_f)}.$$

We use the above three ratios as stock selection criteria to rank the DAX 30 stocks to the top (large ratio value) and bottom (small value) groups in our empirical data at the hourly base. We consider a intra-day momentum strategy that is implemented by simultaneously buying the top group and selling (or shorting) the bottom one at the end of the ranking period, and holding the portfolio over the training period. In our implementation, we consider the top and bottom group both have 5 stocks. The ranking period is from one day to ten day and the trading period is one hour.

We show the annualized performance of different portfolio trading strategies in Table 5. We see that when we use GODWA denoised data, the annualized returns of three risk-rewards based trading strategies are much higher than that based on the original data.

5 Conclusion

Identification of the optimal combination of wavelet function, level of decomposition, and thresholding rule challenges the efficiency of classic methods of denoising data based on wavelet transform (e.g., DWT). Inefficient decomposition of the systematic pattern (the trend) and noise of the target data will tremendously reduce the efficiency and effectiveness of any decision sup- port system. When working with high-frequency financial data, its irregularities and roughness reinforce the necessity of more efficient tools for data mining.

In this paper, we propose a new trend extraction method for high-frequency financial data named generalized optimal wavelet decomposing algorithm (GOWDA), which can optimally de- termine the combination of denoising factors (i.e., wavelet function, level of decomposition, and thresholding rule) based on a smoothness-oriented score function that is designed for detecting global and local extremum. The method can be applied with classic DWT approach. When work it with the big financial data, this algorithm is able to preserve a smooth trend and effectively displays the noise since all information can be contained in the wavelet multiresolution decom- position optimally after specifying the level of smoothness in reconstructing wavelet coefficients.

We define GOWDA's requirements and its input parameters and specify the smoothness score function. In order to show the reliability of GOWDA, we first conduct an experiment based on simulations. We consider two different stylized data patterns that are often observed in big financial market data. In all simulation settings we investigated, GOWDA illustrates its robustness independent of the input parameters. We then empirically show the potential application of GOWDA by fitting and forecasting the real high frequency data (aggregated at the 5 minute-frequency level) of the German DAX 30 component stock price data. The results confirm our conclusion that GOWDA can significantly improve the efficiency of data analysis.

We apply GOWDA to assess risk measures and select portfolio for day trading. We find that GOWDA can increase the accuracy of VaR and CVaR estimation. When applying GOWDA for portfolio selection, we show it can create profitability significantly to beat the market portfolio.

Based on these results, we conclude that GOWDA is a robust algorithm which enriches the class of intelligent denoising methods in big data mining. The proposed algorithm is expected to provide a significant improvement of the accuracy of modeling, forecasting, risk and portfolio management with big financial data . Since data denoising is fundamental for intelligent decision making, performing it efficiently and effectively will help us build more reliable decision support system.

Corporate repurchases and insider buying are two ways that managers of heavily shorted companies can "draw a line in the sand that says that our stock goes this low and no lower." Although short sellers have a market power to punish a firm, managers are unlikely to be upcoming about this practice because it may be regarded as price manipulation. Managers' beliefs about equity valuation are therefore difficult to determine and only can be inferred indirectly. This study proposes to explore interrelationship between short-selling activity and manager repurchase to verify whether managers trade with short sellers to support an overvalued equity, or managers trade against shorts when they have private information that fundamentals will improve, or managers believe the shorts have made a mistake and the shares are fairly valued or even undervalued. We find corporate managers trade with short sellers regardless of big or small stocks, but insiders of big market-capitalization stocks trade against short sellers and insiders of small market-capitalization stocks trade with them in Taiwan stock market. We also investigate whether market frictions and type of short sellers affects this link. Furthermore, our sample spans a period, 2000 to 2014, in order to examine whether a high stock price has increased when buying back shares.

Keywords: Repurchase, buyback, short sale, insiders, informed trading.

JEL Classifications: D53, G13, G14, G15

1. Introduction

Although short sellers correctly predict future negative returns and keep prices closer to fundamental values (see Diether, Lee and Werner 2009, Karpoff and Lou 2010), research on how companies respond to short sellers is limited. To our knowledge, the only two prior studies investigating a relation between corporate share repurchases and short interest is by de Jong et al. (2011), who examine a specialized transaction involving issuance of convertible debt, and by Liu and Swanson (2012), which disclose managers trade against the shorts when shorts are mistaken. Jim Cramer, host of the CNBC show Mad Money, commented during July 23, 2010 episode, that corporate repurchases and insider buying are two ways that managers of heavily shorted companies can "draw a line in the sand that says that our stock goes this low and no lower." Although short sellers have a market power to punish a firm, managers are unlikely to be upcoming about this practice because it may be regarded as price manipulation. Since no academic evidence exists on whether the use of repurchase to trade against short seller is a common practice, we wonder the practice might not reasonably common or only sustain under a certain market structure. Owing to different repurchase law[1] and market mechanism between US and Taiwan, we suspect trading-against relationship between insiders and short sellers as in Liu and Swanson (2012) might not be the case in Taiwan. Size of firm associates with the supply of shares and might have an impact on manager's decision for repurchase and firm's goals to buyback. Firm size also indirectly relates to the extent and speed which short sellers can inflict on short sold stocks. Therefore, we explore whether type of firms (big-, medium-, or small-size) determines repurchase to trade against shorts to prevent, or at least delay, a decline in stock price or contrarily to trade with or trade with no relation to shorts. Furthermore, the type of shorts (e.g. individual or institution), the channel short sellers adopt, and its shorting cost produce additional sources of impact on the link between repurchase and short interest. Securities and Exchange Commission (SEC) of Taiwan regulate companies to report their buyback purpose which we believe somehow disclose manager's view for their stock as being undervalued, fairly valued or overvalued. In addition, officers, directors, managers and shareholders holding more than 10% shares outstanding have to report number of shares sold in advance if sold shares are over 10,000 per day and these stakeholders are not allowed to sell shares while company is buying shares back. The regulation might reverse the causality of above story that shorts might act to retreat, take no action or go forward to trade against repurchase when firms make an announcement to buy back shares. Finally, we look into how market friction (e.g. short-selling restriction or financial crisis) affects the link between repurchases and shorts.

Managers can easily monitor the aggregate short position in their company's stock because short interest is publicly reported by the stock exchange every day. However, the insiders' holding only needs to be reported once a month and is not necessary to report to authority before trading if the trade amount is less than 10000 shares per day. If trading amount is more than 10000 shares, the trader is obligated to report to the authority three days in advance in order to trade. Although the latter is the case, short sellers still do not have timely information.

Corporate share repurchases are expected to increase when the stock price drops. Expectations about the future price are also likely to influence share repurchases. If managers

[1] During the Asian financial crisis period, many firms in Taiwan experienced a big drop in stock price, but couldn't repurchase their own shares directly from the market because Taiwan corporations are not allowed to buy back shares until 2000.

expect a future price decline, they would reduce repurchases in the current quarter and buy at a lower price in the future. If short sellers have a similar expectation, they would increase their positions during the quarter to profit from a lower price in the later quarters. Then a negative association between repurchases and short interest is observed. On the contrary, a positive association would be observed if shorts and managers consistently (systematically) hold conflicting views about the future stock price. A third possibility is that repurchase and short sale is unrelated on average. However, a more plausible explanation for a positive association is managers either increase repurchase to counter an increase in shorts or decrease repurchase to go against an decrease in shorts.

Short sales constraints allow stocks to be substantially overpriced and any overpricing gets corrected only slowly. Lamont (2004) identifies a sample of 266 companies that took a variety of publicly stated actions to constrain short sellers[2] and concludes that firms are not just passively responding to market signals but are in fact actively trying to prop up their stock prices. Recent studies focus on short selling bans imposed by regulators in response to lobbying by corporate managers (see Beber and Pagano 2012, Boehmer et al. 2011). Liu and Swanson (2012) add to this literature by documenting that average stock price declines only modestly after corporate share repurchases increase in response to an increase in short interest. Lamont's sample firms experienced monthly abnormal returns by -2 percent on average over the next year, their efforts to support the stock price are not very successful.

Managers can influence market opinion by using their own funds to buy shares of the companies that employ them to silently wage war on shorts. To support this assertion, Liu and Swanson (2012) uncover evidence in stock prices, financial statements, and insider trading. This strategy can damage shorts especially those who are naked[3] because insider stock purchases are widely seen as a signal that a stock is underpriced. Nevertheless, this strategy only works if the market believes these purchases are a reliable price signal, yet it is weakened as share price rises. Even so, the sums that managers can invest are small relative to their companies' market capitalization and have little influence on shorts. Where managers can wield a powerful influence is in using their companies' money to buy back shares. However, an agency relationship exists when managers use corporate capital to repurchase shares. An especially interesting result would be if managers sell shares from their personal account while buying shares with corporate capital, as this would suggest repurchases are being used to support overvalued equity. On the contrary, if managers buy shares from their personal account while buying shares with corporate capital, this would suggest repurchases are being used to support undervalued equity and another agency problem arises.

Managers' beliefs about equity valuation are difficult to determine and only can be inferred indirectly. This study proposes an interrelationship between short selling and manager repurchase to verify Managers' beliefs. We find corporate managers trade with short sellers regardless of big or small stocks, but insiders of big market-capitalization stocks trade against short sellers and insiders of small market-capitalization stocks trade with them in Taiwan stock market. We also find market frictions and type of short sellers affects this link. Furthermore, we observe a high stock price has increased when buying back shares.

[2] For example, belligerent statements refuting or denouncing shorts for improper actions, lawsuits, appeals to authorities to investigate the shorts, requests to shareholders to withdraw their shares from the lending market.
[3] Short sellers did not borrow shares and sell them.

The remainder of the study proceeds as follows. The next section provides additional background about the regulation of corporate share repurchases and describes in more detail how our study relates to prior research. Section 3 presents research hypotheses, data collection and descriptive statistics. Section 4 reports empirical results on share repurchases, subsample analyses, and robustness tests, Section 5 extends to consider trading by insiders. The final section concludes and proposes additional research.

2. Literature review

Much of the past literature on corporate share repurchases considers program announcements and the stock returns that follow those announcements, rather than actual repurchase transactions. For example, Ikenberry, Lakonishok, and Vermaelen (1995) and Peyer and Vermaelen (2009) show that in the U.S. open market share repurchase announcements are accompanied by a positive short-term abnormal return of about 3% and long-run abnormal returns in the order of 30% over three to four years. Research on short term announcement returns (see Vermaelen 1981, Ikenberry et al 1995, Grullon and Michaely 2004) shows that these returns are higher when the percentage of shares repurchased is larger, when the firm has excess cash and is a value stock, and when the management states “undervaluation” as a motivation for the repurchase. These results are consistent with a variety of non-mutually exclusive explanations for the benefits from open market share buybacks: signaling, reduction in agency costs of equity, and corporate tax savings from increased leverage. Peyer and Vermaelen (2009) claim the results on long term returns imply that the U.S. market systematically underreacts to open market buyback announcements, especially for beaten up small firms, downgraded by analysts prior to the buyback announcement. Using robust data, McLean (2011) shows that a much stronger explanation is risk adverse. Prior to McLean (2011), the results are attributed to managers’ being able to time the market by taking advantage of market mistakes and buying back undervalued stock.

Manconi, Peyer and Vermaelen (2012) declare that share buybacks can be driven by non-value maximizing incentives such as fighting a takeover bid by repurchasing shares from “pessimistic” shareholders, stabilizing the stock price by buying shares above “fair” value, manipulating earnings per share, or acting in the interest of a majority stockholder at the expense of minority shareholders. The latter argument is particularly important in European firms, where Faccio and Lang (2002) find a minority of the publicly traded firms to be widely held. Manconi, Peyer and Vermaelen (2012) conclude that when corporate governance quality is high, markets do not expect that managers use buybacks to engage in these non-value maximizing activities. Likewise, McLean (2011) and Liu and Swanson (2012) illustrate how much share prices are influenced not by investors judging reported results and risks, but rather by insiders whose superior knowledge gives them an inherent advantage in the market for their companies' shares.

3. Data and markets

The data used in this study come from two sources: (1) the component stocks of Taiwan Stock Exchange Capitalization Weighted Stock Index (TAIEX) provided by the Taiwan Stock Exchange Co. Ltd (TWSE), and (2) the repurchased stock data and financial statement fundamentals, provided by the Taiwan Economic Journal (TEJ). For the present study, the unit of analysis for examining buybacks at the time of traders sold short is per trade data taken from August 10, 2000 to December 31, 2013, a sample period long enough to analyze all the managers' buyback against short sellers' trading in the Taiwan market, in particular around global financial crisis and the time periods during which short-selling price restrictions are lifted. Beginning from 7 August 2000, companies are allowed to buy back shares on open market and buyback should be completed within two months after announcement.

3.1. *Lifting of short-selling price constraints*

Phillips (2011) argues that since institutional investors are the primary source of borrowed stocks, institutional holding of stocks can be used as proxy for the level of short sale constraints. This study also serves to explore whether managers trade against /with /with no relation to short sellers will be different upon facing a lifting of short-selling price restriction. Our results should be more robust than the results in Phillips (2011) because the traits of our data allow us to directly evidence the hypotheses.

In May 2005, short-selling-price restriction on the 50 component stocks of Taiwan ETF 50 was removed for individual trader accounts only. In November 2007, the component stocks of the Taiwan Mid-cap 100 index exempts from the above-previous-closing price rule for both individual and institutional traders. On September 23, 2013, Taiwan Security Exchange Corporation lifted the restrictions of short-selling price that is not allowed to be lower than the previous closing on 1052 stocks. Furthermore, 200 stocks are allowed to be day traded since January 6, 2014.

3.2. *Global financial crisis*

The global financial crisis (GFC) or global economic crisis is commonly believed to have begun in July 2007 with the credit crunch and hit the world in 2008. The collapse of Lehman Brothers on September 14, 2008 marked the beginning of a new phase in the global financial crisis. From September 22, 2008 through October 3, 2008, short selling in Taiwan is completely prohibited for all stocks for the sake of worldwide financial crisis and reinstates afterwards, but short selling price is not allowed to be lower than the previous closing price without any exceptions until January 2009 with exemption of constituent stocks of Taiwan Top 50 and Taiwan Mid-cap 100. This study will follow the definition of TSEC's uptick rule in Lin, Lee and Wang (2013) and break the sample period into three subperiods: 1) September 14 to September 21 was the"preliminary"intervention period because during this window intervention on a small scale was taking place. 2) September 22 was the day of all-out stock market intervention. 3) September 23 to October 3, 2008, was the immediate aftermath of the intervention. The period allows an examination of the impact of government intervention before the reintroduction of restrictions on short selling of stocks on October 4. October 4 to 4 January, 2009 provides information on the net effect of the interplay between the fading of the effect of direct intervention and the impact of the reinstitution of the TSEC up-tick rule against short selling on Taiwan Top 50 and Taiwan Mid-cap 100.

4. Preliminary results

4.1. *Summary description*

The final sample consists of 1917 firm repurchase events. We drop firm events without full information including stock price, short sales, financial fundamental, insider trading, institutional holding, option granted, and so on. Table 1 presents descriptive statistics. Panel A reports summary statistics of stock and firm level characteristics by percentile, Panel B classifies Panel A by year to observe variation, and Panel C reports pair-wise correlation statistics. The average firm in the sample has a market capitalization of 1.30 billion NTD, a book-to-market ratio of 1.12, a quarterly stock price
17.44 NTD, repurchase 2%, short sale 0.8% and lending sale 0.05% of outstanding shares, and 36% institutional ownership. The figure in Panel B shows repurchase is negatively related to stock price and this pattern evidences an underpriced hypothesis.

The pair-wise correlation statistics reveal a negative relationship between Repurchase and Lending sale (and Institutional ownership) and also between lagged Repurchase and Short sale. Insider sale is positively correlated with short sale, but negatively correlated with return and insider holding.

4.2. *Hypotheses*

To test whether managers trade with short sellers to support an overvalued equity, or managers trade against shorts when they have private information that fundamentals will improve, or managers believe the shorts have made a mistake and the shares are fairly valued or even undervalued, we hypothesize:

H1: Is an increase in repurchases negatively / positively / non-relatively associated with an increase in short interest?

Short-selling constraints allow stocks to be substantially overpriced. Removal of short-selling price restriction may induce managers to react to short sellers oppositely. To support or retain a fair stock price, more buy bucks may be needed during a financial crisis or a downward market.

H2: Does the link between repurchases and shorts sale differ in firm size (type of short sellers, lifting of short-selling price restriction, or a global financial crisis) ?

We examine future stock prices, accounting fundamentals, insider trading and an overvaluation measure $OP_{i,t}$ in equation (1) for evidence of overvaluation.

$$OP_{i,t} = \frac{PE_{i,t} - PE_{pilot,t}}{PE_{pilot,t}} \tag{1}$$

where $PE_{pilot,t}$ is the price earning ratio of pilot stock and $PE_{i,t}$ is price earning ratio of matching stock i in the same industry as pilot stock. Pilot stocks are defined as those stocks which are lift of short-selling price restriction.

To examine whether managers use personal fund to support an overvalued equity or whether there is an agency problem when corporate repurchases shares, we hypothesize:

H3: Is an increase in insider's net selling negatively / positively / non-relatedly associated with an increase in short interest?

Inconsistent with other stock markets, Taiwan stock market disallow officers, directors, managers and shareholders holding more than 10% shares outstanding to sell shares while manager is buying back company stocks. This regulation leads to insider selling either unrelatedly or negatively associated with share repurchase, but how about the relation between short sale and insider sale? We also wonder whether this relationship will be enforced / reduced while corporate does not launch share repurchase.

In Taiwan market, short sale performs by individuals, but lending sale mostly conducts by institutional traders. Therefore, we also would like to test hypotheses H1 to H3 for lending sale to examine whether the result is different in trader type.

5. Main results

5.1. *The Repurchase model*

We follow Liu and Swanson (2012) and other studies in repurchase or short selling literature to model repurchases as

$$\begin{aligned} Rep_{i,t} = {} & \beta_0 + \beta_1 SI_{i,t} + \beta_2 SI_{i,t-1} + \beta_3 Rep_{i,t-1} + \beta_4 BTM_{i,t-1} + \beta_5 Ret_{i,t} + \beta_6 Cash_{i,t-1} + \beta_7 Debt_{i,t-1} + \beta_8 FCF_{i,t} \\ & + \beta_9 ROA_{i,t-1} + \beta_{10} Ins_{i,t} + \beta_{11} Size_{i,t-1} + \beta_{12} Div_{i,t-1} + \beta_{13} MOpt_{i,t} + \beta_{14} InsO_{i,t} \\ & + \beta_{15} Up_{i,t} + \beta_{16} Crsis_t + \beta_{17} Rep_{i,t-1} + \Sigma\beta_m Industry_m + \Sigma\beta_n Year\text{-}Qtr_n + e_{i,t} \end{aligned} \tag{2}$$

The dependent variable, $Rep_{i,t}$, is a company's repurchases of common stock in quarter t scaled by outstanding shares at the beginning of the quarter multiplied by 100 to present as a percentage. The explanatory variable of primary interest, $SI_{i,t}$, is short interest in quarter t and $SI_{i,t-1}$, is short interest in quarter t-1, where short interest is the number of shares sold short divided by common shares outstanding multiplied by 100. If managers use repurchases to trade against short sellers, the coefficient on $SI_{i,t}$ would be positive, indicating that firms increase their share repurchases concurrently with an increase in short interest. If managers instead trade with the shorts, which would occur if mispricing drives the trades of the shorts and both have similar views about the mispricing, the coefficient on $SI_{i,t}$ would be negative. The results of these arguments reveal in Table 3. In this study, we split the dataset into TSE50, TM 100, and the Rest according to the index-linked ETFs traded at the TWSE. Focusing first on the aggregate dataset, results show a significantly negative relation between repurchase and short interests. The negative relation also consistently reveals in TSE50, TM100, and the Rest splits with a waning degree by this order. Repurchase demonstrates a momentum effect in aggregate, TSE50, TM100, and the Rest splits.

To control for cross-sectional factors, we include several market and accounting variables from prior research on corporate share repurchases. $BTM_{i,t-1}$ equals the ratio of book value of equity to the market value of equity at the end of quarter t-1. $Ret_{i,t}$ is the raw stock return during quarter t. $Cash_{i,t-1}$ is calculated as cash and short term-investments at the end of quarter t-1, deflated by total assets at that time. $Debt_{i,t-1}$ is calculated as the ratio of current plus long term debt to total assets at the end of quarter t-1. $FCF_{i,t-1}$ is free cash flow (operating cash flow minus capital expenditures) in quarter t-1, scaled by total assets at the end of quarter t-1. $ROA_{i,t-1}$ is the ratio of earning before income tax, interest, and depreciation for quarter t-1, divided by total assets at the end of quarter t-1. $Ins_{i,t}$ is the shares hold by insiders (including board members and managers) during the last month of quarter t. $Size_{i,t-1}$ equals the natural log of total assets at the end of quarter t-1. $Div_{i,t-1}$ is dividends per share for quarter t-1 divided by stock price at the end of that quarter. $MOpt_t$ is the total number of stock options granted to managers in quarter t, scaled by common shares outstanding. $InsO_{i,t}$ is institutional ownership of stocks in quarter t. $Up_{i,t}$ /$SS_{i,t}$ is a dummy to control for stocks/regimes with / without TWSE-uptick-rules (see Lin, Lee, and Wang 2013)[4]. Crsist is a dummy variable, taking one to represent global financial crisis period, zero otherwise.

Book-to-market ratio has been used in the share repurchase literature to indicate whether the firm's stock is undervalued, but we find a significant and positive coefficient only in TM100 split. The coefficient on cash and short-term investments is positive in the Rest and aggregate splits because firms with more resources on hand more easily increase share repurchases. Debt servicing requires that firms keep cash on hand, and some debt covenants have strict limitations on payouts to shareholders. As Dittmar (2000) and Core et al. (2006), we find a significant and negative coefficient on debt in TSE50, TM100 and the Rest splits. Firms with increasing free cash flow are more able to increase share repurchases, but we observe an insignificantly positive coefficient on FCF, a finding inconsistent with Stephens and Weisbach (1998). Because profitable firms are not necessary to increase earnings per share by reducing outstanding shares, we find a strong and consistently negative sign on ROA in all sample splits with a decreasing degree in firm size. Insider holding is negatively associated with manager repurchase. There is less needs for managers to increase shares of control when the shares owned by mangers are high. Firm size is expected to be positively related to repurchases according to Dittmar (2000), Core et al. (2006), and Blouin and Krull (2009). Unlike Skinner (2008), dividend yield does not have a significantly negative coefficient assuming that share repurchases and dividends are substitutes in returning capital to shareholders. According to Phillips (2011), it is harder and more expensive to borrow a stock with lower institutional holding because short seller of this stock is more likely possess negative information of this firm. Institutional holding is negatively related to repurchases with a stronger effect to larger than smaller firms. If shorts are triggered by overpriced stock, lifting of short-selling price restriction would decrease the amount of shares sold or increase the amount of shares repurchased. Traders might behave differently from normal time during a depressed economy period, we thus control for global financial crisis and observe a positive coefficient on repurchase. Likewise, we find a negative/positive relation between $Up_{i,t}$ /$SS_{i,t}$ and share repurchase.

5.2. *The Netsell model*

[4] In Taiwan, short selling or lending selling is inhibited to execute at a price below the previous closing. We refer to this rule as the "TWSE uptick rule."

Insiders' superior knowledge gives them an inherent advantage in the market for their companies' shares. To provide additional information on whether managers use share repurchases to support overvalued equity, we would like to examine insiders' personal trades. We define insider as Cohen, Malloy and Pomorsky (2012) and Massa, Qian, Xu and Zhang (2015) to focus on officers and directors as our insiders in this study.

We use the following model:

$$\begin{aligned} NetSell_{i,t} = {} & \beta_0 + \beta_1 SI_{i,t} + \beta_2 Rep_{i,t} + \beta_3 BTM_{i,t-1} + \beta_4 AbRet_{i,t} + \beta_5 AbRet_{i,(t+1,t+4)} \\ & + \beta_6 MOpt_{i,t} + \beta_7 Size_{i,t-1} + \beta_8 Accrual_{i,t-1} + \beta_9 Crsis_t \\ & + \Sigma_m Industry_m + \Sigma_n Year\text{-}Qtr_n + e_{i,t} \end{aligned} \tag{3}$$

$NetSell_{i,t}$ is the amount of insider sales less insider purchases during quarter t, divided by the sum of those two amounts. We choose the sell version of the trading ratio because sales of stock by insiders are much more frequent than are purchases. Other studies that use variations of a trading ratio as the dependent variable, and use only periods with insider activity, include Rozeff and Zaman (1988), Lakonishok and Lee (2001), Frankel and Li (2004), Piotroski and Roulstone (2005), Rogers and Stockton (2005), and Core et al. (2006).

SI_t is short interest in quarter t. Although a greater amount of lendable shares increases the insiders' incentives to sell, particularly for the information-related insider sales, the more informed the insider is, the more they wish to pre-empt short sellers to exploit their informational advantage according to Massa, Qian, Xu and Zhang (2015). We do not predict a sign for SIt because short interest could be negatively related, positively related, or unrelated to insider net selling. The sign would be negative if managers trade against short sellers with their personal capital. Although their trades are too small by themselves to be effective in trading against shorts, their trades could influence outside investors to trade against the shorts. Recall that Cramer identifies insider trades as a way that managers of heavily shorted companies can draw "a line in the sand that says that our stock goes this low and no lower." A positive sign would be observed if managers, instead trade consistently with shorts. This could occur because prior research indicates that both short sellers (Drake et al. 2011) and insiders (Rozeff and Zaman 1988, Piotroski and Roulstone 2005) are value investors. To our knowledge, Liu and Swanson (2012) is the first to investigate if insiders and short sellers trade in a consistent or conflicting manner; however, they are not the first to investigate whether insider trading is related to corporate share repurchases. Core et al. (2006) find that when accruals are high, firms decrease repurchases and managers sell more shares. Griffin and Zhu (2010) find that CEO stock options influence the amount and timing of funds used for repurchasing stock.

The model includes several other variables that have been shown by prior research to influence insider trades. Rozeff and Zaman (1988) and Piotroski and Roulstone (2005) find that insider selling increases (decreases) in response to recent stock price increases (decreases). We extend their research by using quarterly, rather than annual, returns and we expect a positive association between insider net sales and AbReti,t. Prior research shows insiders tend to purchase value stocks, possibly because they are often undervalued based on fundamental information (Piotroski 2000). We therefore expect a negative coefficient, indicating less selling of firms with a high *Rank of BTM*. Consistent with Piotroski and Roulstone (2005), we include the one-year-ahead buy-and-hold return, $AbRet_{t+1 \text{ to } t+4}$, since insiders may have better information for predicting future returns than the market. All abnormal returns are characteristic-based and benchmark-adjusted as in Daniel et al. (1997). We expect a negative sign because insiders would reduce current selling when they expect positive future returns. We include stock option grants (*MOpt*) and expect a positive sign, reasoning that insiders receiving large option grants would sell shares to diversify their investment portfolio. We include *Size* and expect the coefficient to be positive, as prior research indicates that insiders of larger firms sell more stock than those of smaller firms (Seyhun 1986, Rozeff and Zaman 1988). Core et al. (2006) suggest that insiders sell more shares when accruals are high, which supports a positive sign on $Accrual_{i,t-1}$. Based on the recent study by Hafzalla et al. (2011) which shows accruals better predict future returns when deflated by earnings, we use the percent operating accrual (i.e., scaling accruals by the absolute value of net income). Finally, we control for global financial crisis period (*Crsist*).

6. Conclusions

In this study, we uncover whether managers trade against / with / with no relation to short sellers to support undervalued / overvalued shares during our sample period, and investigate whether the results differ in firm size and type of short sellers, and explore whether there are other factors drive firm size to obtain these results. We examine future stock prices, accounting fundamentals, and insider trading and also calculate an overvaluation measure to confirm evidence of undervaluation/overvaluation. We provide evidence whether the link between repurchases and shorts is different after removal of short-selling price restrictions and global financial crisis period.

We find that managers trade with shorts when they buck back shares to support an undervaluation hypothesis in Taiwan stock market. Also, we find small-size firms would have a different trading behavior from medium- and big-size firms regarding the association because of traits like higher insiders' holding and less liquidity. In addition, we expect there is a negative relation between insider's net sell and shorts, and also a negative relation between insider's net sell and corporate repurchase owing to the regulation of buyback act launched in 2000.

Appendix : Variable Definitions

Variables	Definitions
Shointq	Number of shares sold short by individuals in quarter t scaled by shares outstanding multiplied by 100
Return	Return in quarter t calculated by stock price at end of quarter divided by the price at beginning of quarter minus one
Repurchase	Number of shares repurchased by corporation in quarter t scaled by shares outstanding multiplied by 100
Qopgnt	Number of stock options granted to managers in quarter t scaled by common shares outstanding multiplied by 100.
Qopgntdum	Dummy variable equals one if qopgnt>0 and zero otherewise
Netsell	Number of shares sold by officers and directors in quarter t
Netselldum	Dummy variable equals one if netsell>0 and zero otherewise
MV	Market value at the end of quarter t calculated by stock price multipled by shares outstanding
Lendingsale	Number of shares lent and sold by institutions (and less than 5% by individuals) in quarter t scaled by shares outstandii multiplied by 100
$Size_{t-1}$	Logarithm of total asset in quarter t-1
Roa_{t-1}	Lagged return on asset before interest, tax and depreciation
$Repurchase_{t-1}$	Lagged share repurchased
$Operaccrual_{t-1}$	Lagged operating Accrual computed by the difference between net income and operating cash flow scaled by the absolı of net income
$Lendingsale_{t-1}$	Lagged lent and sold shares
Fcf_{t-1}	Lagged free cash flow computed by sum of operating cash flow and purchased fixed asset scaled by total capital multip 100
Div_{t-1}	Lagged dividend yield computed by dividends per share divided by stock price at the end of quarter t-1
$Debt_{t-1}$	Lagged debt computed by sum of current debt and long term debt scaled by total asset
$Cash_{t-1}$	Lagged cash computed by sum of cash and short term-investments at the end of quarter t-1 scaled by total asset multipl
Btm_{t-1}	Lagged book to market value
Instiown	Institutional ownership, excluding repurchased shares, scaled by shares outsanding
Insider	Number of shares owned by officers and directors at the end of quarter t scaled by shares outsanding
Insiderdum	Dummy variable equals one if insider holding is euqal to or greater than the industrial median and zero otherwise
Illiquidity	Amihud (2002) illiquidity measure
Crisis	Dummy variable euqals one for date between July 1, 2007 and January 4, 2009 and zero otherwise
Abreturn	Abnormal return in quarter t is calculated by individual stock return minus group average return obtained by characteri sorting on Btm, previous quarter return, and size into five groups each (5x5x5).
Abreturn4	One-year-ahead buy-and-hold return computed by (1+abreturn_1)(1+abreturn_2)(1+abreturn_3)(1+abreturn_4)-1
UPss50	Dummy variable equals zero if firms belong to TSE50 and date is greater than 2005Q2 or among 2005Q2 or 2008Q4 a otherwise.
UPls50	Dummy variable equals zero if firms belong to TSE50 and date is greater than 2007Q2 or among 2007Q2 or 2008Q4 aı otherwise.
UPss100	Dummy variable equals zero if firms belong to TM 100 and date is greater than 2007Q4 or among 2007Q4 or 2008Q4 : otherwise.
UPls100	Dummy variable equal to zero if firms belong to TM 100 and date greater than 2007Q4 or among 2007Q4 or 2008Q4 : otherwise.
SS50	Dummy variable equals one if date is greater than 2005Q2 or among 2005Q2 or 2008Q4 and zero otherwise.
LS50	Dummy variable equals one if date is greater than 2007Q2 or among 2007Q2 or 2008Q4 and zero otherwise.
SS100	Dummy variable equals one if date is greater than 2007Q4 or among 2007Q4 or 2008Q4 and zero otherwise.
LS100	Dummy variable equals one if date is greater than 2007Q4 or among 2007Q4 or 2008Q4 and zero otherwise.

In this study, we empirically investigate the information content of the spending on pollution prevention reported in the companies' corporate social responsibility (CSR) reports. The findings are mixed. Companies' expenditures on long-term assets are associated with economic benefits. Nevertheless, pollution prevention expenses are not associated with economic benefits. We also find that companies' CSR reports are value relevant on stock returns and cash flows. Overall, the findings support that non-for- profit expenditures are consistent with shareholders wealth maximization. Several caveats are noticed.

Keywords: corporate social responsibility; economic benefit; value relevance.

JEL Classifications: F31, F37, F47

1. Introduction

In recent years, the global community has called for companies' close attention to corporate social responsibility (CSR). Some companies have responded to this vocal by allocating more resources to CSR. Other companies' managers have been hastate and argued that additional expenditure of CSR is inconsistent with their missions to pursue profit maximization for shareholders.

The resulting controversy has induced the academics to investigate the relationship between investment in CSR and financial performance. However, a major weakness of using profit-based measures lies in that these measures do not truly reflect the wealth that has been created. In addition to accounting profits, shareholders should also gain wealth from economic profit created by a company. This is extremely important for the evaluation of the CSR performance because the benefits from the actions that appear to further some social good may not be fully captured by financial performance. Therefore, this paper mainly aims to examine whether companies' CSR expenditure is associated with future economic benefit.

As early as early 2000s, the Taiwanese government embarked on a series of actions to encourage companies to undertake additional investments in CSR. These actions include the incorporation of CSR into national policy, the establishment of CSR indices, and the enactment of "CSR Best Practice Principles". To date, a growing number of Taiwanese publicly held companies have responded to the government's requirement by specifying what they have achieved for environment and global climate change in the CSR report in accordance with the Global Reporting Initiative (GRI) certified by independent institutes.

In this paper, we have two purposes. The first purpose is to examine whether companies' CSR costs are related to future economic benefit. Tobins'Q and EVA are used to capture a company's economic benefit. The second purpose is to investigate whether CSR report can be considered as part of accounting information which is consistent with shareholders' wealth maximization.

We utilize Taiwanese semiconductor companies as our sample firms for two reasons. First, some Taiwanese companies disclose environmental protection expenditures in their CSR reports. In addition, we can reduce potential differences among industries by shedding light on single industry.

By focusing on a sample of Taiwanese publicly held semiconductor companies during 2006 and 2013, we show that the investments in capitalized environment protection assets are accompanied with future economic benefits. However, environment protection costs that are recognized as an expense in the income statement fail to produce future economic benefits. In addition, we find that CSR ports convey incremental value relevance to semiconductor companies' stock returns and cash flows, excepted for stock price. The findings are consistent with GRI who attempts to provide guidelines as regard to what non-for profit activities a company has taken and how those activities benefit the society. Several caveats are mentioned in the concluding remarks.

The remainder of the paper is organized as follows: The next section reviews CSR in Taiwan and related research. Section Three explains the data selection and research design. The empirical results are presented and discussed in Section Four, while value relevance of CSR report are provided in Section Five. The final section offers conclusions.

2. A brief discussion about gri and literature review

2.1. *Taiwan's Efforts on CSR*

GRI, established in 1997, is an international not-for-profit organization belonging to the Coalition for Environmentally Responsible Economies (CERES). Its mission is to make sustainability reporting standard practice for all companies and organizations. GRI contains members from several companies in different areas, NGOs and the United Nations Environment Program (UNEP). To make sure that the guidelines are serving its purpose, GRI continuously evaluates and revises the CSR reporting frameworks.

Up to date there are four generations of GRI's Guidance. The first generation, known as G1, was released in 2000 and tested on a number of pilot companies worldwide. Subsequently, GRI revised and released generations G2, G3, G3.1, and G4 of guidelines in 2002, 2006, 2011, and 2013. Among the guidelines, G3.1 is the one that is commonly followed by Taiwanese companies. It is made up of two parts. Part 1 features guidance on how to report. Part 2 features guidance on what should be reported, in the form of Disclosures on Management Approach and Performance Indicators. G3.1's Performance Indicators are organized into categories: Economic, Environment and Social. The Social category is broken down further by Labor, Human Rights, Society and Product Responsibility sub-categories. Indicator Protocols are the 'recipe' behind the Performance Indicators; they define key terms in the Indicator, compilation methodologies, the intended scope and relevance of the Indicator, and technical references. Indicator Protocols provide guidance on how Disclosures on Management Approach and Performance Indicators should be reported.

2.2. *Literature Review*

2.2.1. *CSR and Financial Performance*

There are two streams of empirical studies investigating the relationship between CSR and financial performance. One stream of studies addresses the impact of companies' CSR acts on short-term financial performance.[1] The results of these studies have been mixed. For instance, Wright and Ferris (1997) found a negative impact of CSR on short-term stock prices when examining divestitures from South Africa during the Apartheid controversy. Teoh et al. (1999) found no relationship between CSR and financial performances. Posnikoff (1997) and Tang et al. (2012) reported a positive impact of CSR on financial performance. Other studies concerning the relationship between CSR and short run financial performances, discussed in McWilliams and Siegel (1997), are similarly inconsistent. The evidences on the relationship between CSR and long-term financial performance are also mixed (e.g. Aupperle et al. 1985; McGuire et al. 1988; and Waddock and Graves, 1997; Hillman and Keim 2001). Aupperle et al. (1985) found no relationship between CSP and long term performance. McGuire et al. (1988) found that prior performance was more closely related to

[1] E. g. Clinebell and Clinebell, (1994); Hannon and Milkovich, (1996); Posnikoff, (1997); Teoh, Welch and Wazzan, (1999); Worrell et al., (1991); Wright and Ferris, (1997); Brammer et al., (2006); Tang et al., (2012).

CSR than was subsequent performance. Waddock and Graves (1997) and Hillman and Keim (2001) found that the increased CSR leads to enhanced financial performance.

2.2.2. formation Content of CSR Reports

Prior studies exploring the information content of CSR reports mainly focus on qualitative analyses (Grayet al., 1988; Deegan 2002; Hedberg, and von Malmborg, 2003; Idowu and Towler, 2004; Wanderley et al. 2008; Du et al. 2010; Burritt and Schaltegger, 2010). For example, Wanderley et al. (2008) analyze the websites of 127 companies from emerging countries and addressed whether CSR information disclosure on these companies' websites is influenced by country of origin and industry sector. They concluded that country of origin has a stronger influence over CSR information disclosure on the web than industry sector.

3. Data and methodology

3.1. *Data*

The sample contains Taiwanese publicly held semiconductor companies during the period of 2006-2013. The sample period begins from 2006 because 2007 is the earliest year semiconductor companies released their CSR reports. Financial data and stock returns are retrieved from Taiwan Economic Journal (TEJ) database. Environment protection costs are manually collected from the companies' CSR reports, and are crossly checked with the companies' annual financial reports if available. Most of the companies disclose both capitalized environment protection costs and expensed environment protection costs. Environment protection cost are assumed to be expensed if they are unidentifiable.

The preliminary sample contains 21 semiconductor companies that released CSR reports, corresponding to 60 firm-years. We exclude 10 companies because they did not report environment protection costs in their CSR reports and because they have missing values required for the regression analysis. The final sample contains 11 semiconductor companies that released CSR reports, corresponding to 32 firm-years.

3.2. *Research Methodology*

3.2.1. *Measurement of Economic Benefits*

We use Tobins'Q and Economic Value Added (EVA) to capture a company's economic benefits. Tobins'Q is calculated as the sum of market value of equity and book value of total liabilities divided by the firm's total assets at the end of the year. We estimate EVA by following Palliam (2006), expressed by Equation (1).

$$EVA_{it} = (ROE_{it} - r_e) \times BV_{it-1} \tag{1}$$

where EVA_{it} represents Economic Value Added for firm *i* in year *t*[2]. ROE_{it} represents net income for firm *i* in year *t* divided by beginning total shareholder's equity, multiplied by 100. r_e represents cost of capital. It is risk-free rate, plus the expected market risk premium estimated from Capital Assets Pricing Model. We use one year certified of deposit rate in Bank of Taiwan as the risk-free rate. In the estimation of market risk premium, we use annualized monthly stock returns. BV_{it-1} represents total shareholder's equity for firm *i* in year *t-1*.

3.2.2. *Regression Model*

We then conduct regression analysis. Because companies' efforts on CSR may not be converted immediately into outcomes, we regress future economic benefits on capitalized environment protection cost, expensed environment protection cost, and several control variables that control for size, risk, R&D intensity, year-specific effects, following prior studies (McWilliams and Siegel 2000; Inoue and Lee, 2011). In addition, we include an indicator variable that equals one if the company is traded over-the counter. We mainly focus on capitalized environment protection cost and expensed environment protection cost. We expect a positive relation between capitalized environment protection cost and future economic benefits because expenditures that are capitalized as assets are more likely to produce potential economic benefits. We expect a negative or insignificant relation between expensed environment protection cost and future economic benefits because expenditures that are recognized as expenses are expected not to generate potential economic benefits. The regression model is expressed by Equation (2).

$$EcoBenefit_{it+1} = \alpha_0 + \alpha_1 CapCSR_{it} + \alpha_2 ExCSR_{it} + \alpha_3 Log\ (Rev)_{it} + \alpha_4 Risk_{it} + \alpha_5 R\&D_{it} + \alpha_5 OTC_{it} + \alpha_6 \sum year + \varepsilon \tag{2}$$

where $EcoBenefit_{it+1}$ represents either Tobins'Q or EVA estimated from Equation (1) for firm *i* in year *t+1*. $CapCSR_{it}$ represents capitalized environment protection cost for firm *i* in year *t*, deflated by beginning total assets. $ExCSR_{it}$ represents expensed environment protection cost for firm *i* in year *t*, deflated by beginning total assets. $Log(Rev)_{it}$ represents the natural logarithm of net sales for firm *i* in year *t*. $Risk_{it}$ represents total debt-to-total asset ratio for firm *i* in year *t*. $R\&D_{it}$ represents R&D expenses divided by net sales for firm *i* in year *t*. OTC_{it} represents an indicator variable that equals one if the company is traded over-the counter, and zero otherwise. $\Sigma year$ represents a set of indicator variables that control for year-specific effects.

4. Empirical results

4.1. *Descriptive Statistics*

[2] EVA is multiplied by 1,000 in order to make the coefficients readable.

Table 1 reports descriptive statistics. The sample firms on average spent 0.3% of the total assets on capitalized environment protection cost (*CapCSR*), and the corresponding expenditures on environment protection expense (*ExCSR*) is 59.9%. The sample companies on average have debts 34.8% of the total assets (*Risk*). The sample companies on average spent 22.7% of revenues on R&D. The mean and median values of *Tobins'Q* are 0.173 and 0.014, respectively, exhibiting right-skewed distributions.

[Insert Table 1 here]

Table 2 reports the cross-sectional Pearson correlation coefficients among the variables. The sample firms' environment protection expense is negatively correlated with current *EVA* (-0.339; p=0.07). The sample firms' capitalized environment protection cost is not correlated with *Tobins'Q* in the current year. In addition, bothcapitalized environment protection cost and expensed environment protection cost are not correlated with EVA in the current year. This implies that the sample firms' CSR efforts are not associated with current-year economic benefits.

[Insert Table 2 here]

4.2. *Regression Analysis*

Table 3 shows the results of regression analysis. The coefficients on $CapCSR_{it}$ in Columns (1) and (2) are 1.380 and 0.874, respectively, and are all statistically significant at 5% significance level. This indicates that investments in environment protection assets are related to future economic profits. However, the coefficients on $ExCSR_{it}$ in Columns (1) and (2) are statistically insignificant, suggesting that environment protection expense does not produce future benefits.

Overall, the findings suggest a positive relationship between capitalized CSR expenditure and future economic benefits and an insignificant link between CSR expenses and future economic benefits.

[Insert Table 3 here]

5. Value relevance of CSR report

In this section, we further investigate whether CSR report can be considered as part of accounting information which conveys a goal consistent with shareholders' wealth maximization. Although the non-for-profit efforts listed in the CSR report might not bring sure gains, they transmit a positive massage to shareholders with respect to what the companies have contributed to the social good. Investors might consider CSR report as valuable information if they believe the companies are doing things that are consistent with their interests. However, it is also likely that investors consider CSR report ambiguous because the companies are not required to state non-for-profit efforts in a formal format.

Therefore, we empirically examine the value relevance of CSR reports. To do this, we compare semiconductor companies providing CSR reports with those not providing CSR reports. There are totally 138 semiconductor companies with data available for the regression analysis, of which 21 companies released CSR reports.

Following previous studies,[3] we use three value relevance metrics: stock price metric, stock return metric, and cash flow metric. For each value relevance metric, we focus on the difference in R-squared from the regression models between those two groups. Equation (3), (4), and (5) express the value relevance metrics. We estimate significance levels for all comparisons of R-squared following Harris et al. (1994)[4].

$$P_{it} = \beta_0 + \beta_1 BVE_{it} + \beta_2 EPS_{it} + \varepsilon_{it}, \tag{3}$$

$$Return_{it} = \beta_0 + \beta_1 \frac{EPS_{it}}{P_{it-1}} + \beta_2 \frac{\Delta EPS_{it}}{P_{it-1}} + \beta_3 LOSS_{it} + \beta_4 LOSS_{it} \times \frac{EPS_{it}}{P_{it-1}} + \beta_5 LOSS_{it} \times \frac{\Delta EPS_{it}}{P_{it-1}} + \varepsilon_{it}, \tag{4}$$

$$\frac{CF_{it+1}}{TA_{it}} = \beta_0 + \beta_1 \frac{NI_{it}}{TA_{it-1}} + \varepsilon_{it}, \tag{5}$$

where P_{it} is the mean value of twelve-moth stock price three months after the beginning of the fiscal year. BVE_{it} is book value of equity per share of the ith firm in year t. EPS_{it} is net income before extraordinary items per share of the ith firm in year t. $Return_{it}$ is annualized monthly stock returns three months after the beginning of the fiscal year. $LOSS_{it}$ is a dummy variable that equals one if the EPS of the ith firm in year t is negative, and zero otherwise. CF_{it+1} is net cash flow from operations of the ith firm in year $t+1$. NI_{it} is net income of the ith firm in year t. TA_{it-1} is total assets of the ith firm in year $t-1$.

Table 4 reports the results. For the stock price metric, the R-squared for semiconductor companies providing CSR reports is 0.54, which is lower than those without CSR reports (0.56) by 2% (Z=-1.96). This indicates that CSR reports fail to convey incremental value relevant information for the explanation of share price. By contrast, semiconductor companies providing CSR reports have significantly higher R- squared value (0.42) for the return matric than those without CSR reports (0.34). Similarly, semiconductor companies providing CSR reports have significantly higher R-squared values (0.66) for the cash flow matric than those without CSR reports (0.16).These results indicate that CSR reports contain incremental value relevant information for the explanations of stock returns and cash flows.

Collectively, the findings in Table 4 suggest that CSR reports convey incremental value relevance to the users regarding the semiconductor companies' stock returns and cash flows. Not surprisingly, these findings are consistent with GRI who attempts to provide guidelines

---

6. Concluding remarks

In this paper, we have two missions. The first mission is to examine whether companies' CSR expenditures are associated with future economic benefit. Tobins'Q and EVA are used to capture a company's economic benefit. By focusing on a sample of Taiwanese publicly held semiconductor companies during 2006 and 2013, we show that the investments in capitalized environment protection assets are associated with future economic benefits. However, environment protection costs that are recognized as an expense in the income statement do not produce future economic benefits.

The second mission is to investigate whether CSR report can be considered as part of accounting information which conveys a goal consistent with shareholders' wealth maximization. Three value relevance metrics, stock price metric, stock return metric, and cash flow metric are used to measure value relevance. Our findings suggest that CSR ports convey incremental value relevance to semiconductor companies' stock returns and cash flows, excepted for stock price. The findings are consistent with GRI who attempts to provide guidelines as regard to what non-for profit activities a company has taken and how those activities benefit the society.

There are several caveats and suggestions. First, CSR reports may vary with industries although GRI provide systemic guidance, so our findings might not be generalized to other industries. Future studies are encouraged to extend this study by expending the sample to other industries. Secondly, while GRI guidelines provide a good framework for companies to comply with, some companies selectively and unsystematically report the items. This may reduce the value relevance conveyed to the users. As a result, we suggest the authorities to ask companies to report CSR activities in a more systematic manner.
